JavaScript

JavaScript (**JS**) is a lightweight interpreted (or just-in-time compiled) programming language with first-class functions. While it is most well-known as the scripting language for Web pages, many non-browser environments also use it, such as Node.js, Apache CouchDB and Adobe Acrobat. JavaScript is a prototype-based, garbage-collected, dynamic language, supporting multiple paradigms such as imperative, functional, and object-oriented.

JavaScript's dynamic capabilities include runtime object construction, variable parameter lists, function variables, dynamic script creation (via `eval`), object introspection (via `for...in` and `Object` utilities), and source-code recovery (JavaScript functions store their source text and can be retrieved through `toString()`).

This section is dedicated to the JavaScript language itself, and not the parts that are specific to Web pages or other host environments. For information about APIs that are specific to Web pages, please see Web APIs and DOM.

The standards for JavaScript are the ECMAScript Language Specification (ECMA-262) and the ECMAScript Internationalization API specification (ECMA-402). As soon as one browser implements a feature, we try to document it. This means that cases where some proposals for new ECMAScript features have already been implemented in browsers, documentation and examples in MDN articles may use some of those new features. Most of the time, this happens between the stages 3 and 4, and is usually before the spec is officially published.

Do not confuse JavaScript with the Java programming language — **JavaScript is *not* "Interpreted Java"**. Both "Java" and "JavaScript" are trademarks or registered trademarks of Oracle in the U.S. and other countries. However, the two programming languages have very different syntax, semantics, and use.

JavaScript documentation of core language features (pure ECMAScript, for the most part) includes the following:

- The JavaScript guide
- The JavaScript reference

For more information about JavaScript specifications and related technologies, see JavaScript technologies overview.

Beginner's tutorials

Our learn web development core modules contain modern, up-to-date tutorials covering JavaScript fundamentals.

Your first website: Adding interactivity

> This article provides a brief tour of what JavaScript is and how to use it, aimed at people who are completely new to web development.

Dynamic scripting with JavaScript

> This module focuses on the essentials of the core JavaScript language, plus some key surrounding topics — learning these topics will give you a solid basis to work from.

JavaScript frameworks and libraries

> JavaScript frameworks are an essential part of modern front-end web development, providing developers with tried and tested tools for building scalable, interactive web applications. Many modern companies use frameworks as a standard part of their tooling, so many front-end development jobs now require framework experience. This set of articles provides a comfortable starting point to help you begin learning frameworks.

JavaScript guides

Fundamental language guides

JavaScript Guide

> A much more detailed guide to the JavaScript language, aimed at those with previous programming experience either in JavaScript or another language.

Intermediate

Advanced JavaScript objects

> The object-oriented nature of JavaScript is important to understand if you want to go further with your knowledge of the language and write more efficient code, therefore we've provided this module to help you.

Asynchronous JavaScript

> In this module, we take a look at asynchronous JavaScript, why it is important, and how it can be used to effectively handle potential blocking operations, such as fetching resources from a server.

Client-side web APIs

> Explores what APIs are, and how to use some of the most common APIs you'll come across often in your development work.

JavaScript language overview

> An overview of the basic syntax and semantics of JavaScript for those coming from other programming languages to get up to speed.

JavaScript data structures

> Overview of available data structures in JavaScript.

Equality comparisons and sameness

> JavaScript provides three different value comparison operations: strict equality using `===`, loose equality using `==`, and the `Object.is()` method.

Enumerability and ownership of properties

How different methods that visit a group of object properties one-by-one handle the enumerability and ownership of properties.

Closures

A closure is the combination of a function and the lexical environment within which that function was declared.

Advanced

Inheritance and the prototype chain

Explanation of the widely misunderstood and underestimated prototype-based inheritance.

Memory Management

Memory life cycle and garbage collection in JavaScript.

Reference

Browse the complete JavaScript reference documentation.

Standard objects

Get to know standard built-in objects: `Array`, `Boolean`, `Error`, `Function`, `JSON`, `Math`, `Number`, `Object`, `RegExp`, `String`, `Map`, `Set`, `WeakMap`, `WeakSet`, and others.

Expressions and operators

Learn more about the behavior of JavaScript's operators `instanceof`, `typeof`, `new`, `this`, the operator precedence, and more.

Statements and declarations

Learn how `do-while`, `for-in`, `for-of`, `try-catch`, `let`, `var`, `const`, `if-else`, `switch`, and more JavaScript statements and keywords work.

Functions

Learn how to work with JavaScript's functions to develop your applications.

Classes

JavaScript classes are the most appropriate way to do object-oriented programming.

JavaScript Guide

The JavaScript Guide shows you how to use JavaScript and gives an overview of the language. If you need exhaustive information about a language feature, have a look at the JavaScript reference.

This Guide is divided into the following chapters.

Introduction

Overview: Introduction

- About this guide
- About JavaScript
- JavaScript and Java
- ECMAScript
- Tools
- What's next

Grammar and types

Overview: Grammar and types

- Basic syntax & comments
- Declarations
- Variable scope
- Variable hoisting
- Data structures and types
- Literals

Control flow and error handling

Overview: Control flow and error handling

- `if...else`
- `switch`
- `try/catch/throw`
- Error objects

Loops and iteration

Overview: Loops and iteration

- `for`
- `while`
- `do...while`
- `continue`
- `break`
- `for...in`
- `for...of`

Functions

Overview: Functions

- Defining functions
- Calling functions
- Function scopes and closures
- Arguments & parameters
- Arrow functions

Expressions and operators

Overview: Expressions and operators

- Assignment & Comparisons
- Arithmetic operators
- Bitwise & logical operators
- Conditional (ternary) operator

Numbers and strings

Overview: Numbers and strings

- Numbers
- `Number` object
- `Math` object
- Strings
- `String` object
- Template literals

Representing dates & times

Overview: Representing dates & times

- `Date` object

Regular expressions

Overview: Regular expressions

- Creating a regular expression
- Writing a regular expression pattern
  - Assertions
  - Character classes
  - Groups and backreferences
  - Quantifiers

Indexed collections

Overview: Indexed collections

Keyed collections

Overview: Keyed collections

- `Map`
- `WeakMap`
- `Set`
- `WeakSet`

Working with objects

Overview: Working with objects

- Objects and properties
- Creating objects
- Defining methods
- Getter and setter

Using classes

Overview: Using classes

- Declaring a class
- Various class features
- Extends and inheritance
- Why classes?

Promises

Overview: Promises

- Guarantees
- Chaining
- Error handling
- Composition
- Timing

Typed arrays

Overview: Typed arrays

Iterators and generators

Overview: Iterators and generators

- Iterators
- Iterables
- Generators

Resource management

Overview: JavaScript resource management

- The `using` and `await using` declarations
- The `DisposableStack` and `AsyncDisposableStack` objects
- Error handling

Internationalization

Overview: Internationalization

- Date and time formatting
- Number formatting
- Collation

JavaScript modules

Overview: JavaScript modules

- Exporting
- Importing
- Default exports
- Renaming features
- Aggregating modules
- Dynamic module loading

Advanced topics

After you have learned all fundamental features of JavaScript, you can explore some more niche features, or dive deeper into the language's mechanisms and concepts.

- Language overview
- Data structures
- Enumerability and ownership of properties
- Inheritance and the prototype chain
- Equality comparisons and sameness
- Closures
- Meta programming
- Memory management

- Next

Closures

A **closure** is the combination of a function bundled together (enclosed) with references to its surrounding state (the **lexical environment**). In other words, a closure gives a function access to its outer scope. In JavaScript, closures are created every time a function is created, at function creation time.

Lexical scoping

Consider the following example code:

```
function init() {
  var name = "Mozilla"; // name is a local variable created by init
```

```
  function displayName() {
    // displayName() is the inner function, that forms a closure
    console.log(name); // use variable declared in the parent function
  }
  displayName();
}
init();
```

`init()` creates a local variable called `name` and a function called `displayName()`. The `displayName()` function is an inner function that is defined inside `init()` and is available only within the body of the `init()` function. Note that the `displayName()` function has no local variables of its own. However, since inner functions have access to the variables of outer scopes, `displayName()` can access the variable `name` declared in the parent function, `init()`.

If you run this code in your console, you can see that the `console.log()` statement within the `displayName()` function successfully displays the value of the `name` variable, which is declared in its parent function. This is an example of *lexical scoping*, which describes how a parser resolves variable names when functions are nested. The word *lexical* refers to the fact that lexical scoping uses the location where a variable is declared within the source code to determine where that variable is available. Nested functions have access to variables declared in their outer scope.

Scoping with let and const

Traditionally (before ES6), JavaScript variables only had two kinds of scopes: *function scope* and *global scope*. Variables declared with `var` are either function-scoped or global-scoped, depending on whether they are declared within a function or outside a function. This can be tricky, because blocks with curly braces do not create scopes:

```
if (Math.random() > 0.5) {
  var x = 1;
} else {
  var x = 2;
}
console.log(x);
```

For people from other languages (e.g., C, Java) where blocks create scopes, the above code should throw an error on the `console.log` line, because we are outside the scope of `x` in either block. However, because blocks don't create scopes for `var`, the `var` statements here actually create a global variable. There is also a practical example introduced below that illustrates how this can cause actual bugs when combined with closures.

In ES6, JavaScript introduced the `let` and `const` declarations, which, among other things like temporal dead zones, allow you to create block-scoped variables.

```
if (Math.random() > 0.5) {
  const x = 1;
} else {
  const x = 2;
}
console.log(x); // ReferenceError: x is not defined
```

In essence, blocks are finally treated as scopes in ES6, but only if you declare variables with `let` or `const`. In addition, ES6 introduced modules, which introduced another kind of scope. Closures are able to capture variables in all these scopes, which we will introduce later.

Closure

Consider the following code example:

```
function makeFunc() {
  const name = "Mozilla";
  function displayName() {
    console.log(name);
  }
  return displayName;
}

const myFunc = makeFunc();
myFunc();
```

Running this code has exactly the same effect as the previous example of the `init()` function above. What's different (and interesting) is that the `displayName()` inner function is returned from the outer function *before being executed*.

At first glance, it might seem unintuitive that this code still works. In some programming languages, the local variables within a function exist for just the duration of that function's execution. Once `makeFunc()` finishes executing, you might expect that the `name` variable would no longer be accessible. However, because the code still works, this is obviously not the case in JavaScript.

The reason is that functions in JavaScript form closures. A *closure* is the combination of a function and the lexical environment within which that function was declared. This environment consists of any variables that were in-scope at the time the closure was created. In this case, `myFunc` is a reference to the instance of the function `displayName` that is created when `makeFunc` is run. The instance of `displayName` maintains a reference to its lexical environment, within which the variable `name` exists. For this reason, when `myFunc` is invoked, the variable `name` remains available for use, and "Mozilla" is passed to `console.log`.

Here's a slightly more interesting example—a `makeAdder` function:

```
function makeAdder(x) {
  return function (y) {
    return x + y;
  };
}

const add5 = makeAdder(5);
```

```
const add10 = makeAdder(10);

console.log(add5(2)); // 7
console.log(add10(2)); // 12
```

In this example, we have defined a function `makeAdder(x)`, that takes a single argument `x`, and returns a new function. The function it returns takes a single argument `y`, and returns the sum of `x` and `y`.

In essence, `makeAdder` is a function factory. It creates functions that can add a specific value to their argument. In the above example, the function factory creates two new functions—one that adds five to its argument, and one that adds 10.

`add5` and `add10` both form closures. They share the same function body definition, but store different lexical environments. In `add5`'s lexical environment, `x` is 5, while in the lexical environment for `add10`, `x` is 10.

Practical closures

Closures are useful because they let you associate data (the lexical environment) with a function that operates on that data. This has obvious parallels to object-oriented programming, where objects allow you to associate data (the object's properties) with one or more methods.

Consequently, you can use a closure anywhere that you might normally use an object with only a single method.

Situations where you might want to do this are particularly common on the web. Much of the code written in front-end JavaScript is event-based. You define some behavior, and then attach it to an event that is triggered by the user (such as a click or a keypress). The code is attached as a callback (a single function that is executed in response to the event).

For instance, suppose we want to add buttons to a page to adjust the text size. One way of doing this is to specify the font-size of the `body` element (in pixels), and then set the size of the other elements on the page (such as headers) using the relative `em` unit:

```
body {
  font-family: "Helvetica", "Arial", sans-serif;
  font-size: 12px;
}

h1 {
  font-size: 1.5em;
}

h2 {
  font-size: 1.2em;
}
```

Such interactive text size buttons can change the `font-size` property of the `body` element, and the adjustments are picked up by other elements on the page thanks to the relative units.

Here's the JavaScript:

```
function makeSizer(size) {
  return () => {
    document.body.style.fontSize = `${size}px`;
  };
}

const size12 = makeSizer(12);
const size14 = makeSizer(14);
const size16 = makeSizer(16);
```

`size12`, `size14`, and `size16` are now functions that resize the body text to 12, 14, and 16 pixels, respectively. You can attach them to buttons as demonstrated in the following code example.

```
document.getElementById("size-12").onclick = size12;
document.getElementById("size-14").onclick = size14;
document.getElementById("size-16").onclick = size16;
```

```
<button id="size-12">12</button>
<button id="size-14">14</button>
<button id="size-16">16</button>
<p>This is some text that will change size when you click the buttons above.</p>
```

Emulating private methods with closures

Languages such as Java allow you to declare methods as private, meaning that they can be called only by other methods in the same class.

JavaScript, prior to classes, didn't have a native way of declaring private methods, but it was possible to emulate private methods using closures. Private methods aren't just useful for restricting access to code. They also provide a powerful way of managing your global namespace.

The following code illustrates how to use closures to define public functions that can access private functions and variables. Note that these closures follow the Module Design Pattern.

```
const counter = (function () {
  let privateCounter = 0;
  function changeBy(val) {
    privateCounter += val;
```

```
  }

  return {
    increment() {
      changeBy(1);
    },

    decrement() {
      changeBy(-1);
    },

    value() {
      return privateCounter;
    },
  };
})();

console.log(counter.value()); // 0.

counter.increment();
counter.increment();
console.log(counter.value()); // 2.

counter.decrement();
console.log(counter.value()); // 1.
```

In previous examples, each closure had its own lexical environment. Here though, there is a single lexical environment that is shared by the three functions: `counter.increment`, `counter.decrement`, and `counter.value`.

The shared lexical environment is created in the body of an anonymous function, *which is executed as soon as it has been defined* (also known as an IIFE). The lexical environment contains two private items: a variable called `privateCounter`, and a function called `changeBy`. You can't access either of these private members from outside the anonymous function. Instead, you indirectly access them using the three public functions that are returned from the anonymous wrapper.

Those three public functions form closures that share the same lexical environment. Thanks to JavaScript's lexical scoping, they each have access to the `privateCounter` variable and the `changeBy` function.

```
function makeCounter() {
  let privateCounter = 0;
  function changeBy(val) {
    privateCounter += val;
  }
  return {
    increment() {
      changeBy(1);
    },

    decrement() {
      changeBy(-1);
    },

    value() {
      return privateCounter;
    },
  };
}

const counter1 = makeCounter();
const counter2 = makeCounter();

console.log(counter1.value()); // 0.

counter1.increment();
counter1.increment();
console.log(counter1.value()); // 2.

counter1.decrement();
console.log(counter1.value()); // 1.
console.log(counter2.value()); // 0.
```

Notice how the two counters maintain their independence from one another. Each closure references a different version of the `privateCounter` variable through its own closure. Each time one of the counters is called, its lexical environment changes by changing the value of this variable. Changes to the variable value in one closure don't affect the value in the other closure.

> **Note:** Using closures in this way provides benefits that are normally associated with object-oriented programming. In particular, *data hiding* and *encapsulation*.

Closure scope chain

A nested function's access to the outer function's scope includes the enclosing scope of the outer function—effectively creating a chain of function scopes. To demonstrate, consider the following example code.

```
// global scope
const e = 10;
```

```
function sum(a) {
  return function (b) {
    return function (c) {
      // outer functions scope
      return function (d) {
        // local scope
        return a + b + c + d + e;
      };
    };
  };
}

console.log(sum(1)(2)(3)(4)); // 20
```

You can also write without anonymous functions:

```
// global scope
const e = 10;
function sum(a) {
  return function sum2(b) {
    return function sum3(c) {
      // outer functions scope
      return function sum4(d) {
        // local scope
        return a + b + c + d + e;
      };
    };
  };
}

const sum2 = sum(1);
const sum3 = sum2(2);
const sum4 = sum3(3);
const result = sum4(4);
console.log(result); // 20
```

In the example above, there's a series of nested functions, all of which have access to the outer functions' scope. In this context, we can say that closures have access to *all* outer scopes.

Closures can capture variables in block scopes and module scopes as well. For example, the following creates a closure over the block-scoped variable `y`:

```
function outer() {
  let getY;
  {
    const y = 6;
    getY = () => y;
  }
  console.log(typeof y); // undefined
  console.log(getY()); // 6
}

outer();
```

Closures over modules can be more interesting.

```
// myModule.js
let x = 5;
export const getX = () => x;
export const setX = (val) => {
  x = val;
};
```

Here, the module exports a pair of getter-setter functions, which close over the module-scoped variable `x`. Even when `x` is not directly accessible from other modules, it can be read and written with the functions.

```
import { getX, setX } from "./myModule.js";

console.log(getX()); // 5
setX(6);
console.log(getX()); // 6
```

Closures can close over imported values as well, which are regarded as *live bindings*, because when the original value changes, the imported one changes accordingly.

```
// myModule.js
export let x = 1;
export const setX = (val) => {
  x = val;
};
```

```
// closureCreator.js
import { x } from "./myModule.js";
```

```
export const getX = () => x; // Close over an imported live binding
```

```
import { getX } from "./closureCreator.js";
import { setX } from "./myModule.js";

console.log(getX()); // 1
setX(2);
console.log(getX()); // 2
```

Creating closures in loops: A common mistake

Prior to the introduction of the `let` keyword, a common problem with closures occurred when you created them inside a loop. To demonstrate, consider the following example code.

```
<p id="help">Helpful notes will appear here</p>
<p>Email: <input type="text" id="email" name="email" /></p>
<p>Name: <input type="text" id="name" name="name" /></p>
<p>Age: <input type="text" id="age" name="age" /></p>
```

```
function showHelp(help) {
  document.getElementById("help").textContent = help;
}

function setupHelp() {
  var helpText = [
    { id: "email", help: "Your email address" },
    { id: "name", help: "Your full name" },
    { id: "age", help: "Your age (you must be over 16)" },
  ];

  for (var i = 0; i < helpText.length; i++) {
    // Culprit is the use of `var` on this line
    var item = helpText[i];
    document.getElementById(item.id).onfocus = function () {
      showHelp(item.help);
    };
  }
}

setupHelp();
```

The `helpText` array defines three helpful hints, each associated with the ID of an input field in the document. The loop cycles through these definitions, hooking up an `onfocus` event to each one that shows the associated help method.

If you try this code out, you'll see that it doesn't work as expected. No matter what field you focus on, the message about your age will be displayed.

The reason for this is that the functions assigned to `onfocus` form closures; they consist of the function definition and the captured environment from the `setupHelp` function's scope. Three closures have been created by the loop, but each one shares the same single lexical environment, which has a variable with changing values (`item`). This is because the variable `item` is declared with `var` and thus has function scope due to hoisting. The value of `item.help` is determined when the `onfocus` callbacks are executed. Because the loop has already run its course by that time, the `item` variable object (shared by all three closures) has been left pointing to the last entry in the `helpText` list.

One solution in this case is to use more closures: in particular, to use a function factory as described earlier:

```
function showHelp(help) {
  document.getElementById("help").textContent = help;
}

function makeHelpCallback(help) {
  return function () {
    showHelp(help);
  };
}

function setupHelp() {
  var helpText = [
    { id: "email", help: "Your email address" },
    { id: "name", help: "Your full name" },
    { id: "age", help: "Your age (you must be over 16)" },
  ];

  for (var i = 0; i < helpText.length; i++) {
    var item = helpText[i];
    document.getElementById(item.id).onfocus = makeHelpCallback(item.help);
  }
}

setupHelp();
```

This works as expected. Rather than the callbacks all sharing a single lexical environment, the `makeHelpCallback` function creates *a new lexical environment* for each callback, in which `help` refers to the corresponding string from the `helpText` array.

One other way to write the above using anonymous closures is:

```
function showHelp(help) {
  document.getElementById("help").textContent = help;
}

function setupHelp() {
  var helpText = [
    { id: "email", help: "Your email address" },
    { id: "name", help: "Your full name" },
    { id: "age", help: "Your age (you must be over 16)" },
  ];

  for (var i = 0; i < helpText.length; i++) {
    (function () {
      var item = helpText[i];
      document.getElementById(item.id).onfocus = function () {
        showHelp(item.help);
      };
    })(); // Immediate event listener attachment with the current value of item (preserved until iteration).
  }
}

setupHelp();
```

If you don't want to use more closures, you can use the `let` or `const` keyword:

```
function showHelp(help) {
  document.getElementById("help").textContent = help;
}

function setupHelp() {
  const helpText = [
    { id: "email", help: "Your email address" },
    { id: "name", help: "Your full name" },
    { id: "age", help: "Your age (you must be over 16)" },
  ];

  for (let i = 0; i < helpText.length; i++) {
    const item = helpText[i];
    document.getElementById(item.id).onfocus = () => {
      showHelp(item.help);
    };
  }
}

setupHelp();
```

This example uses `const` instead of `var`, so every closure binds the block-scoped variable, meaning that no additional closures are required.

If you are writing modern JavaScript anyway, you can consider more alternatives to the plain `for` loop, such as using `for...of` loop and declaring `item` as `let` or `const`, or using the `forEach()` method, which both avoid the closure problem.

```
for (const item of helpText) {
  document.getElementById(item.id).onfocus = () => {
    document.getElementById("help").textContent = item.help;
  };
}

helpText.forEach((item) => {
  document.getElementById(item.id).onfocus = () => {
    showHelp(item.help);
  };
});
```

Performance considerations

As mentioned previously, each function instance manages its own scope and closure. Therefore, it is unwise to unnecessarily create functions within other functions if closures are not needed for a particular task, as it will negatively affect script performance both in terms of processing speed and memory consumption.

For instance, when creating a new object/class, methods should normally be associated to the object's prototype rather than defined into the object constructor. The reason is that whenever the constructor is called, the methods would get reassigned (that is, for every object creation).

Consider the following case:

```
function MyObject(name, message) {
  this.name = name.toString();
  this.message = message.toString();
  this.getName = function () {
    return this.name;
  };

  this.getMessage = function () {
    return this.message;
```

```
  };
}
```

Because the previous code does not take advantage of the benefits of using closures in this particular instance, we could instead rewrite it to avoid using closures as follows:

```
function MyObject(name, message) {
  this.name = name.toString();
  this.message = message.toString();
}
MyObject.prototype = {
  getName() {
    return this.name;
  },
  getMessage() {
    return this.message;
  },
};
```

However, redefining the prototype is not recommended. The following example instead appends to the existing prototype:

```
function MyObject(name, message) {
  this.name = name.toString();
  this.message = message.toString();
}
MyObject.prototype.getName = function () {
  return this.name;
};
MyObject.prototype.getMessage = function () {
  return this.message;
};
```

In the two previous examples, the inherited prototype can be shared by all objects and the method definitions need not occur at every object creation. See Inheritance and the prototype chain for more.

Control flow and error handling

- Previous
- Next

JavaScript supports a compact set of statements, specifically control flow statements, that you can use to incorporate a great deal of interactivity in your application. This chapter provides an overview of these statements.

The JavaScript reference contains exhaustive details about the statements in this chapter. The semicolon (`;`) character is used to separate statements in JavaScript code.

Any JavaScript expression is also a statement. See Expressions and operators for complete information about expressions.

Block statement

The most basic statement is a *block statement*, which is used to group statements. The block is delimited by a pair of curly braces:

```
{
  statement1;
  statement2;
  // …
  statementN;
}
```

Example

Block statements are commonly used with control flow statements (`if`, `for`, `while`).

```
while (x < 10) {
  x++;
}
```

Here, `{ x++; }` is the block statement.

> **Note:** `var`-declared variables are not block-scoped, but are scoped to the containing function or script, and the effects of setting them persist beyond the block itself. For example:
>
> ```
> var x = 1;
> {
>   var x = 2;
> }
> console.log(x); // 2
> ```
>
> This outputs `2` because the `var x` statement within the block is in the same scope as the `var x` statement before the block. (In C or Java, the equivalent code would have output `1`.)

> This scoping effect can be mitigated by using `let` or `const`.

Conditional statements

A conditional statement is a set of commands that executes if a specified condition is true. JavaScript supports two conditional statements: `if...else` and `switch`.

if...else statement

Use the `if` statement to execute a statement if a logical condition is `true`. Use the optional `else` clause to execute a statement if the condition is `false`.

An `if` statement looks like this:

```
if (condition) {
  statement1;
} else {
  statement2;
}
```

Here, the `condition` can be any expression that evaluates to `true` or `false`. (See Boolean for an explanation of what evaluates to `true` and `false`.)

If `condition` evaluates to `true`, `statement1` is executed. Otherwise, `statement2` is executed. `statement1` and `statement2` can be any statement, including further nested `if` statements.

You can also compound the statements using `else if` to have multiple conditions tested in sequence, as follows:

```
if (condition1) {
  statement1;
} else if (condition2) {
  statement2;
} else if (conditionN) {
  statementN;
} else {
  statementLast;
}
```

In the case of multiple conditions, only the first logical condition which evaluates to `true` will be executed. To execute multiple statements, group them within a block statement (`{ /* … */ }`).

Best practice

In general, it's good practice to always use block statements—*especially* when nesting `if` statements:

```
if (condition) {
  // Statements for when condition is true
  // …
} else {
  // Statements for when condition is false
  // …
}
```

In general it's good practice to not have an `if...else` with an assignment like `x = y` as a condition:

```
if (x = y) {
  // statements here
}
```

However, in the rare case you find yourself wanting to do something like that, the `while` documentation has a Using an assignment as a condition section with guidance on a general best-practice syntax you should know about and follow.

Falsy values

The following values evaluate to `false` (also known as Falsy values):

- `false`
- `undefined`
- `null`
- `0`
- `NaN`
- the empty string (`""`)

All other values—including all objects—evaluate to `true` when passed to a conditional statement.

> **Note:** Do not confuse the primitive boolean values `true` and `false` with the true and false values of the `Boolean` object!
>
> For example:
>
> ```
> const b = new Boolean(false);
> if (b) {
>   // this condition evaluates to true
> }
> ```

```
if (b == true) {
  // this condition evaluates to false
}
```

Example

In the following example, the function `checkData` returns `true` if the number of characters in a `Text` object is three. Otherwise, it displays an alert and returns `false`.

```
function checkData() {
  if (document.form1.threeChar.value.length === 3) {
    return true;
  }
  alert(
    `Enter exactly three characters. ${document.form1.threeChar.value} is not valid.`,
  );
  return false;
}
```

switch statement

A `switch` statement allows a program to evaluate an expression and attempt to match the expression's value to a `case` label. If a match is found, the program executes the associated statement.

A `switch` statement looks like this:

```
switch (expression) {
  case label1:
    statements1;
    break;
  case label2:
    statements2;
    break;
  // …
  default:
    statementsDefault;
}
```

JavaScript evaluates the above switch statement as follows:

- The program first looks for a `case` clause with a label matching the value of expression and then transfers control to that clause, executing the associated statements.
- If no matching label is found, the program looks for the optional `default` clause:
  - If a `default` clause is found, the program transfers control to that clause, executing the associated statements.
  - If no `default` clause is found, the program resumes execution at the statement following the end of `switch`.
  - (By convention, the `default` clause is written as the last clause, but it does not need to be so.)

break statements

The optional `break` statement associated with each `case` clause ensures that the program breaks out of `switch` once the matched statement is executed, and then continues execution at the statement following `switch`. If `break` is omitted, the program continues execution inside the `switch` statement (and will execute statements under the next `case`, and so on).

Example

In the following example, if `fruitType` evaluates to `"Bananas"`, the program matches the value with `case "Bananas"` and executes the associated statement. When `break` is encountered, the program exits the `switch` and continues execution from the statement following `switch`. If `break` were omitted, the statement for `case "Cherries"` would also be executed.

```
switch (fruitType) {
  case "Oranges":
    console.log("Oranges are $0.59 a pound.");
    break;
  case "Apples":
    console.log("Apples are $0.32 a pound.");
    break;
  case "Bananas":
    console.log("Bananas are $0.48 a pound.");
    break;
  case "Cherries":
    console.log("Cherries are $3.00 a pound.");
    break;
  case "Mangoes":
    console.log("Mangoes are $0.56 a pound.");
    break;
  case "Papayas":
    console.log("Papayas are $2.79 a pound.");
    break;
  default:
    console.log(`Sorry, we are out of ${fruitType}.`);
}
console.log("Is there anything else you'd like?");
```

Exception handling statements

You can throw exceptions using the `throw` statement and handle them using the `try...catch` statements.

- `throw` statement
- `try...catch` statement

Exception types

Just about any object can be thrown in JavaScript. Nevertheless, not all thrown objects are created equal. While it is common to throw numbers or strings as errors, it is frequently more effective to use one of the exception types specifically created for this purpose:

- ECMAScript exceptions
- `DOMException`

throw statement

Use the `throw` statement to throw an exception. A `throw` statement specifies the value to be thrown:

```
throw expression;
```

You may throw any expression, not just expressions of a specific type. The following code throws several exceptions of varying types:

```
throw "Error2"; // String type
throw 42; // Number type
throw true; // Boolean type
throw {
  toString() {
    return "I'm an object!";
  },
};
```

try...catch statement

The `try...catch` statement marks a block of statements to try, and specifies one or more responses should an exception be thrown. If an exception is thrown, the `try...catch` statement catches it.

The `try...catch` statement consists of a `try` block, which contains one or more statements, and a `catch` block, containing statements that specify what to do if an exception is thrown in the `try` block.

In other words, you want the `try` block to succeed—but if it does not, you want control to pass to the `catch` block. If any statement within the `try` block (or in a function called from within the `try` block) throws an exception, control *immediately* shifts to the `catch` block. If no exception is thrown in the `try` block, the `catch` block is skipped. The `finally` block executes after the `try` and `catch` blocks execute but before the statements following the `try...catch` statement.

The following example uses a `try...catch` statement. The example calls a function that retrieves a month name from an array based on the value passed to the function. If the value does not correspond to a month number (`1` – `12`), an exception is thrown with the value `'Invalid month code'` and the statements in the `catch` block set the `monthName` variable to `'unknown'`.

```
function getMonthName(mo) {
  mo--; // Adjust month number for array index (so that 0 = Jan, 11 = Dec)
  // prettier-ignore
  const months = [
    "Jan", "Feb", "Mar", "Apr", "May", "Jun",
    "Jul", "Aug", "Sep", "Oct", "Nov", "Dec",
  ];
  if (!months[mo]) {
    throw new Error("Invalid month code"); // throw keyword is used here
  }
  return months[mo];
}

try {
  // statements to try
  monthName = getMonthName(myMonth); // function could throw exception
} catch (e) {
  monthName = "unknown";
  logMyErrors(e); // pass exception object to error handler (i.e. your own function)
}
```

The catch block

You can use a `catch` block to handle all exceptions that may be generated in the `try` block.

```
catch (exception) {
  statements
}
```

The `catch` block specifies an identifier (`exception` in the preceding syntax) that holds the value specified by the `throw` statement. You can use this identifier to get information about the exception that was thrown.

JavaScript creates this identifier when the `catch` block is entered. The identifier lasts only for the duration of the `catch` block. Once the `catch` block finishes executing, the identifier no longer exists.

For example, the following code throws an exception. When the exception occurs, control transfers to the `catch` block.

```
try {
  throw "myException"; // generates an exception
} catch (err) {
  // statements to handle any exceptions
  logMyErrors(err); // pass exception object to error handler
}
```

> **Note:** When logging errors to the console inside a `catch` block, using `console.error()` rather than `console.log()` is advised for debugging. It formats the message as an error, and adds it to the list of error messages generated by the page.

The finally block

The `finally` block contains statements to be executed *after* the `try` and `catch` blocks execute. Additionally, the `finally` block executes *before* the code that follows the `try...catch...finally` statement.

It is also important to note that the `finally` block will execute *whether or not* an exception is thrown. If an exception is thrown, however, the statements in the `finally` block execute even if no `catch` block handles the exception that was thrown.

You can use the `finally` block to make your script fail gracefully when an exception occurs. For example, you may need to release a resource that your script has tied up.

The following example opens a file and then executes statements that use the file. (Server-side JavaScript allows you to access files.) If an exception is thrown while the file is open, the `finally` block closes the file before the script fails. Using `finally` here *ensures* that the file is never left open, even if an error occurs.

```
openMyFile();
try {
  writeMyFile(theData); // This may throw an error
} catch (e) {
  handleError(e); // If an error occurred, handle it
} finally {
  closeMyFile(); // Always close the resource
}
```

If the `finally` block returns a value, this value becomes the return value of the entire `try...catch...finally` production, regardless of any `return` statements in the `try` and `catch` blocks:

```
function f() {
  try {
    console.log(0);
    throw "bogus";
  } catch (e) {
    console.log(1);
    // This return statement is suspended
    // until finally block has completed
    return true;
    console.log(2); // not reachable
  } finally {
    console.log(3);
    return false; // overwrites the previous "return"
    // `f` exits here
    console.log(4); // not reachable
  }
  console.log(5); // not reachable
}
console.log(f()); // 0, 1, 3, false
```

Overwriting of return values by the `finally` block also applies to exceptions thrown or re-thrown inside of the `catch` block:

```
function f() {
  try {
    throw "bogus";
  } catch (e) {
    console.log('caught inner "bogus"');
    // This throw statement is suspended until
    // finally block has completed
    throw e;
  } finally {
    return false; // overwrites the previous "throw"
    // `f` exits here
  }
}

try {
  console.log(f());
} catch (e) {
  // this is never reached!
  // while f() executes, the `finally` block returns false,
  // which overwrites the `throw` inside the above `catch`
  console.log('caught outer "bogus"');
```

```
}

// Logs:
// caught inner "bogus"
// false
```

Nesting try...catch statements

You can nest one or more `try...catch` statements.

If an inner `try` block does *not* have a corresponding `catch` block:

1. it *must* contain a `finally` block, and
2. the enclosing `try...catch` statement's `catch` block is checked for a match.

For more information, see nested try-blocks on the `try...catch` reference page.

Utilizing Error objects

Depending on the type of error, you may be able to use the `name` and `message` properties to get a more refined message.

The `name` property provides the general class of `Error` (such as `DOMException` or `Error`), while `message` generally provides a more succinct message than one would get by converting the error object to a string.

If you are throwing your own exceptions, in order to take advantage of these properties (such as if your `catch` block doesn't discriminate between your own exceptions and system ones), you can use the `Error` constructor.

For example:

```
function doSomethingErrorProne() {
  if (ourCodeMakesAMistake()) {
    throw new Error("The message");
  }
  doSomethingToGetAJavaScriptError();
}

try {
  doSomethingErrorProne();
} catch (e) {
  // Now, we actually use `console.error()`
  console.error(e.name); // 'Error'
  console.error(e.message); // 'The message', or a JavaScript error message
}
```

JavaScript data types and data structures

Programming languages all have built-in data structures, but these often differ from one language to another. This article attempts to list the built-in data structures available in JavaScript and what properties they have. These can be used to build other data structures.

The language overview offers a similar summary of the common data types, but with more comparisons to other languages.

Dynamic and weak typing

JavaScript is a dynamic language with dynamic types. Variables in JavaScript are not directly associated with any particular value type, and any variable can be assigned (and re-assigned) values of all types:

```
let foo = 42; // foo is now a number
foo = "bar"; // foo is now a string
foo = true; // foo is now a boolean
```

JavaScript is also a weakly typed language, which means it allows implicit type conversion when an operation involves mismatched types, instead of throwing type errors.

```
const foo = 42; // foo is a number
const result = foo + "1"; // JavaScript coerces foo to a string, so it can be concatenated with the other operand
console.log(result); // 421
```

Implicit coercions are very convenient, but can create subtle bugs when conversions happen where they are not expected, or where they are expected to happen in the other direction (for example, string to number instead of number to string). For symbols and BigInts, JavaScript has intentionally disallowed certain implicit type conversions.

Primitive values

All types except Object define immutable values represented directly at the lowest level of the language. We refer to values of these types as *primitive values*.

All primitive types, except `null`, can be tested by the `typeof` operator. `typeof null` returns `"object"`, so one has to use `=== null` to test for `null`.

All primitive types, except `null` and `undefined`, have their corresponding object wrapper types, which provide useful methods for working with the primitive values. For example, the `Number` object provides methods like `toExponential()`. When a property is accessed on a primitive value, JavaScript automatically wraps the value into the

corresponding wrapper object and accesses the property on the object instead. However, accessing a property on `null` or `undefined` throws a `TypeError` exception, which necessitates the introduction of the optional chaining operator.

Type	`typeof` return value	Object wrapper
Null	`"object"`	N/A
Undefined	`"undefined"`	N/A
Boolean	`"boolean"`	`Boolean`
Number	`"number"`	`Number`
BigInt	`"bigint"`	`BigInt`
String	`"string"`	`String`
Symbol	`"symbol"`	`Symbol`

The object wrapper classes' reference pages contain more information about the methods and properties available for each type, as well as detailed descriptions for the semantics of the primitive types themselves.

Null type

The Null type is inhabited by exactly one value: `null`.

Undefined type

The Undefined type is inhabited by exactly one value: `undefined`.

Conceptually, `undefined` indicates the absence of a *value*, while `null` indicates the absence of an *object* (which could also make up an excuse for `typeof null === "object"`). The language usually defaults to `undefined` when something is devoid of a value:

- A `return` statement with no value (`return;`) implicitly returns `undefined`.
- Accessing a nonexistent object property (`obj.iDontExist`) returns `undefined`.
- A variable declaration without initialization (`let x;`) implicitly initializes the variable to `undefined`.
- Many methods, such as `Array.prototype.find()` and `Map.prototype.get()`, return `undefined` when no element is found.

`null` is used much less often in the core language. The most important place is the end of the prototype chain — subsequently, methods that interact with prototypes, such as `Object.getPrototypeOf()`, `Object.create()`, etc., accept or return `null` instead of `undefined`.

`null` is a keyword, but `undefined` is a normal identifier that happens to be a global property. In practice, the difference is minor, since `undefined` should not be redefined or shadowed.

Boolean type

The `Boolean` type represents a logical entity and is inhabited by two values: `true` and `false`.

Boolean values are usually used for conditional operations, including ternary operators, `if...else`, `while`, etc.

Number type

The `Number` type is a double-precision 64-bit binary format IEEE 754 value. It is capable of storing positive floating-point numbers between 2^{-1074} (`Number.MIN_VALUE`) and $2^{1023} \times (2 - 2^{-52})$ (`Number.MAX_VALUE`) as well as negative floating-point numbers of the same magnitude, but it can only safely store integers in the range $-(2^{53} - 1)$ (`Number.MIN_SAFE_INTEGER`) to $2^{53} - 1$ (`Number.MAX_SAFE_INTEGER`). Outside this range, JavaScript can no longer safely represent integers; they will instead be represented by a double-precision floating point approximation. You can check if a number is within the range of safe integers using `Number.isSafeInteger()`.

Values outside the representable range are automatically converted:

- Positive values greater than `Number.MAX_VALUE` are converted to `Infinity`.
- Positive values smaller than `Number.MIN_VALUE` are converted to `0`.
- Negative values smaller than `-Number.MAX_VALUE` are converted to `-Infinity`.
- Negative values greater than `-Number.MIN_VALUE` are converted to `-0`.

`Infinity` and `-Infinity` behave similarly to mathematical infinity, but with some slight differences; see `Number.POSITIVE_INFINITY` and `Number.NEGATIVE_INFINITY` for details.

The Number type has only one value with multiple representations: `0` is represented as both `-0` and `+0` (where `0` is an alias for `+0`). In practice, there is almost no difference between the different representations; for example, `+0 === -0` is `true`. However, you are able to notice this when you divide by zero:

```
console.log(42 / +0); // Infinity
console.log(42 / -0); // -Infinity
```

`NaN` ("**N**ot **a** **N**umber") is a special kind of number value that's typically encountered when the result of an arithmetic operation cannot be expressed as a number. It is also the only value in JavaScript that is not equal to itself.

Although a number is conceptually a "mathematical value" and is always implicitly floating-point-encoded, JavaScript provides bitwise operators. When applying bitwise operators, the number is first converted to a 32-bit integer.

> **Note:** Although bitwise operators *can* be used to represent several Boolean values within a single number using bit masking, this is usually considered a bad practice. JavaScript offers other means to represent a set of Booleans (like an array of Booleans, or an object with Boolean values assigned to named properties). Bit masking also tends to make the code more difficult to read, understand, and maintain.

It may be necessary to use such techniques in very constrained environments, like when trying to cope with the limitations of local storage, or in extreme cases (such as when each bit over the network counts). This technique should only be considered when it is the last measure that can be taken to optimize size.

BigInt type

The `BigInt` type is a numeric primitive in JavaScript that can represent integers with arbitrary magnitude. With BigInts, you can safely store and operate on large integers even beyond the safe integer limit (`Number.MAX_SAFE_INTEGER`) for Numbers.

A BigInt is created by appending `n` to the end of an integer or by calling the `BigInt()` function.

This example demonstrates where incrementing the `Number.MAX_SAFE_INTEGER` returns the expected result:

```
// BigInt
const x = BigInt(Number.MAX_SAFE_INTEGER); // 9007199254740991n
x + 1n === x + 2n; // false because 9007199254740992n and 9007199254740993n are unequal

// Number
Number.MAX_SAFE_INTEGER + 1 === Number.MAX_SAFE_INTEGER + 2; // true because both are 9007199254740992
```

You can use most operators to work with BigInts, including `+`, `*`, `-`, `**`, and `%` — the only forbidden one is `>>>`. A BigInt is not strictly equal to a Number with the same mathematical value, but it is loosely so.

BigInt values are neither always more precise nor always less precise than numbers, since BigInts cannot represent fractional numbers, but can represent big integers more accurately. Neither type entails the other, and they are not mutually substitutable. A `TypeError` is thrown if BigInt values are mixed with regular numbers in arithmetic expressions, or if they are implicitly converted to each other.

String type

The `String` type represents textual data and is encoded as a sequence of 16-bit unsigned integer values representing UTF-16 code units. Each element in the string occupies a position in the string. The first element is at index `0`, the next at index `1`, and so on. The length of a string is the number of UTF-16 code units in it, which may not correspond to the actual number of Unicode characters; see the `String` reference page for more details.

JavaScript strings are immutable. This means that once a string is created, it is not possible to modify it. String methods create new strings based on the content of the current string — for example:

- A substring of the original using `substring()`.
- A concatenation of two strings using the concatenation operator (+) or `concat()`.

Beware of "stringly-typing" your code!

It can be tempting to use strings to represent complex data. Doing this comes with short-term benefits:

- It is easy to build complex strings with concatenation.
- Strings are easy to debug (what you see printed is always what is in the string).
- Strings are the common denominator of a lot of APIs (input fields, local storage values, `fetch()` responses when using `Response.text()`, etc.) and it can be tempting to only work with strings.

With conventions, it is possible to represent any data structure in a string. This does not make it a good idea. For instance, with a separator, one could emulate a list (while a JavaScript array would be more suitable). Unfortunately, when the separator is used in one of the "list" elements, then, the list is broken. An escape character can be chosen, etc. All of this requires conventions and creates an unnecessary maintenance burden.

Use strings for textual data. When representing complex data, *parse* strings, and use the appropriate abstraction.

Symbol type

A `Symbol` is a **unique** and **immutable** primitive value and may be used as the key of an Object property (see below). In some programming languages, Symbols are called "atoms". The purpose of symbols is to create unique property keys that are guaranteed not to clash with keys from other code.

Objects

In computer science, an object is a value in memory which is possibly referenced by an identifier. In JavaScript, objects are the only mutable values. Functions are, in fact, also objects with the additional capability of being *callable*.

Properties

In JavaScript, objects can be seen as a collection of properties. With the object literal syntax, a limited set of properties are initialized; then properties can be added and removed. Object properties are equivalent to key-value pairs. Property keys are either strings or symbols. When other types (such as numbers) are used to index objects, the values are implicitly converted to strings. Property values can be values of any type, including other objects, which enables building complex data structures.

There are two types of object properties: The *data* property and the *accessor* property. Each property has corresponding *attributes*. Each attribute is accessed internally by the JavaScript engine, but you can set them through `Object.defineProperty()`, or read them through `Object.getOwnPropertyDescriptor()`. You can read more about the various nuances on the `Object.defineProperty()` page.

Data property

Data properties associate a key with a value. It can be described by the following attributes:

`value`

> The value retrieved by a get access of the property. Can be any JavaScript value.

`writable`

A boolean value indicating if the property can be changed with an assignment.

`enumerable`

A boolean value indicating if the property can be enumerated by a `for...in` loop. See also Enumerability and ownership of properties for how enumerability interacts with other functions and syntaxes.

`configurable`

A boolean value indicating if the property can be deleted, can be changed to an accessor property, and can have its attributes changed.

Accessor property

Associates a key with one of two accessor functions (`get` and `set`) to retrieve or store a value.

> **Note:** It's important to recognize it's accessor *property* — not accessor *method*. We can give a JavaScript object class-like accessors by using a function as a value — but that doesn't make the object a class.

An accessor property has the following attributes:

`get`

A function called with an empty argument list to retrieve the property value whenever a get access to the value is performed. See also getters. May be `undefined`.

`set`

A function called with an argument that contains the assigned value. Executed whenever a specified property is attempted to be changed. See also setters. May be `undefined`.

`enumerable`

A boolean value indicating if the property can be enumerated by a `for...in` loop. See also Enumerability and ownership of properties for how enumerability interacts with other functions and syntaxes.

`configurable`

A boolean value indicating if the property can be deleted, can be changed to a data property, and can have its attributes changed.

The prototype of an object points to another object or to `null` — it's conceptually a hidden property of the object, commonly represented as `[[Prototype]]`. Properties of the object's `[[Prototype]]` can also be accessed on the object itself.

Objects are ad-hoc key-value pairs, so they are often used as maps. However, there can be ergonomics, security, and performance issues. Use a `Map` for storing arbitrary data instead. The `Map` reference contains a more detailed discussion of the pros & cons between plain objects and maps for storing key-value associations.

Dates

JavaScript provides two sets of APIs for representing dates: the legacy `Date` object and the modern `Temporal` object. `Date` has many undesirable design choices and should be avoided in new code if possible.

Indexed collections: Arrays and typed Arrays

Arrays are regular objects for which there is a particular relationship between integer-keyed properties and the `length` property.

Additionally, arrays inherit from `Array.prototype`, which provides a handful of convenient methods to manipulate arrays. For example, `indexOf()` searches a value in the array and `push()` appends an element to the array. This makes Arrays a perfect candidate to represent ordered lists.

Typed Arrays present an array-like view of an underlying binary data buffer, and offer many methods that have similar semantics to the array counterparts. "Typed array" is an umbrella term for a range of data structures, including `Int8Array`, `Float32Array`, etc. Check the typed array page for more information. Typed arrays are often used in conjunction with `ArrayBuffer` and `DataView`.

Keyed collections: Maps, Sets, WeakMaps, WeakSets

These data structures take object references as keys. `Set` and `WeakSet` represent a collection of unique values, while `Map` and `WeakMap` represent a collection of key-value associations.

You could implement `Maps` and `Sets` yourself. However, since objects cannot be compared (in the sense of `<` "less than", for instance), neither does the engine expose its hash function for objects, look-up performance would necessarily be linear. Native implementations of them (including `WeakMaps`) can have look-up performance that is approximately logarithmic to constant time.

Usually, to bind data to a DOM node, one could set properties directly on the object, or use `data-*` attributes. This has the downside that the data is available to any script running in the same context. `Maps` and `WeakMaps` make it easy to *privately* bind data to an object.

`WeakMap` and `WeakSet` only allow garbage-collectable values as keys, which are either objects or non-registered symbols, and the keys may be collected even when they remain in the collection. They are specifically used for memory usage optimization.

Structured data: JSON

JSON (**J**ava**S**cript **O**bject **N**otation) is a lightweight data-interchange format, derived from JavaScript, but used by many programming languages. JSON builds universal data structures that can be transferred between different environments and even across languages. See `JSON` for more details.

More objects in the standard library

JavaScript has a standard library of built-in objects. Read the reference to find out more about the built-in objects.

Type coercion

As mentioned above, JavaScript is a weakly typed language. This means that you can often use a value of one type where another type is expected, and the language will convert it to the right type for you. To do so, JavaScript defines a handful of coercion rules.

Primitive coercion

The primitive coercion process is used where a primitive value is expected, but there's no strong preference for what the actual type should be. This is usually when a string, a number, or a BigInt are equally acceptable. For example:

- The `Date()` constructor, when it receives one argument that's not a `Date` instance — strings represent date strings, while numbers represent timestamps.
- The `+` operator — if one operand is a string, string concatenation is performed; otherwise, numeric addition is performed.
- The `==` operator — if one operand is a primitive while the other is an object, the object is converted to a primitive value with no preferred type.

This operation does not do any conversion if the value is already a primitive. Objects are converted to primitives by calling its `[Symbol.toPrimitive]()` (with `"default"` as hint), `valueOf()`, and `toString()` methods, in that order. Note that primitive conversion calls `valueOf()` before `toString()`, which is similar to the behavior of number coercion but different from string coercion.

The `[Symbol.toPrimitive]()` method, if present, must return a primitive — returning an object results in a `TypeError`. For `valueOf()` and `toString()`, if one returns an object, the return value is ignored and the other's return value is used instead; if neither is present, or neither returns a primitive, a `TypeError` is thrown. For example, in the following code:

```
console.log({} + []); // "[object Object]"
```

Neither `{}` nor `[]` have a `[Symbol.toPrimitive]()` method. Both `{}` and `[]` inherit `valueOf()` from `Object.prototype.valueOf`, which returns the object itself. Since the return value is an object, it is ignored. Therefore, `toString()` is called instead. `{}.toString()` returns `"[object Object]"`, while `[].toString()` returns `""`, so the result is their concatenation: `"[object Object]"`.

The `[Symbol.toPrimitive]()` method always takes precedence when doing conversion to any primitive type. Primitive conversion generally behaves like number conversion, because `valueOf()` is called in priority; however, objects with custom `[Symbol.toPrimitive]()` methods can choose to return any primitive. `Date` and `Symbol` objects are the only built-in objects that override the `[Symbol.toPrimitive]()` method. `Date.prototype[Symbol.toPrimitive]()` treats the `"default"` hint as if it's `"string"`, while `Symbol.prototype[Symbol.toPrimitive]()` ignores the hint and always returns a symbol.

Numeric coercion

There are two numeric types: Number and BigInt. Sometimes the language specifically expects a number or a BigInt (such as `Array.prototype.slice()`, where the index must be a number); other times, it may tolerate either and perform different operations depending on the operand's type. For strict coercion processes that do not allow implicit conversion from the other type, see number coercion and BigInt coercion.

Numeric coercion is nearly the same as number coercion, except that BigInts are returned as-is instead of causing a `TypeError`. Numeric coercion is used by all arithmetic operators, since they are overloaded for both numbers and BigInts. The only exception is unary plus, which always does number coercion.

Other coercions

All data types, except Null, Undefined, and Symbol, have their respective coercion process. See string coercion, boolean coercion, and object coercion for more details.

As you may have noticed, there are three distinct paths through which objects may be converted to primitives:

- Primitive coercion: `[Symbol.toPrimitive]("default")` → `valueOf()` → `toString()`
- Numeric coercion, number coercion, BigInt coercion: `[Symbol.toPrimitive]("number")` → `valueOf()` → `toString()`
- String coercion: `[Symbol.toPrimitive]("string")` → `toString()` → `valueOf()`

In all cases, `[Symbol.toPrimitive]()`, if present, must be callable and return a primitive, while `valueOf` or `toString` will be ignored if they are not callable or return an object. At the end of the process, if successful, the result is guaranteed to be a primitive. The resulting primitive is then subject to further coercions depending on the context.

Enumerability and ownership of properties

Every property in JavaScript objects can be classified by three factors:

- Enumerable or non-enumerable;
- String or symbol;
- Own property or inherited property from the prototype chain.

Enumerable properties are those properties whose internal enumerable flag is set to true, which is the default for properties created via simple assignment or via a property initializer. Properties defined via `Object.defineProperty` and such are not enumerable by default. Most iteration means (such as `for...in` loops and `Object.keys`) only visit enumerable keys.

Ownership of properties is determined by whether the property belongs to the object directly and not to its prototype chain.

All properties, enumerable or not, string or symbol, own or inherited, can be accessed with dot notation or bracket notation. In this section, we will focus on the means provided by JavaScript to visit a group of object properties one-by-one.

Querying object properties

There are four built-in ways to query a property of an object. They all support both string and symbol keys. The following table summarizes when each method returns `true`.

	Enumerable, own	Enumerable, inherited	Non-enumerable, own	Non-enumerable, inherited
`propertyIsEnumerable()`	`true` ✅	`false` ❌	`false` ❌	`false` ❌
`hasOwnProperty()`	`true` ✅	`false` ❌	`true` ✅	`false` ❌
`Object.hasOwn()`	`true` ✅	`false` ❌	`true` ✅	`false` ❌
`in`	`true` ✅	`true` ✅	`true` ✅	`true` ✅

Traversing object properties

There are many methods in JavaScript that traverse a group of properties of an object. Sometimes, these properties are returned as an array; sometimes, they are iterated one-by-one in a loop; sometimes, they are used for constructing or mutating another object. The following table summarizes when a property may be visited.

Methods that only visit string properties or only symbol properties will have an extra note. ✅ means a property of this type will be visited; ❌ means it will not.

	Enumerable, own	Enumerable, inherited	Non-enumerable, own	Non-enumerable, inherited

`Object.keys`
`Object.values`
`Object.entries`
	✅ (strings)	❌	❌	❌

`Object.getOwnPropertyNames`	✅ (strings)	❌	✅ (strings)	❌
`Object.getOwnPropertySymbols`	✅ (symbols)	❌	✅ (symbols)	❌
`Object.getOwnPropertyDescriptors`	✅	❌	✅	❌
`Reflect.ownKeys`	✅	❌	✅	❌
`for...in`	✅ (strings)	✅ (strings)	❌	❌
`Object.assign` (After the first parameter)	✅	❌	❌	❌
Object spread	✅	❌	❌	❌

Obtaining properties by enumerability/ownership

Note that this is not the most efficient algorithm for all cases, but useful for a quick demonstration.

- Detection can occur by `SimplePropertyRetriever.theGetMethodYouWant(obj).includes(prop)`
- Iteration can occur by `SimplePropertyRetriever.theGetMethodYouWant(obj).forEach((value, prop) => {});` (or use `filter()`, `map()`, etc.)

```
const SimplePropertyRetriever = {
  getOwnEnumProps(obj) {
    return this._getPropertyNames(obj, true, false, this._enumerable);
    // Or could use for...in filtered with Object.hasOwn or just this: return Object.keys(obj);
  },
  getOwnNonEnumProps(obj) {
    return this._getPropertyNames(obj, true, false, this._notEnumerable);
  },
  getOwnProps(obj) {
    return this._getPropertyNames(
      obj,
      true,
      false,
      this._enumerableAndNotEnumerable,
    );
    // Or just use: return Object.getOwnPropertyNames(obj);
  },
  getPrototypeEnumProps(obj) {
    return this._getPropertyNames(obj, false, true, this._enumerable);
  },
  getPrototypeNonEnumProps(obj) {
    return this._getPropertyNames(obj, false, true, this._notEnumerable);
  },
  getPrototypeProps(obj) {
    return this._getPropertyNames(
      obj,
      false,
      true,
      this._enumerableAndNotEnumerable,
    );
  },
  getOwnAndPrototypeEnumProps(obj) {
    return this._getPropertyNames(obj, true, true, this._enumerable);
    // Or could use unfiltered for...in
  },
  getOwnAndPrototypeNonEnumProps(obj) {
```

```
    return this._getPropertyNames(obj, true, true, this._notEnumerable);
  },
  getOwnAndPrototypeEnumAndNonEnumProps(obj) {
    return this._getPropertyNames(
      obj,
      true,
      true,
      this._enumerableAndNotEnumerable,
    );
  },
  // Private static property checker callbacks
  _enumerable(obj, prop) {
    return Object.prototype.propertyIsEnumerable.call(obj, prop);
  },
  _notEnumerable(obj, prop) {
    return !Object.prototype.propertyIsEnumerable.call(obj, prop);
  },
  _enumerableAndNotEnumerable(obj, prop) {
    return true;
  },
  // Inspired by http://stackoverflow.com/a/8024294/271577
  _getPropertyNames(obj, iterateSelf, iteratePrototype, shouldInclude) {
    const props = [];
    do {
      if (iterateSelf) {
        Object.getOwnPropertyNames(obj).forEach((prop) => {
          if (props.indexOf(prop) === -1 && shouldInclude(obj, prop)) {
            props.push(prop);
          }
        });
      }
      if (!iteratePrototype) {
        break;
      }
      iterateSelf = true;
      obj = Object.getPrototypeOf(obj);
    } while (obj);
    return props;
  },
};
```

Equality comparisons and sameness

JavaScript provides three different value-comparison operations:

- `===` — strict equality (triple equals)
- `==` — loose equality (double equals)
- `Object.is()`

Which operation you choose depends on what sort of comparison you are looking to perform. Briefly:

- Double equals (`==`) will perform a type conversion when comparing two things, and will handle `NaN`, `-0`, and `+0` specially to conform to IEEE 754 (so `NaN != NaN`, and `-0 == +0`);
- Triple equals (`===`) will do the same comparison as double equals (including the special handling for `NaN`, `-0`, and `+0`) but without type conversion; if the types differ, `false` is returned.
- `Object.is()` does no type conversion and no special handling for `NaN`, `-0`, and `+0` (giving it the same behavior as `===` except on those special numeric values).

They correspond to three of four equality algorithms in JavaScript:

- IsLooselyEqual: `==`
- IsStrictlyEqual: `===`
- SameValue: `Object.is()`
- SameValueZero: used by many built-in operations

Note that the distinctions between these all have to do with their handling of primitives; none of them compares whether the parameters are conceptually similar in structure. For any non-primitive objects `x` and `y` which have the same structure but are distinct objects themselves, all of the above forms will evaluate to `false`.

Comparing the contents of distinct objects or arrays recursively is called deep equality. JavaScript does not provide a general deep comparison operator; libraries and host APIs can provide comparison utilities with different rules.

Strict equality using ===

Strict equality compares two values for equality. Neither value is implicitly converted to some other value before being compared. If the values have different types, the values are considered unequal. If the values have the same type, are not numbers, and have the same value, they're considered equal. Finally, if both values are numbers, they're considered equal if they're both not `NaN` and are the same value, or if one is `+0` and one is `-0`.

```
const num = 0;
const obj = new String("0");
const str = "0";

console.log(num === num); // true
console.log(obj === obj); // true
console.log(str === str); // true

console.log(num === obj); // false
console.log(num === str); // false
console.log(obj === str); // false
console.log(null === undefined); // false
console.log(obj === null); // false
console.log(obj === undefined); // false
```

Strict equality is almost always the correct comparison operation to use. For all values except numbers, it uses the obvious semantics: a value is only equal to itself. For numbers it uses slightly different semantics to gloss over two different edge cases. The first is that floating point zero is either positively or negatively signed. This is useful in representing certain mathematical solutions, but as most situations don't care about the difference between `+0` and `-0`, strict equality treats them as the same value. The second is that floating point includes the concept of a not-a-number value, `NaN`, to represent the solution to certain ill-defined mathematical problems: negative infinity added to positive infinity, for example. Strict equality treats `NaN` as unequal to every other value — including itself. (The only case in which `(x !== x)` is `true` is when `x` is `NaN`.)

Besides `===`, strict equality is also used by array index-finding methods including `Array.prototype.indexOf()`, `Array.prototype.lastIndexOf()`, `TypedArray.prototype.indexOf()`, `TypedArray.prototype.lastIndexOf()`, and `case`-matching. This means you cannot use `indexOf(NaN)` to find the index of a `NaN` value in an array, or use `NaN` as a `case` value in a `switch` statement and make it match anything.

```
console.log([NaN].indexOf(NaN)); // -1
switch (NaN) {
  case NaN:
    console.log("Surprise"); // Nothing is logged
}
```

Loose equality using ==

Loose equality is *symmetric*: `A == B` always has identical semantics to `B == A` for any values of `A` and `B` (except for the order of applied conversions). The behavior for performing loose equality using `==` is as follows:

1. If the operands have the same type, they are compared as follows:
   - Object: return `true` only if both operands reference the same object.
   - String: return `true` only if both operands have the same characters in the same order.
   - Number: return `true` only if both operands have the same value. `+0` and `-0` are treated as the same value. If either operand is `NaN`, return `false`; so `NaN` is never equal to `NaN`.
   - Boolean: return `true` only if operands are both `true` or both `false`.
   - BigInt: return `true` only if both operands have the same value.
   - Symbol: return `true` only if both operands reference the same symbol.
2. If one of the operands is `null` or `undefined`, the other must also be `null` or `undefined` to return `true`. Otherwise return `false`.
3. If one of the operands is an object and the other is a primitive, convert the object to a primitive.
4. At this step, both operands are converted to primitives (one of String, Number, Boolean, Symbol, and BigInt). The rest of the conversion is done case-by-case.
   - If they are of the same type, compare them using step 1.
   - If one of the operands is a Symbol but the other is not, return `false`.
   - If one of the operands is a Boolean but the other is not, convert the boolean to a number: `true` is converted to 1, and `false` is converted to 0. Then compare the two operands loosely again.
   - Number to String: convert the string to a number. Conversion failure results in `NaN`, which will guarantee the equality to be `false`.
   - Number to BigInt: compare by their mathematical value. If the number is ±Infinity or `NaN`, return `false`.
   - String to BigInt: convert the string to a BigInt using the same algorithm as the `BigInt()` constructor. If conversion fails, return `false`.

Traditionally, and according to ECMAScript, all primitives and objects are loosely unequal to `undefined` and `null`. But most browsers permit a very narrow class of objects (specifically, the `document.all` object for any page), in some contexts, to act as if they *emulate* the value `undefined`. Loose equality is one such context: `null == A` and `undefined == A` evaluate to true if, and only if, A is an object that *emulates* `undefined`. In all other cases an object is never loosely equal to `undefined` or `null`.

In most cases, using loose equality is discouraged. The result of a comparison using strict equality is easier to predict, and may evaluate more quickly due to the lack of type coercion.

The following example demonstrates loose equality comparisons involving the number primitive `0`, the bigint primitive `0n`, the string primitive `'0'`, and an object whose `toString()` value is `'0'`.

```
const num = 0;
const big = 0n;
const str = "0";
const obj = new String("0");

console.log(num == str); // true
console.log(big == num); // true
console.log(str == big); // true
```

```
console.log(num == obj); // true
console.log(big == obj); // true
console.log(str == obj); // true
```

Loose equality is only used by the == operator.

Same-value equality using Object.is()

Same-value equality determines whether two values are *functionally identical* in all contexts. (This use case demonstrates an instance of the Liskov substitution principle.) One instance occurs when an attempt is made to mutate an immutable property:

```
// Add an immutable NEGATIVE_ZERO property to the Number constructor.
Object.defineProperty(Number, "NEGATIVE_ZERO", {
  value: -0,
  writable: false,
  configurable: false,
  enumerable: false,
});

function attemptMutation(v) {
  Object.defineProperty(Number, "NEGATIVE_ZERO", { value: v });
}
```

`Object.defineProperty` will throw an exception when attempting to change an immutable property, but it does nothing if no actual change is requested. If `v` is `-0`, no change has been requested, and no error will be thrown. Internally, when an immutable property is redefined, the newly-specified value is compared against the current value using same-value equality.

Same-value equality is provided by the `Object.is` method. It's used almost everywhere in the language where a value of equivalent identity is expected.

Same-value-zero equality

Similar to same-value equality, but +0 and -0 are considered equal.

Same-value-zero equality is not exposed as a JavaScript API, but can be implemented with custom code:

```
function sameValueZero(x, y) {
  if (typeof x === "number" && typeof y === "number") {
    // x and y are equal (may be -0 and 0) or they are both NaN
    return x === y || (x !== x && y !== y);
  }
  return x === y;
}
```

Same-value-zero only differs from strict equality by treating `NaN` as equivalent, and only differs from same-value equality by treating `-0` as equivalent to `0`. This makes it usually have the most sensible behavior during searching, especially when working with `NaN`. It's used by `Array.prototype.includes()`, `TypedArray.prototype.includes()`, as well as `Map` and `Set` methods for comparing key equality.

Comparing equality methods

People often compare double equals and triple equals by saying one is an "enhanced" version of the other. For example, double equals could be said as an extended version of triple equals, because the former does everything that the latter does, but with type conversion on its operands — for example, `6 == "6"`. Alternatively, it can be claimed that double equals is the baseline, and triple equals is an enhanced version, because it requires the two operands to be the same type, so it adds an extra constraint.

However, this way of thinking implies that the equality comparisons form a one-dimensional "spectrum" where "totally strict" lies on one end and "totally loose" lies on the other. This model falls short with `Object.is`, because it isn't "looser" than double equals or "stricter" than triple equals, nor does it fit somewhere in between (i.e., being both stricter than double equals, but looser than triple equals). We can see from the sameness comparisons table below that this is due to the way that `Object.is` handles `NaN`. Notice that if `Object.is(NaN, NaN)` evaluated to `false`, we *could* say that it fits on the loose/strict spectrum as an even stricter form of triple equals, one that distinguishes between `-0` and `+0`. The `NaN` handling means this is untrue, however. Unfortunately, `Object.is` has to be thought of in terms of its specific characteristics, rather than its looseness or strictness with regard to the equality operators.

x	y	==	===	Object.is	SameValueZero
undefined	undefined	✅ true	✅ true	✅ true	✅ true
null	null	✅ true	✅ true	✅ true	✅ true
true	true	✅ true	✅ true	✅ true	✅ true
false	false	✅ true	✅ true	✅ true	✅ true
'foo'	'foo'	✅ true	✅ true	✅ true	✅ true
0	0	✅ true	✅ true	✅ true	✅ true
+0	-0	✅ true	✅ true	❌ false	✅ true
+0	0	✅ true	✅ true	✅ true	✅ true
-0	0	✅ true	✅ true	❌ false	✅ true
0n	-0n	✅ true	✅ true	✅ true	✅ true
0	false	✅ true	❌ false	❌ false	❌ false
""	false	✅ true	❌ false	❌ false	❌ false

x	y	==	===	Object.is	SameValueZero
""	0	✅ true	❌ false	❌ false	❌ false
'0'	0	✅ true	❌ false	❌ false	❌ false
'17'	17	✅ true	❌ false	❌ false	❌ false
[1, 2]	'1,2'	✅ true	❌ false	❌ false	❌ false
new String('foo')	'foo'	✅ true	❌ false	❌ false	❌ false
null	undefined	✅ true	❌ false	❌ false	❌ false
null	false	❌ false	❌ false	❌ false	❌ false
undefined	false	❌ false	❌ false	❌ false	❌ false
{ foo: 'bar' }	{ foo: 'bar' }	❌ false	❌ false	❌ false	❌ false
new String('foo')	new String('foo')	❌ false	❌ false	❌ false	❌ false
0	null	❌ false	❌ false	❌ false	❌ false
0	NaN	❌ false	❌ false	❌ false	❌ false
'foo'	NaN	❌ false	❌ false	❌ false	❌ false
NaN	NaN	❌ false	❌ false	✅ true	✅ true

When to use Object.is() versus triple equals

In general, the only time `Object.is`'s special behavior towards zeros is likely to be of interest is in the pursuit of certain meta-programming schemes, especially regarding property descriptors, when it is desirable for your work to mirror some of the characteristics of `Object.defineProperty`. If your use case does not require this, it is suggested to avoid `Object.is` and use `===` instead. Even if your requirements involve having comparisons between two `NaN` values evaluate to `true`, generally it is easier to special-case the `NaN` checks (using the `isNaN` method available from previous versions of ECMAScript) than it is to work out how surrounding computations might affect the sign of any zeros you encounter in your comparison.

Here's a non-exhaustive list of built-in methods and operators that might cause a distinction between `-0` and `+0` to manifest itself in your code:

`-` (unary negation)

> Consider the following example:
>
> ```
> const stoppingForce = obj.mass * -obj.velocity;
> ```
>
> If `obj.velocity` is `0` (or computes to `0`), a `-0` is introduced at that place and propagates out into `stoppingForce`.

`Math.atan2`, `Math.ceil`, `Math.pow`, `Math.round`

> In some cases, it's possible for a `-0` to be introduced into an expression as a return value of these methods even when no `-0` exists as one of the parameters. For example, using `Math.pow` to raise `-Infinity` to the power of any negative, odd exponent evaluates to `-0`. Refer to the documentation for the individual methods.

`Math.floor`, `Math.max`, `Math.min`, `Math.sin`, `Math.sqrt`, `Math.tan`

> It's possible to get a `-0` return value out of these methods in some cases where a `-0` exists as one of the parameters. E.g., `Math.min(-0, +0)` evaluates to `-0`. Refer to the documentation for the individual methods.

`~`, `<<`, `>>`

> Each of these operators uses the ToInt32 algorithm internally. Since there is only one representation for 0 in the internal 32-bit integer type, `-0` will not survive a round trip after an inverse operation. E.g., both `Object.is(~~(-0), -0)` and `Object.is(-0 << 2 >> 2, -0)` evaluate to `false`.

Relying on `Object.is` when the sign of zeros is not taken into account can be hazardous. Of course, when the intent is to distinguish between `-0` and `+0`, it does exactly what's desired.

Caveat: Object.is() and NaN

`Object.is()` treats all instances of `NaN` as the same value. However, since typed arrays are available, we can have distinct floating point representations of `NaN` which don't behave identically in all contexts. For example:

```
const f2b = (x) => new Uint8Array(new Float64Array([x]).buffer);
const b2f = (x) => new Float64Array(x.buffer)[0];
// Get a byte representation of NaN
const n = f2b(NaN);
// Change the first bit, which is the sign bit and doesn't matter for NaN
n[7] |= 0x80;
const nan2 = b2f(n);
console.log(nan2); // NaN
console.log(Object.is(nan2, NaN)); // true
console.log(f2b(NaN)); // Uint8Array(8) [0, 0, 0, 0, 0, 0, 248, 127]
console.log(f2b(nan2)); // Uint8Array(8) [0, 0, 0, 0, 0, 0, 248, 255]
```

> **Note:** Implementations are allowed to canonicalize the bit representation of `NaN`, so `nan2`, when converted back to floating point, may have the same bit representation as the original `NaN`.

Expressions and operators

- Previous
- Next

This chapter describes JavaScript's expressions and operators, including assignment, comparison, arithmetic, bitwise, logical, string, ternary and more.

At a high level, an *expression* is a valid unit of code that resolves to a value. There are two types of expressions: those that have side effects (such as assigning values) and those that purely *evaluate*.

The expression `x = 7` is an example of the first type. This expression uses the `=` *operator* to assign the value seven to the variable `x`. The expression itself evaluates to `7`.

The expression `3 + 4` is an example of the second type. This expression uses the `+` operator to add `3` and `4` together and produces a value, `7`. However, if it's not eventually part of a bigger construct (for example, a variable declaration like `const z = 3 + 4`), its result will be immediately discarded — this is usually a programmer mistake because the evaluation doesn't produce any effects.

As the examples above also illustrate, all complex expressions are joined by *operators*, such as `=` and `+`. In this section, we will introduce the following operators:

- Assignment operators
- Comparison operators
- Arithmetic operators
- Bitwise operators
- Logical operators
- BigInt operators
- String operators
- Conditional (ternary) operator
- Comma operator
- Unary operators
- Relational operators

These operators join operands either formed by higher-precedence operators or one of the basic expressions. A complete and detailed list of operators and expressions is also available in the reference.

The *precedence* of operators determines the order they are applied when evaluating an expression. For example:

```
const x = 1 + 2 * 3;
const y = 2 * 3 + 1;
```

Despite `*` and `+` coming in different orders, both expressions would result in `7` because `*` has precedence over `+`, so the `*`-joined expression will always be evaluated first. You can override operator precedence by using parentheses (which creates a grouped expression — the basic expression). To see a complete table of operator precedence as well as various caveats, see the Operator Precedence Reference page.

JavaScript has both *binary* and *unary* operators, and one special ternary operator, the conditional operator. A binary operator requires two operands, one before the operator and one after the operator:

```
operand1 operator operand2
```

For example, `3 + 4` or `x * y`. This form is called an *infix* binary operator, because the operator is placed between two operands. All binary operators in JavaScript are infix.

A unary operator requires a single operand, either before or after the operator:

```
operator operand
operand operator
```

For example, `x++` or `++x`. The `operator operand` form is called a *prefix* unary operator, and the `operand operator` form is called a *postfix* unary operator. `++` and `--` are the only postfix operators in JavaScript — all other operators, like `!`, `typeof`, etc. are prefix.

Assignment operators

An assignment operator assigns a value to its left operand based on the value of its right operand. The simple assignment operator is equal (`=`), which assigns the value of its right operand to its left operand. That is, `x = f()` is an assignment expression that assigns the value of `f()` to `x`.

There are also compound assignment operators that are shorthand for the operations listed in the following table:

Name	Shorthand operator	Meaning
Assignment	`x = f()`	`x = f()`
Addition assignment	`x += f()`	`x = x + f()`
Subtraction assignment	`x -= f()`	`x = x - f()`
Multiplication assignment	`x *= f()`	`x = x * f()`
Division assignment	`x /= f()`	`x = x / f()`
Remainder assignment	`x %= f()`	`x = x % f()`
Exponentiation assignment	`x **= f()`	`x = x ** f()`
Left shift assignment	`x <<= f()`	`x = x << f()`

Name	Shorthand operator	Meaning
Right shift assignment	`x >>= f()`	`x = x >> f()`
Unsigned right shift assignment	`x >>>= f()`	`x = x >>> f()`
Bitwise AND assignment	`x &= f()`	`x = x & f()`
Bitwise XOR assignment	`x ^= f()`	`x = x ^ f()`
Bitwise OR assignment	`x |= f()`	`x = x | f()`
Logical AND assignment	`x &&= f()`	`x && (x = f())`
Logical OR assignment	`x ||= f()`	`x || (x = f())`
Nullish coalescing assignment	`x ??= f()`	`x ?? (x = f())`

Assigning to properties

If an expression evaluates to an object, then the left-hand side of an assignment expression may make assignments to properties of that expression. For example:

```
const obj = {};

obj.x = 3;
console.log(obj.x); // Prints 3.
console.log(obj); // Prints { x: 3 }.

const key = "y";
obj[key] = 5;
console.log(obj[key]); // Prints 5.
console.log(obj); // Prints { x: 3, y: 5 }.
```

For more information about objects, read Working with Objects.

If an expression does not evaluate to an object, then assignments to properties of that expression do not assign:

```
const val = 0;
val.x = 3;

console.log(val.x); // Prints undefined.
console.log(val); // Prints 0.
```

In strict mode, the code above throws, because one cannot assign properties to primitives.

It is an error to assign values to unmodifiable properties or to properties of an expression without properties (`null` or `undefined`).

Destructuring

For more complex assignments, the destructuring syntax is a JavaScript expression that makes it possible to extract data from arrays or objects using a syntax that mirrors the construction of array and object literals.

Without destructuring, it takes multiple statements to extract values from arrays and objects:

```
const foo = ["one", "two", "three"];

const one = foo[0];
const two = foo[1];
const three = foo[2];
```

With destructuring, you can extract multiple values into distinct variables using a single statement:

```
const [one, two, three] = foo;
```

Evaluation and nesting

In general, assignments are used within a variable declaration (i.e., with `const`, `let`, or `var`) or as standalone statements.

```
// Declares a variable x and initializes it to the result of f().
// The result of the x = f() assignment expression is discarded.
let x = f();

x = g(); // Reassigns the variable x to the result of g().
```

However, like other expressions, assignment expressions like `x = f()` evaluate into a result value. Although this result value is usually not used, it can then be used by another expression.

Chaining assignments or nesting assignments in other expressions can result in surprising behavior. For this reason, some JavaScript style guides discourage chaining or nesting assignments. Nevertheless, assignment chaining and nesting may occur sometimes, so it is important to be able to understand how they work.

By chaining or nesting an assignment expression, its result can itself be assigned to another variable. It can be logged, it can be put inside an array literal or function call, and so on.

```
let x;
const y = (x = f()); // Or equivalently: const y = x = f();
```

```
console.log(y); // Logs the return value of the assignment x = f().

console.log(x = f()); // Logs the return value directly.

// An assignment expression can be nested in any place
// where expressions are generally allowed,
// such as array literals' elements or as function calls' arguments.
console.log([0, x = f(), 0]);
console.log(f(0, x = f(), 0));
```

The evaluation result matches the expression to the right of the `=` sign in the "Meaning" column of the table above. That means that `x = f()` evaluates into whatever `f()`'s result is, `x += f()` evaluates into the resulting sum `x + f()`, `x **= f()` evaluates into the resulting power `x ** f()`, and so on.

In the case of logical assignments, `x &&= f()`, `x ||= f()`, and `x ??= f()`, the return value is that of the logical operation without the assignment, so `x && f()`, `x || f()`, and `x ?? f()`, respectively.

When chaining these expressions without parentheses or other grouping operators like array literals, the assignment expressions are **grouped right to left** (they are right-associative), but they are **evaluated left to right**.

Note that, for all assignment operators other than `=` itself, the resulting values are always based on the operands' values *before* the operation.

For example, assume that the following functions `f` and `g` and the variables `x` and `y` have been declared:

```
function f() {
  console.log("F!");
  return 2;
}
function g() {
  console.log("G!");
  return 3;
}
let x, y;
```

Consider these three examples:

```
y = x = f();
y = [f(), x = g()];
x[f()] = g();
```

Evaluation example 1

`y = x = f()` is equivalent to `y = (x = f())`, because the assignment operator `=` is right-associative. However, it evaluates from left to right:

1. The assignment expression `y = x = f()` starts to evaluate.
    1. The `y` on this assignment's left-hand side evaluates into a reference to the variable named `y`.
    2. The assignment expression `x = f()` starts to evaluate.
        1. The `x` on this assignment's left-hand side evaluates into a reference to the variable named `x`.
        2. The function call `f()` prints "F!" to the console and then evaluates to the number `2`.
        3. That `2` result from `f()` is assigned to `x`.
    3. The assignment expression `x = f()` has now finished evaluating; its result is the new value of `x`, which is `2`.
    4. That `2` result in turn is also assigned to `y`.
2. The assignment expression `y = x = f()` has now finished evaluating; its result is the new value of `y` – which happens to be `2`. `x` and `y` are assigned to `2`, and the console has printed "F!".

Evaluation example 2

`y = [ f(), x = g() ]` also evaluates from left to right:

1. The assignment expression `y = [ f(), x = g() ]` starts to evaluate.
    1. The `y` on this assignment's left-hand evaluates into a reference to the variable named `y`.
    2. The inner array literal `[ f(), x = g() ]` starts to evaluate.
        1. The function call `f()` prints "F!" to the console and then evaluates to the number `2`.
        2. The assignment expression `x = g()` starts to evaluate.
            1. The `x` on this assignment's left-hand side evaluates into a reference to the variable named `x`.
            2. The function call `g()` prints "G!" to the console and then evaluates to the number `3`.
            3. That `3` result from `g()` is assigned to `x`.
        3. The assignment expression `x = g()` has now finished evaluating; its result is the new value of `x`, which is `3`. That `3` result becomes the next element in the inner array literal (after the `2` from the `f()`).
    3. The inner array literal `[ f(), x = g() ]` has now finished evaluating; its result is an array with two values: `[ 2, 3 ]`.
    4. That `[ 2, 3 ]` array is now assigned to `y`.
2. The assignment expression `y = [ f(), x = g() ]` has now finished evaluating; its result is the new value of `y` – which happens to be `[ 2, 3 ]`. `x` is now assigned to `3`, `y` is now assigned to `[ 2, 3 ]`, and the console has printed "F!" then "G!".

Evaluation example 3

`x[f()] = g()` also evaluates from left to right. (This example assumes that `x` is already assigned to some object. For more information about objects, read Working with Objects.)

1. The assignment expression `x[f()] = g()` starts to evaluate.
    1. The `x[f()]` property access on this assignment's left-hand starts to evaluate.

    1. The `x` in this property access evaluates into a reference to the variable named `x`.
    2. Then the function call `f()` prints "F!" to the console and then evaluates to the number `2`.
  2. The `x[f()]` property access on this assignment has now finished evaluating; its result is a variable property reference: `x[2]`.
  3. Then the function call `g()` prints "G!" to the console and then evaluates to the number `3`.
  4. That `3` is now assigned to `x[2]`. (This step will succeed only if `x` is assigned to an object.)
2. The assignment expression `x[f()] = g()` has now finished evaluating; its result is the new value of `x[2]` – which happens to be `3`. `x[2]` is now assigned to `3`, and the console has printed "F!" then "G!".

Avoid assignment chains

Chaining assignments or nesting assignments in other expressions can result in surprising behavior. For this reason, chaining assignments in the same statement is discouraged.

In particular, putting a variable chain in a `const`, `let`, or `var` statement often does *not* work. Only the outermost/leftmost variable would get declared; other variables within the assignment chain are *not* declared by the `const`/`let`/`var` statement. For example:

```
const z = y = x = f();
```

This statement seemingly declares the variables `x`, `y`, and `z`. However, it only actually declares the variable `z`. `y` and `x` are either invalid references to nonexistent variables (in strict mode) or, worse, would implicitly create global variables for `x` and `y` in sloppy mode.

Comparison operators

A comparison operator compares its operands and returns a logical value based on whether the comparison is true. The operands can be numerical, string, logical, or object values. Strings are compared based on standard lexicographical ordering, using Unicode values. In most cases, if the two operands are not of the same type, JavaScript attempts to convert them to an appropriate type for the comparison. This behavior generally results in comparing the operands numerically. The sole exceptions to type conversion within comparisons involve the `===` and `!==` operators, which perform strict equality and inequality comparisons. These operators do not attempt to convert the operands to compatible types before checking equality. The following table describes the comparison operators in terms of this sample code:

```
const var1 = 3;
const var2 = 4;
```

Comparison operators

Operator	Description	Examples returning true

Equal (`==`)	Returns `true` if the operands are equal.	`3 == var1`
		`"3" == var1`
		`3 == '3'`

Not equal (`!=`)	Returns `true` if the operands are not equal.	`var1 != 4` `var2 != "3"`
Strict equal (`===`)	Returns `true` if the operands are equal and of the same type. See also `Object.is` and sameness in JS.	`3 === var1`
Strict not equal (`!==`)	Returns `true` if the operands are of the same type but not equal, or are of different type.	`var1 !== "3"` `3 !== '3'`
Greater than (`>`)	Returns `true` if the left operand is greater than the right operand.	`var2 > var1` `"12" > 2`
Greater than or equal (`>=`)	Returns `true` if the left operand is greater than or equal to the right operand.	`var2 >= var1` `var1 >= 3`
Less than (`<`)	Returns `true` if the left operand is less than the right operand.	`var1 < var2` `"2" < 12`
Less than or equal (`<=`)	Returns `true` if the left operand is less than or equal to the right operand.	`var1 <= var2` `var2 <= 5`

> **Note:** `=>` is not a comparison operator but rather is the notation for Arrow functions.

Arithmetic operators

An arithmetic operator takes numerical values (either literals or variables) as their operands and returns a single numerical value. The standard arithmetic operators are addition (`+`), subtraction (`-`), multiplication (`*`), and division (`/`). These operators work as they do in most other programming languages when used with floating point numbers (in particular, note that division by zero produces `Infinity`). For example:

```
1 / 2; // 0.5
1 / 2 === 1.0 / 2.0; // this is true
```

In addition to the standard arithmetic operations (`+`, `-`, `*`, `/`), JavaScript provides the arithmetic operators listed in the following table:

Arithmetic operators

Operator	Description	Example
Remainder (`%`)	Binary operator. Returns the integer remainder of dividing the two operands.	12 % 5 returns 2.

Operator	Description	Example
Increment (++)	Unary operator. Adds one to its operand. If used as a prefix operator (++x), returns the value of its operand after adding one; if used as a postfix operator (x++), returns the value of its operand before adding one.	If x is 3, then ++x sets x to 4 and returns 4, whereas x++ returns 3 and, only then, sets x to 4.
Decrement (--)	Unary operator. Subtracts one from its operand. The return value is analogous to that for the increment operator.	If x is 3, then --x sets x to 2 and returns 2, whereas x-- returns 3 and, only then, sets x to 2.
Unary negation (-)	Unary operator. Returns the negation of its operand.	If x is 3, then -x returns -3.
Unary plus (+)	Unary operator. Attempts to convert the operand to a number, if it is not already.	+"3" returns 3. +true returns 1.
Exponentiation operator (**)	Calculates the base to the exponent power, that is, base^exponent	2 ** 3 returns 8. 10 ** -1 returns 0.1.

Bitwise operators

A bitwise operator treats their operands as a set of 32 bits (zeros and ones), rather than as decimal, hexadecimal, or octal numbers. For example, the decimal number nine has a binary representation of 1001. Bitwise operators perform their operations on such binary representations, but they return standard JavaScript numerical values.

The following table summarizes JavaScript's bitwise operators.

Operator	Usage	Description
Bitwise AND	a & b	Returns a one in each bit position for which the corresponding bits of both operands are ones.
Bitwise OR	a | b	Returns a zero in each bit position for which the corresponding bits of both operands are zeros.
Bitwise XOR	a ^ b	Returns a zero in each bit position for which the corresponding bits are the same. [Returns a one in each bit position for which the corresponding bits are different.]
Bitwise NOT	~ a	Inverts the bits of its operand.
Left shift	a << b	Shifts a in binary representation b bits to the left, shifting in zeros from the right.
Sign-propagating right shift	a >> b	Shifts a in binary representation b bits to the right, discarding bits shifted off.
Zero-fill right shift	a >>> b	Shifts a in binary representation b bits to the right, discarding bits shifted off, and shifting in zeros from the left.

Bitwise logical operators

Conceptually, the bitwise logical operators work as follows:

- The operands are converted to thirty-two-bit integers and expressed by a series of bits (zeros and ones). Numbers with more than 32 bits get their most significant bits discarded. For example, the following integer with more than 32 bits will be converted to a 32-bit integer:

```
Before: 1110 0110 1111 1010 0000 0000 0000 0110 0000 0000 0001
After:              1010 0000 0000 0000 0110 0000 0000 0001
```

- Each bit in the first operand is paired with the corresponding bit in the second operand: first bit to first bit, second bit to second bit, and so on.
- The operator is applied to each pair of bits, and the result is constructed bitwise.

For example, the binary representation of nine is 1001, and the binary representation of fifteen is 1111. So, when the bitwise operators are applied to these values, the results are as follows:

Expression	Result	Binary Description
15 & 9	9	1111 & 1001 = 1001
15 | 9	15	1111 | 1001 = 1111
15 ^ 9	6	1111 ^ 1001 = 0110
~15	-16	~ 0000 0000 … 0000 1111 = 1111 1111 … 1111 0000
~9	-10	~ 0000 0000 … 0000 1001 = 1111 1111 … 1111 0110

Note that all 32 bits are inverted using the Bitwise NOT operator, and that values with the most significant (left-most) bit set to 1 represent negative numbers (two's-complement representation). ~x evaluates to the same value that -x - 1 evaluates to.

Bitwise shift operators

The bitwise shift operators take two operands: the first is a quantity to be shifted, and the second specifies the number of bit positions by which the first operand is to be shifted. The direction of the shift operation is controlled by the operator used.

Shift operators convert their operands to thirty-two-bit integers and return a result of either type Number or BigInt: specifically, if the type of the left operand is BigInt, they return BigInt; otherwise, they return Number.

The shift operators are listed in the following table.

Bitwise shift operators

Operator	Description	Example
Left shift (<<)	This operator shifts the first operand the specified number of bits to the left. Excess bits shifted off to the left are discarded. Zero bits are shifted in from the right.	`9<<2` yields 36, because 1001 shifted 2 bits to the left becomes 100100, which is 36.
Sign-propagating right shift (>>)	This operator shifts the first operand the specified number of bits to the right. Excess bits shifted off to the right are discarded. Copies of the leftmost bit are shifted in from the left.	`9>>2` yields 2, because 1001 shifted 2 bits to the right becomes 10, which is 2. Likewise, `-9>>2` yields -3, because the sign is preserved.
Zero-fill right shift (>>>)	This operator shifts the first operand the specified number of bits to the right. Excess bits shifted off to the right are discarded. Zero bits are shifted in from the left.	`19>>>2` yields 4, because 10011 shifted 2 bits to the right becomes 100, which is 4. For non-negative numbers, zero-fill right shift and sign-propagating right shift yield the same result.

Logical operators

Logical operators are typically used with Boolean (logical) values; when they are, they return a Boolean value. However, the `&&`, `||`, and `??` operators actually return the value of one of the specified operands, so if these operators are used with non-Boolean values, they may return a non-Boolean value. As such, they are more adequately called "value selection operators". The logical operators are described in the following table.

Logical operators

Operator	Usage	Description
Logical AND (`&&`)	`expr1 && expr2`	Returns `expr1` if it can be converted to `false`; otherwise, returns `expr2`. Thus, when used with Boolean values, `&&` returns `true` if both operands are true; otherwise, returns `false`.
Logical OR (`||`)	`expr1 || expr2`	Returns `expr1` if it can be converted to `true`; otherwise, returns `expr2`. Thus, when used with Boolean values, `||` returns `true` if either operand is true; if both are false, returns `false`.
Nullish coalescing operator (`??`)	`expr1 ?? expr2`	Returns `expr1` if it is neither `null` nor `undefined`; otherwise, returns `expr2`.
Logical NOT (`!`)	`!expr`	Returns `false` if its single operand can be converted to `true`; otherwise, returns `true`.

Examples of expressions that can be converted to `false` are those that evaluate to `null`, `0`, `0n`, `NaN`, the empty string (`""`), or `undefined`.

The following code shows examples of the `&&` (logical AND) operator.

```
const a1 = true && true; // t && t returns true
const a2 = true && false; // t && f returns false
const a3 = false && true; // f && t returns false
const a4 = false && 3 === 4; // f && f returns false
const a5 = "Cat" && "Dog"; // t && t returns Dog
const a6 = false && "Cat"; // f && t returns false
const a7 = "Cat" && false; // t && f returns false
```

The following code shows examples of the `||` (logical OR) operator.

```
const o1 = true || true; // t || t returns true
const o2 = false || true; // f || t returns true
const o3 = true || false; // t || f returns true
const o4 = false || 3 === 4; // f || f returns false
const o5 = "Cat" || "Dog"; // t || t returns Cat
const o6 = false || "Cat"; // f || t returns Cat
const o7 = "Cat" || false; // t || f returns Cat
```

The following code shows examples of the `??` (nullish coalescing) operator.

```
const n1 = null ?? 1; // 1
const n2 = undefined ?? 2; // 2
const n3 = false ?? 3; // false
const n4 = 0 ?? 4; // 0
```

Note how `??` works like `||`, but it only returns the second expression when the first one is "nullish", i.e., `null` or `undefined`. `??` is a better alternative than `||` for setting defaults for values that might be `null` or `undefined`, in particular when values like `''` or `0` are valid values and the default should not apply.

The following code shows examples of the `!` (logical NOT) operator.

```
const n1 = !true; // !t returns false
const n2 = !false; // !f returns true
const n3 = !"Cat"; // !t returns false
```

Short-circuit evaluation

As logical expressions are evaluated left to right, they are tested for possible "short-circuit" evaluation using the following rules:

- `falsy && anything` is short-circuit evaluated to the falsy value.
- `truthy || anything` is short-circuit evaluated to the truthy value.
- `nonNullish ?? anything` is short-circuit evaluated to the non-nullish value.

The rules of logic guarantee that these evaluations are always correct. Note that the *anything* part of the above expressions is not evaluated, so any side effects of doing so do not take effect.

BigInt operators

Most operators that can be used between numbers can be used between `BigInt` values as well.

```
// BigInt addition
const a = 1n + 2n; // 3n
// Division with BigInts round towards zero
const b = 1n / 2n; // 0n
// Bitwise operations with BigInts do not truncate either side
const c = 4000000000000000n >> 2n; // 1000000000000000n
```

One exception is unsigned right shift (>>>), which is not defined for BigInt values. This is because a BigInt does not have a fixed width, so technically it does not have a "highest bit".

```
const d = 8n >>> 2n; // TypeError: BigInts have no unsigned right shift, use >> instead
```

BigInts and numbers are not mutually replaceable — you cannot mix them in calculations.

```
const a = 1n + 2; // TypeError: Cannot mix BigInt and other types
```

This is because BigInt is neither a subset nor a superset of numbers. BigInts have higher precision than numbers when representing large integers, but cannot represent decimals, so implicit conversion on either side might lose precision. Use explicit conversion to signal whether you wish the operation to be a number operation or a BigInt one.

```
const a = Number(1n) + 2; // 3
const b = 1n + BigInt(2); // 3n
```

You can compare BigInts with numbers.

```
const a = 1n > 2; // false
const b = 3 > 2n; // true
```

String operators

In addition to the comparison operators, which can be used on string values, the concatenation operator (+) concatenates two string values together, returning another string that is the union of the two operand strings.

For example,

```
console.log("my " + "string"); // console logs the string "my string".
```

The shorthand assignment operator += can also be used to concatenate strings.

For example,

```
let myString = "alpha";
myString += "bet"; // evaluates to "alphabet" and assigns this value to myString.
```

Conditional (ternary) operator

The conditional operator is the only JavaScript operator that takes three operands. The operator can have one of two values based on a condition. The syntax is:

```
condition ? val1 : val2
```

If `condition` is true, the operator has the value of `val1`. Otherwise it has the value of `val2`. You can use the conditional operator anywhere you would use a standard operator.

For example,

```
const status = age >= 18 ? "adult" : "minor";
```

This statement assigns the value "adult" to the variable `status` if `age` is eighteen or more. Otherwise, it assigns the value "minor" to `status`.

Comma operator

The comma operator (`,`) evaluates both of its operands and returns the value of the last operand. This operator is primarily used inside a `for` loop, to allow multiple variables to be updated each time through the loop. It is regarded bad style to use it elsewhere, when it is not necessary. Often two separate statements can and should be used instead.

For example, if `a` is a 2-dimensional array with 10 elements on a side, the following code uses the comma operator to update two variables at once. The code prints the values of the diagonal elements in the array:

```
const x = [0, 1, 2, 3, 4, 5, 6, 7, 8, 9];
const a = [x, x, x, x, x];

for (let i = 0, j = 9; i <= j; i++, j--) {
  //              ^
  console.log(`a[${i}][${j}]= ${a[i][j]}`);
}
```

Unary operators

A unary operation is an operation with only one operand.

delete

The `delete` operator deletes an object's property. The syntax is:

```
delete object.property;
delete object[propertyKey];
delete objectName[index];
```

where `object` is the name of an object, `property` is an existing property, and `propertyKey` is a string or symbol referring to an existing property.

If the `delete` operator succeeds, it removes the property from the object. Trying to access it afterwards will yield `undefined`. The `delete` operator returns `true` if the operation is possible; it returns `false` if the operation is not possible.

```
delete Math.PI; // returns false (cannot delete non-configurable properties)

const myObj = { h: 4 };
delete myObj.h; // returns true (can delete user-defined properties)
```

Deleting array elements

Since arrays are just objects, it's technically possible to `delete` elements from them. This is, however, regarded as a bad practice — try to avoid it. When you delete an array property, the array length is not affected and other elements are not re-indexed. To achieve that behavior, it is much better to just overwrite the element with the value `undefined`. To actually manipulate the array, use the various array methods such as `splice`.

typeof

The `typeof` operator returns a string indicating the type of the unevaluated operand. `operand` is the string, variable, keyword, or object for which the type is to be returned. The parentheses are optional.

Suppose you define the following variables:

```
const myFun = () => 5 + 2;
const shape = "round";
const size = 1;
const foo = ["Apple", "Mango", "Orange"];
const today = new Date();
```

The `typeof` operator returns the following results for these variables:

```
typeof myFun; // returns "function"
typeof shape; // returns "string"
typeof size; // returns "number"
typeof foo; // returns "object"
typeof today; // returns "object"
typeof doesntExist; // returns "undefined"
```

For the keywords `true` and `null`, the `typeof` operator returns the following results:

```
typeof true; // returns "boolean"
typeof null; // returns "object"
```

For a number or string, the `typeof` operator returns the following results:

```
typeof 62; // returns "number"
typeof "Hello world"; // returns "string"
```

For property values, the `typeof` operator returns the type of value the property contains:

```
typeof document.lastModified; // returns "string"
typeof window.length; // returns "number"
typeof Math.LN2; // returns "number"
```

For methods and functions, the `typeof` operator returns results as follows:

```
typeof blur; // returns "function"
typeof parseInt; // returns "function"
typeof shape.split; // returns "function"
```

For predefined objects, the `typeof` operator returns results as follows:

```
typeof Date; // returns "function"
typeof Function; // returns "function"
typeof Math; // returns "object"
typeof Option; // returns "function"
typeof String; // returns "function"
```

void

The `void` operator specifies an expression to be evaluated without returning a value. `expression` is a JavaScript expression to evaluate. The parentheses surrounding the expression are optional, but it is good style to use them to avoid precedence issues.

Relational operators

A relational operator compares its operands and returns a Boolean value based on whether the comparison is true.

in

The `in` operator returns `true` if the specified property is in the specified object. The syntax is:

```
propNameOrNumber in objectName
```

where `propNameOrNumber` is a string, numeric, or symbol expression representing a property name or array index, and `objectName` is the name of an object.

The following examples show some uses of the `in` operator.

```
// Arrays
const trees = ["redwood", "bay", "cedar", "oak", "maple"];
0 in trees; // returns true
3 in trees; // returns true
6 in trees; // returns false
"bay" in trees; // returns false
// (you must specify the index number, not the value at that index)
"length" in trees; // returns true (length is an Array property)

// built-in objects
"PI" in Math; // returns true
const myString = new String("coral");
"length" in myString; // returns true

// Custom objects
const myCar = { make: "Honda", model: "Accord", year: 1998 };
"make" in myCar; // returns true
"model" in myCar; // returns true
```

instanceof

The `instanceof` operator returns `true` if the specified object is of the specified object type. The syntax is:

```
object instanceof objectType
```

where `object` is the object to test against `objectType`, and `objectType` is a constructor representing a type, such as `Map` or `Array`.

Use `instanceof` when you need to confirm the type of an object at runtime. For example, when catching exceptions, you can branch to different exception-handling code depending on the type of exception thrown.

For example, the following code uses `instanceof` to determine whether `obj` is a `Map` object. Because `obj` is a `Map` object, the statements inside the `if` block execute.

```
const obj = new Map();
if (obj instanceof Map) {
  // statements to execute
}
```

Basic expressions

All operators eventually operate on one or more basic expressions. These basic expressions include identifiers and literals, but there are a few other kinds as well. They are briefly introduced below, and their semantics are described in detail in their respective reference sections.

this

The `this` keyword is usually used within a function. In general, when the function is attached to an object as a method, `this` refers to the object that the method is called on. It functions like a hidden parameter that is passed to the function. `this` is an expression that evaluates to the object, so you can use all the object operations we introduced.

```
this["propertyName"];
this.propertyName;
doSomething(this);
```

For example, suppose a function is defined as follows:

```
function getFullName() {
  return `${this.firstName} ${this.lastName}`;
}
```

We can now attach this function to an object, and it will use the properties of that object when called:

```
const person1 = {
  firstName: "Chris",
```

```
  lastName: "Martin",
};

const person2 = {
  firstName: "Chester",
  lastName: "Bennington",
};

// Attach the same function
person1.getFullName = getFullName;
person2.getFullName = getFullName;

console.log(person1.getFullName()); // "Chris Martin"
console.log(person2.getFullName()); // "Chester Bennington"
```

Grouping operator

The grouping operator `( )` controls the precedence of evaluation in expressions. For example, you can override multiplication and division first, then addition and subtraction to evaluate addition first.

```
const a = 1;
const b = 2;
const c = 3;

// default precedence
a + b * c; // 7
// evaluated by default like this
a + (b * c); // 7

// now overriding precedence
// addition before multiplication
(a + b) * c; // 9

// which is equivalent to
a * c + b * c; // 9
```

Property accessor

The property accessor syntax gets property values on objects, using either dot notation or bracket notation.

```
object.property;
object["property"];
```

The working with objects guide goes into more details about object properties.

Optional chaining

The optional chaining syntax (`?.`) performs the chained operation on an object if it is defined and non-`null`, and otherwise short-circuits the operation and returns `undefined`. This allows you to operate on a value that may be `null` or `undefined` without causing a `TypeError`.

```
maybeObject?.property;
maybeObject?.[property];
maybeFunction?.();
```

new

You can use the `new` operator to create an instance of a user-defined object type or of one of the built-in object types. Use `new` as follows:

```
const objectName = new ObjectType(param1, param2, /* …, */ paramN);
```

super

The `super` keyword is used to call functions on an object's parent. It is useful with classes to call the parent constructor, for example.

```
super(args); // calls the parent constructor.
super.functionOnParent(args);
```

Functions

- Previous
- Next

Functions are one of the fundamental building blocks in JavaScript. A function in JavaScript is similar to a procedure—a set of statements that performs a task or calculates a value, but for a procedure to qualify as a function, it should take some input and return an output where there is some obvious relationship between the input and the output. To use a function, you must define it somewhere in the scope from which you wish to call it.

See also the exhaustive reference chapter about JavaScript functions to get to know the details.

Defining functions

Function declarations

A **function definition** (also called a **function declaration**, or **function statement**) consists of the `function` keyword, followed by:

- The name of the function.
- A list of parameters to the function, enclosed in parentheses and separated by commas.
- The JavaScript statements that define the function, enclosed in curly braces, `{ /* … */ }`.

For example, the following code defines a function named `square`:

```
function square(number) {
  return number * number;
}
```

The function `square` takes one parameter, called `number`. The function consists of one statement that says to return the parameter of the function (that is, `number`) multiplied by itself. The `return` statement specifies the value returned by the function, which is `number * number`.

Parameters are essentially passed to functions **by value** — so if the code within the body of a function assigns a completely new value to a parameter that was passed to the function, **the change is not reflected globally or in the code which called that function**.

When you pass an object as a parameter, if the function changes the object's properties, that change is visible outside the function, as shown in the following example:

```
function myFunc(theObject) {
  theObject.make = "Toyota";
}

const myCar = {
  make: "Honda",
  model: "Accord",
  year: 1998,
};

console.log(myCar.make); // "Honda"
myFunc(myCar);
console.log(myCar.make); // "Toyota"
```

When you pass an array as a parameter, if the function changes any of the array's values, that change is visible outside the function, as shown in the following example:

```
function myFunc(theArr) {
  theArr[0] = 30;
}

const arr = [45];

console.log(arr[0]); // 45
myFunc(arr);
console.log(arr[0]); // 30
```

Function declarations and expressions can be nested, which forms a *scope chain*. For example:

```
function addSquares(a, b) {
  function square(x) {
    return x * x;
  }
  return square(a) + square(b);
}
```

See function scopes and closures for more information.

Function expressions

While the function declaration above is syntactically a statement, functions can also be created by a function expression.

Such a function can be **anonymous**; it does not have to have a name. For example, the function `square` could have been defined as:

```
const square = function (number) {
  return number * number;
};

console.log(square(4)); // 16
```

However, a name *can* be provided with a function expression. Providing a name allows the function to refer to itself, and also makes it easier to identify the function in a debugger's stack traces:

```
const factorial = function fac(n) {
  return n < 2 ? 1 : n * fac(n - 1);
};

console.log(factorial(3)); // 6
```

Function expressions are convenient when passing a function as an argument to another function. The following example defines a `map` function that should receive a function as first argument and an array as second argument. Then, it is called with a function defined by a function expression:

```
function map(f, a) {
  const result = new Array(a.length);
  for (let i = 0; i < a.length; i++) {
    result[i] = f(a[i]);
  }
  return result;
}

const numbers = [0, 1, 2, 5, 10];
const cubedNumbers = map(function (x) {
  return x * x * x;
}, numbers);
console.log(cubedNumbers); // [0, 1, 8, 125, 1000]
```

In JavaScript, a function can be defined based on a condition. For example, the following function definition defines `myFunc` only if `num` equals `0`:

```
let myFunc;
if (num === 0) {
  myFunc = function (theObject) {
    theObject.make = "Toyota";
  };
}
```

In addition to defining functions as described here, you can also use the `Function` constructor to create functions from a string at runtime, much like `eval()`.

A **method** is a function that is a property of an object. Read more about objects and methods in Working with objects.

Calling functions

Defining a function does not *execute* it. Defining it names the function and specifies what to do when the function is called.

Calling the function actually performs the specified actions with the indicated parameters. For example, if you define the function `square`, you could call it as follows:

```
square(5);
```

The preceding statement calls the function with an argument of `5`. The function executes its statements and returns the value `25`.

Functions must be *in scope* when they are called, but the function declaration can be hoisted (appear below the call in the code). The scope of a function declaration is the function in which it is declared (or the entire program, if it is declared at the top level).

The arguments of a function are not limited to strings and numbers. You can pass whole objects to a function. The `showProps()` function (defined in Working with objects) is an example of a function that takes an object as an argument.

A function can call itself. For example, here is a function that computes factorials recursively:

```
function factorial(n) {
  if (n === 0 || n === 1) {
    return 1;
  }
  return n * factorial(n - 1);
}
```

You could then compute the factorials of `1` through `5` as follows:

```
console.log(factorial(1)); // 1
console.log(factorial(2)); // 2
console.log(factorial(3)); // 6
console.log(factorial(4)); // 24
console.log(factorial(5)); // 120
```

There are other ways to call functions. There are often cases where a function needs to be called dynamically, or the number of arguments to a function vary, or in which the context of the function call needs to be set to a specific object determined at runtime.

It turns out that *functions are themselves objects* — and in turn, these objects have methods. (See the `Function` object.) The `call()` and `apply()` methods can be used to achieve this goal.

Function hoisting

Consider the example below:

```
console.log(square(5)); // 25

function square(n) {
  return n * n;
}
```

This code runs without any error, despite the `square()` function being called before it's declared. This is because the JavaScript interpreter hoists the entire function declaration to the top of the current scope, so the code above is equivalent to:

```
// All function declarations are effectively at the top of the scope
function square(n) {
  return n * n;
}

console.log(square(5)); // 25
```

Function hoisting only works with function *declarations* — not with function *expressions*. The following code will not work:

```
console.log(square(5)); // ReferenceError: Cannot access 'square' before initialization
const square = function (n) {
  return n * n;
};
```

Recursion

A function can refer to and call itself. It can be referred to either by the function expression or declaration's name, or via any in-scope variable that refers to the function object. For example, consider the following function definition:

```
const foo = function bar() {
  // statements go here
};
```

Within the function body, you can refer to the function itself either as `bar` or `foo`, and call itself using `bar()` or `foo()`.

A function that calls itself is called a *recursive function*. In some ways, recursion is analogous to a loop. Both execute the same code multiple times, and both require a condition (to avoid an infinite loop, or rather, infinite recursion in this case).

For example, consider the following loop:

```
let x = 0;
// "x < 10" is the loop condition
while (x < 10) {
  // do stuff
  x++;
}
```

It can be converted into a recursive function declaration, followed by a call to that function:

```
function loop(x) {
  // "x >= 10" is the exit condition (equivalent to "!(x < 10)")
  if (x >= 10) {
    return;
  }
  // do stuff
  loop(x + 1); // the recursive call
}
loop(0);
```

However, some algorithms cannot be simple iterative loops. For example, getting all the nodes of a tree structure (such as the DOM) is easier via recursion:

```
function walkTree(node) {
  if (node === null) {
    return;
  }
  // do something with node
  for (const child of node.childNodes) {
    walkTree(child);
  }
}
```

Compared to the function `loop`, each recursive call itself makes many recursive calls here.

It is possible to convert any recursive algorithm to a non-recursive one, but the logic is often much more complex, and doing so requires the use of a stack.

In fact, recursion itself uses a stack: the function stack. The stack-like behavior can be seen in the following example:

```
function foo(i) {
  if (i < 0) {
    return;
  }
  console.log(`begin: ${i}`);
  foo(i - 1);
  console.log(`end: ${i}`);
}
foo(3);

// Logs:
// begin: 3
// begin: 2
// begin: 1
// begin: 0
```

```
// end: 0
// end: 1
// end: 2
// end: 3
```

Immediately Invoked Function Expressions (IIFE)

An Immediately Invoked Function Expression (IIFE) is a code pattern that directly calls a function defined as an expression. It looks like this:

```
(function () {
  // Do something
})();

const value = (function () {
  // Do something
  return someValue;
})();
```

Instead of saving the function in a variable, the function is immediately invoked. This is almost equivalent to just writing the function body, but there are a few unique benefits:

- It creates an extra scope of variables, which helps to confine variables to the place where they are useful.
- It is now an *expression* instead of a sequence of *statements*. This allows you to write complex computation logic when initializing variables.

For more information, see the IIFE glossary entry.

Function scopes and closures

Functions form a scope for variables—this means variables defined inside a function cannot be accessed from anywhere outside the function. The function scope inherits from all the upper scopes. For example, a function defined in the global scope can access all variables defined in the global scope. A function defined inside another function can also access all variables defined in its parent function, and any other variables to which the parent function has access. On the other hand, the parent function (and any other parent scope) does *not* have access to the variables and functions defined inside the inner function. This provides a sort of encapsulation for the variables in the inner function.

```
// The following variables are defined in the global scope
const num1 = 20;
const num2 = 3;
const name = "Chamakh";

// This function is defined in the global scope
function multiply() {
  return num1 * num2;
}

console.log(multiply()); // 60

// A nested function example
function getScore() {
  const num1 = 2;
  const num2 = 3;

  function add() {
    return `${name} scored ${num1 + num2}`;
  }

  return add();
}

console.log(getScore()); // "Chamakh scored 5"
```

Closures

We also refer to the function body as a *closure*. A closure is any piece of source code (most commonly, a function) that refers to some variables, and the closure "remembers" these variables even when the scope in which these variables were declared has exited.

Closures are usually illustrated with nested functions to show that they remember variables beyond the lifetime of its parent scope; but in fact, nested functions are unnecessary. Technically speaking, all functions in JavaScript form closures—some just don't capture anything, and closures don't even have to be functions. The key ingredients for a *useful* closure are the following:

- A parent scope that defines some variables or functions. It should have a clear lifetime, which means it should finish execution at some point. Any scope that's not the global scope satisfies this requirement; this includes blocks, functions, modules, and more.
- An inner scope defined within the parent scope, which refers to some variables or functions defined in the parent scope.
- The inner scope manages to survive beyond the lifetime of the parent scope. For example, it is saved to a variable that's defined outside the parent scope, or it's returned from the parent scope (if the parent scope is a function).
- Then, when you call the function outside of the parent scope, you can still access the variables or functions that were defined in the parent scope, even though the parent scope has finished execution.

The following is a typical example of a closure:

```
// The outer function defines a variable called "name"
const pet = function (name) {
  const getName = function () {
```

```
    // The inner function has access to the "name" variable of the outer function
    return name;
  };
  return getName; // Return the inner function, thereby exposing it to outer scopes
};
const myPet = pet("Vivie");

console.log(myPet()); // "Vivie"
```

It can be much more complex than the code above. An object containing methods for manipulating the inner variables of the outer function can be returned.

```
const createPet = function (name) {
  let sex;

  const pet = {
    // setName(newName) is equivalent to setName: function (newName)
    // in this context
    setName(newName) {
      name = newName;
    },

    getName() {
      return name;
    },

    getSex() {
      return sex;
    },

    setSex(newSex) {
      if (
        typeof newSex === "string" &&
        (newSex.toLowerCase() === "male" || newSex.toLowerCase() === "female")
      ) {
        sex = newSex;
      }
    },
  };

  return pet;
};

const pet = createPet("Vivie");
console.log(pet.getName()); // Vivie

pet.setName("Oliver");
pet.setSex("male");
console.log(pet.getSex()); // male
console.log(pet.getName()); // Oliver
```

In the code above, the `name` variable of the outer function is accessible to the inner functions, and there is no other way to access the inner variables except through the inner functions. The inner variables of the inner functions act as safe stores for the outer arguments and variables. They hold "persistent" and "encapsulated" data for the inner functions to work with. The functions do not even have to be assigned to a variable, or have a name.

```
const getCode = (function () {
  const apiCode = "0]Eal(eh&2"; // A code we do not want outsiders to be able to modify…

  return function () {
    return apiCode;
  };
})();

console.log(getCode()); // "0]Eal(eh&2"
```

In the code above, we use the IIFE pattern. Within this IIFE scope, two values exist: a variable `apiCode` and an unnamed function that gets returned and gets assigned to the variable `getCode`. `apiCode` is in the scope of the returned unnamed function but not in the scope of any other part of the program, so there is no way for reading the value of `apiCode` apart from via the `getCode` function.

Multiply-nested functions

Functions can be multiply-nested. For example:

- A function (`A`) contains a function (`B`), which itself contains a function (`C`).
- Both functions `B` and `C` form closures here. So, `B` can access `A`, and `C` can access `B`.
- In addition, since `C` can access `B` which can access `A`, `C` can also access `A`.

Thus, the closures can contain multiple scopes; they recursively contain the scope of the functions containing it. This is called *scope chaining*. Consider the following example:

```
function A(x) {
  function B(y) {
    function C(z) {
      console.log(x + y + z);
    }
```

```
    C(3);
  }
  B(2);
}
A(1); // Logs 6 (which is 1 + 2 + 3)
```

In this example, `C` accesses `B`'s `y` and `A`'s `x`. This can be done because:

1. `B` forms a closure including `A` (i.e., `B` can access `A`'s arguments and variables).
2. `C` forms a closure including `B`.
3. Because `C`'s closure includes `B` and `B`'s closure includes `A`, then `C`'s closure also includes `A`. This means `C` can access *both* `B` *and* `A`'s arguments and variables. In other words, `C` *chains* the scopes of `B` and `A`, *in that order*.

The reverse, however, is not true. `A` cannot access `C`, because `A` cannot access any argument or variable of `B`, which `C` is a variable of. Thus, `C` remains private to only `B`.

Name conflicts

When two arguments or variables in the scopes of a closure have the same name, there is a *name conflict*. More nested scopes take precedence. So, the innermost scope takes the highest precedence, while the outermost scope takes the lowest. This is the scope chain. The first on the chain is the innermost scope, and the last is the outermost scope. Consider the following:

```
function outside() {
  const x = 5;
  function inside(x) {
    return x * 2;
  }
  return inside;
}

console.log(outside()(10)); // 20 (instead of 10)
```

The name conflict happens at the statement `return x * 2` and is between `inside`'s parameter `x` and `outside`'s variable `x`. The scope chain here is `inside` => `outside` => global object. Therefore, `inside`'s `x` takes precedences over `outside`'s `x`, and `20` (`inside`'s `x`) is returned instead of `10` (`outside`'s `x`).

Using the arguments object

The arguments of a function are maintained in an array-like object. Within a function, you can address the arguments passed to it as follows:

```
arguments[i];
```

where `i` is the ordinal number of the argument, starting at `0`. So, the first argument passed to a function would be `arguments[0]`. The total number of arguments is indicated by `arguments.length`.

Using the `arguments` object, you can call a function with more arguments than it is formally declared to accept. This is often useful if you don't know in advance how many arguments will be passed to the function. You can use `arguments.length` to determine the number of arguments actually passed to the function, and then access each argument using the `arguments` object.

For example, consider a function that concatenates several strings. The only formal argument for the function is a string that specifies the characters that separate the items to concatenate. The function is defined as follows:

```
function myConcat(separator) {
  let result = ""; // initialize list
  // iterate through arguments
  for (let i = 1; i < arguments.length; i++) {
    result += arguments[i] + separator;
  }
  return result;
}
```

You can pass any number of arguments to this function, and it concatenates each argument into a string "list":

```
console.log(myConcat(", ", "red", "orange", "blue"));
// "red, orange, blue, "

console.log(myConcat("; ", "elephant", "giraffe", "lion", "cheetah"));
// "elephant; giraffe; lion; cheetah; "

console.log(myConcat(". ", "sage", "basil", "oregano", "pepper", "parsley"));
// "sage. basil. oregano. pepper. parsley. "
```

> **Note:** The `arguments` variable is "array-like", but not an array. It is array-like in that it has a numbered index and a `length` property. However, it does *not* possess all of the array-manipulation methods.

See the `Function` object in the JavaScript reference for more information.

Function parameters

There are two special kinds of parameter syntax: *default parameters* and *rest parameters*.

Default parameters

In JavaScript, parameters of functions default to `undefined`. However, in some situations it might be useful to set a different default value. This is exactly what default parameters do.

In the past, the general strategy for setting defaults was to test parameter values in the body of the function and assign a value if they are `undefined`.

In the following example, if no value is provided for `b`, its value would be `undefined` when evaluating `a*b`, and a call to `multiply` would normally have returned `NaN`. However, this is prevented by the second line in this example:

```
function multiply(a, b) {
  b = typeof b !== "undefined" ? b : 1;
  return a * b;
}

console.log(multiply(5)); // 5
```

With *default parameters*, a manual check in the function body is no longer necessary. You can put `1` as the default value for `b` in the function head:

```
function multiply(a, b = 1) {
  return a * b;
}

console.log(multiply(5)); // 5
```

For more details, see default parameters in the reference.

Rest parameters

The rest parameter syntax allows us to represent an indefinite number of arguments as an array.

In the following example, the function `multiply` uses *rest parameters* to collect arguments from the second one to the end. The function then multiplies these by the first argument.

```
function multiply(multiplier, ...theArgs) {
  return theArgs.map((x) => multiplier * x);
}

const arr = multiply(2, 1, 2, 3);
console.log(arr); // [2, 4, 6]
```

Arrow functions

An arrow function expression (also called a *fat arrow* to distinguish from a hypothetical `->` syntax in future JavaScript) has a shorter syntax compared to function expressions and does not have its own `this`, `arguments`, `super`, or `new.target`. Arrow functions are always anonymous.

Two factors influenced the introduction of arrow functions: *shorter functions* and *non-binding* of `this`.

Shorter functions

In some functional patterns, shorter functions are welcome. Compare:

```
const a = ["Hydrogen", "Helium", "Lithium", "Beryllium"];

const a2 = a.map(function (s) {
  return s.length;
});

console.log(a2); // [8, 6, 7, 9]

const a3 = a.map((s) => s.length);

console.log(a3); // [8, 6, 7, 9]
```

No separate this

Until arrow functions, every new function defined its own `this` value (a new object in the case of a constructor, undefined in strict mode function calls, the base object if the function is called as an "object method", etc.). This proved to be less than ideal with an object-oriented style of programming.

```
function Person() {
  // The Person() constructor defines `this` as itself.
  this.age = 0;

  setInterval(function growUp() {
    // In nonstrict mode, the growUp() function defines `this`
    // as the global object, which is different from the `this`
    // defined by the Person() constructor.
    this.age++;
  }, 1000);
}

const p = new Person();
```

In ECMAScript 3/5, this issue was fixed by assigning the value in `this` to a variable that could be closed over.

```
function Person() {
  // Some choose `that` instead of `self`.
  // Choose one and be consistent.
  const self = this;
  self.age = 0;

  setInterval(function growUp() {
    // The callback refers to the `self` variable of which
    // the value is the expected object.
    self.age++;
  }, 1000);
}
```

Alternatively, a bound function could be created so that the proper `this` value would be passed to the `growUp()` function.

An arrow function does not have its own `this`; the `this` value of the enclosing execution context is used. Thus, in the following code, the `this` within the function that is passed to `setInterval` has the same value as `this` in the enclosing function:

```
function Person() {
  this.age = 0;

  setInterval(() => {
    this.age++; // `this` properly refers to the person object
  }, 1000);
}

const p = new Person();
```

Grammar and types

- Previous
- Next

This chapter discusses JavaScript's basic grammar, variable declarations, data types and literals.

Basics

JavaScript borrows most of its syntax from Java, C, and C++, but it has also been influenced by Awk, Perl, and Python.

JavaScript is **case-sensitive** and uses the **Unicode** character set. For example, the word Früh (which means "early" in German) could be used as a variable name.

```
const Früh = "foobar";
```

But, the variable `früh` is not the same as `Früh` because JavaScript is case sensitive.

In JavaScript, instructions are called statements and are separated by semicolons (;).

A semicolon is not necessary after a statement if it is written on its own line. But if more than one statement on a line is desired, then they *must* be separated by semicolons.

> **Note:** ECMAScript also has rules for automatic insertion of semicolons (ASI) to end statements. (For more information, see the detailed reference about JavaScript's lexical grammar.)

It is considered best practice, however, to always write a semicolon after a statement, even when it is not strictly needed. This practice reduces the chances of bugs getting into the code.

The source text of JavaScript script gets scanned from left to right, and is converted into a sequence of input elements which are *tokens*, *control characters*, *line terminators*, *comments*, or whitespace. (Spaces, tabs, and newline characters are considered whitespace.)

Comments

The syntax of **comments** is the same as in C++ and in many other languages:

```
// a one line comment

/* this is a longer,
 * multi-line comment
 */
```

You can't nest block comments. This often happens when you accidentally include a `*/` sequence in your comment, which will terminate the comment.

```
/* You can't, however, /* nest comments */ SyntaxError */
```

In this case, you need to break up the `*/` pattern. For example, by inserting a backslash:

```
/* You can /* nest comments *\/ by escaping slashes */
```

Comments behave like whitespace, and are discarded during script execution.

> **Note:** You might also see a third type of comment syntax at the start of some JavaScript files, which looks something like this: `#!/usr/bin/env node`.
>
> This is called **hashbang comment** syntax, and is a special comment used to specify the path to a particular JavaScript engine that should execute the script. See Hashbang comments for more details.

Declarations

JavaScript has five kinds of variable declarations.

`var`

: Declares a variable, optionally initializing it to a value.

`let`

: Declares a block-scoped variable, optionally initializing it to a value.

`const`

: Declares a block-scoped variable that cannot be re-assigned, which must be initialized at declaration.

`using`

: Declares a variable like `const` that is *synchronously disposed*.

`await using`

: Declares a variable like `const` that is *asynchronously disposed*.

We will only talk about the first three: `var`, `let`, and `const`, in this article. The `using` and `await using` declarations will be introduced in Resource management.

Variables

You use variables as symbolic names for values in your application. The names of variables, called identifiers, conform to certain rules.

A JavaScript identifier usually starts with a letter, underscore (_), or dollar sign ($). Subsequent characters can also be digits (`0` – `9`). Because JavaScript is case sensitive, letters include the characters `A` through `Z` (uppercase) as well as `a` through `z` (lowercase).

You can use most Unicode letters such as `å` and `ü` in identifiers. (For more details, see the lexical grammar reference.) You can also use Unicode escape sequences to represent characters in identifiers.

Some examples of legal names are `Number_hits`, `temp99`, `$credit`, and `_name`.

Declaring variables

You can declare a variable in two ways:

- With the keyword `var`. For example, `var x = 42`. This syntax can be used to declare both **local** and **global** variables, depending on the *execution context*.
- With the keyword `const` or `let`. For example, `let y = 13`. This syntax can be used to declare a block-scope local variable. (See Variable scope below.)

You can declare variables to unpack values using the destructuring syntax. For example, `const { bar } = foo`. This will create a variable named `bar` and assign to it the value corresponding to the key of the same name from our object `foo`.

Variables should always be declared before they are used. JavaScript used to allow assigning to undeclared variables, which creates an **undeclared global** variable. This is an error in strict mode and should be avoided altogether.

Declaration and initialization

In a statement like `let x = 42`, the `let x` part is called a *declaration*, and the `= 42` part is called an *initializer*. The declaration allows the variable to be accessed later in code without throwing a `ReferenceError`, while the initializer assigns a value to the variable. In `var` and `let` declarations, the initializer is optional. If a variable is declared without an initializer, it is assigned the value `undefined`.

```
let x;
console.log(x); // logs "undefined"
```

In essence, `let x = 42` is equivalent to `let x; x = 42`.

`const` declarations always need an initializer, because they forbid any kind of assignment after declaration, and implicitly initializing it with `undefined` is likely a programmer mistake.

```
const x; // SyntaxError: Missing initializer in const declaration
```

Variable scope

A variable may belong to one of the following scopes:

- Global scope: The default scope for all code running in script mode.
- Module scope: The scope for code running in module mode.
- Function scope: The scope created with a function.

In addition, variables declared with `let` or `const` can belong to an additional scope:

- Block scope: The scope created with a pair of curly braces (a block).

When you declare a variable outside of any function, it is called a *global* variable, because it is available to any other code in the current document. When you declare a variable within a function, it is called a *local* variable, because it is available only within that function.

`let` and `const` declarations can also be scoped to the block statement that they are declared in.

```
if (Math.random() > 0.5) {
  const y = 5;
}
console.log(y); // ReferenceError: y is not defined
```

However, variables created with `var` are not block-scoped, but only local to the *function (or global scope)* that the block resides within.

For example, the following code will log `5`, because the scope of `x` is the global context (or the function context if the code is part of a function). The scope of `x` is not limited to the immediate `if` statement block.

```
if (true) {
  var x = 5;
}
console.log(x); // x is 5
```

Variable hoisting

`var`-declared variables are hoisted, meaning you can refer to the variable anywhere in its scope, even if its declaration isn't reached yet. You can see `var` declarations as being "lifted" to the top of its function or global scope. However, if you access a variable before it's declared, the value is always `undefined`, because only its *declaration* and *default initialization (with `undefined`)* is hoisted, but not its *value assignment*.

```
console.log(x === undefined); // true
var x = 3;

(function () {
  console.log(x); // undefined
  var x = "local value";
})();
```

The above examples will be interpreted the same as:

```
var x;
console.log(x === undefined); // true
x = 3;

(function () {
  var x;
  console.log(x); // undefined
  x = "local value";
})();
```

Because of hoisting, all `var` statements in a function should be placed as near to the top of the function as possible. This best practice increases the clarity of the code.

Whether `let` and `const` are hoisted is a matter of definition debate. Referencing the variable in the block before the variable declaration always results in a `ReferenceError`, because the variable is in a "temporal dead zone" from the start of the block until the declaration is processed.

```
console.log(x); // ReferenceError
const x = 3;

console.log(y); // ReferenceError
let y = 3;
```

Unlike `var` declarations, which only hoist the declaration but not its value, function declarations are hoisted entirely — you can safely call the function anywhere in its scope. See the hoisting glossary entry for more discussion.

Global variables

Global variables are in fact properties of the *global object*.

In web pages, the global object is `window`, so you can read and set global variables using the `window.variable` syntax. In all environments, the `globalThis` variable (which itself is a global variable) may be used to read and set global variables. This is to provide a consistent interface among various JavaScript runtimes.

Consequently, you can access global variables declared in one window or frame from another window or frame by specifying the `window` or `frame` name. For example, if a variable called `phoneNumber` is declared in a document, you can refer to this variable from an `iframe` as `parent.phoneNumber`.

Constants

You can create a read-only, named constant with the `const` keyword. The syntax of a constant identifier is the same as any variable identifier: it must start with a letter, underscore, or dollar sign (`$`), and can contain alphabetic, numeric, or underscore characters.

```
const PI = 3.14;
```

A constant cannot change value through assignment or be re-declared while the script is running. It must be initialized to a value. The scope rules for constants are the same as those for `let` block-scope variables.

You cannot declare a constant with the same name as a function or variable in the same scope. For example:

```
// THIS WILL CAUSE AN ERROR
function f() {}
const f = 5;

// THIS WILL CAUSE AN ERROR TOO
function f() {
  const g = 5;
  var g;
}
```

However, `const` only prevents *re-assignments*, but doesn't prevent *mutations*. The properties of objects assigned to constants are not protected, so the following statement is executed without problems.

```
const MY_OBJECT = { key: "value" };
MY_OBJECT.key = "otherValue";
```

Also, the contents of an array are not protected, so the following statement is executed without problems.

```
const MY_ARRAY = ["HTML", "CSS"];
MY_ARRAY.push("JAVASCRIPT");
console.log(MY_ARRAY); // ['HTML', 'CSS', 'JAVASCRIPT'];
```

Data structures and types

Data types

The latest ECMAScript standard defines eight data types:

- Seven data types that are primitives:
    1. Boolean. `true` and `false`.
    2. null. A special keyword denoting a null value. (Because JavaScript is case-sensitive, `null` is not the same as `Null`, `NULL`, or any other variant.)
    3. undefined. A top-level property whose value is not defined.
    4. Number. An integer or floating point number. For example: `42` or `3.14159`.
    5. BigInt. An integer with arbitrary precision. For example: `900719925474099 2n`.
    6. String. A sequence of characters that represent a text value. For example: `"Howdy"`.
    7. Symbol. A data type whose instances are unique and immutable.
- and Object

Although these data types are relatively few, they enable you to perform useful operations with your applications. Functions are the other fundamental elements of the language. While functions are technically a kind of object, you can think of objects as named containers for values, and functions as procedures that your script can perform.

Data type conversion

JavaScript is a *dynamically typed* language. This means you don't have to specify the data type of a variable when you declare it. It also means that data types are automatically converted as-needed during script execution.

So, for example, you could define a variable as follows:

```
let answer = 42;
```

And later, you could assign the same variable a string value, for example:

```
answer = "Thanks for all the fish!";
```

Because JavaScript is dynamically typed, this assignment does not cause an error message.

Numbers and the '+' operator

In expressions involving numeric and string values with the + operator, JavaScript converts numeric values to strings. For example, consider the following statements:

```
x = "The answer is " + 42; // "The answer is 42"
y = 42 + " is the answer"; // "42 is the answer"
z = "37" + 7; // "377"
```

With all other operators, JavaScript does *not* convert numeric values to strings. For example:

```
"37" - 7; // 30
"37" * 7; // 259
```

Converting strings to numbers

In the case that a value representing a number is in memory as a string, there are methods for conversion.

- `parseInt()`
- `parseFloat()`
- `Number()`

`parseInt` only returns whole numbers, so its use is diminished for decimals.

> **Note:** Additionally, a best practice for `parseInt` is to always include the *radix* parameter. The radix parameter is used to specify which numerical system is to be used.

```
parseInt("101", 2); // 5
```

An alternative method of retrieving a number from a string is with the + (unary plus) operator. This implicitly performs number conversion, which is the same process as the `Number()` function.

```
"1.1" + "1.1"; // '1.11.1'
(+"1.1") + (+"1.1"); // 2.2
// Note: the parentheses are added for clarity, not required.
```

Literals

Literals represent values in JavaScript. These are fixed values—not variables—that you *literally* provide in your script. This section describes the following types of literals:

- Array literals
- Boolean literals
- Numeric literals
- Object literals
- RegExp literals
- String literals

Array literals

An array literal is a list of zero or more expressions, each of which represents an array element, enclosed in square brackets (`[]`). When you create an array using an array literal, it is initialized with the specified values as its elements, and its `length` is set to the number of arguments specified.

The following example creates the `coffees` array with three elements and a `length` of three:

```
const coffees = ["French Roast", "Colombian", "Kona"];
```

An array literal creates a new array object every time the literal is evaluated. For example, an array defined with a literal in the global scope is created once when the script loads. However, if the array literal is inside a function, a new array is instantiated every time that function is called.

> **Note:** Array literals create `Array` objects. See `Array` and Indexed collections for details on `Array` objects.

Extra commas in array literals

If you put two commas in a row in an array literal, the array leaves an empty slot for the unspecified element. The following example creates the `fish` array:

```
const fish = ["Lion", , "Angel"];
```

When you log this array, you will see:

```
console.log(fish);
// [ 'Lion', <1 empty item>, 'Angel' ]
```

Note that the second item is "empty", which is not exactly the same as the actual `undefined` value. When using array-traversing methods like `Array.prototype.map`, empty slots are skipped. However, index-accessing `fish[1]` still returns `undefined`.

If you include a trailing comma at the end of the list of elements, the comma is ignored.

In the following example, the `length` of the array is three. There is no `myList[3]` and `myList[1]` is empty. All other commas in the list indicate a new element.

```
const myList = ["home", , "school"];
```

In the following example, the `length` of the array is four, and `myList[0]` and `myList[2]` are missing.

```
const myList = [, "home", , "school"];
```

In the following example, the `length` of the array is four, and `myList[1]` and `myList[3]` are missing. **Only the last comma is ignored.**

```
const myList = ["home", , "school", ,];
```

> **Note:** Trailing commas help keep git diffs clean when you have a multi-line array, because appending an item to the end only adds one line, but does not modify the previous line.

```
const myList = [
  "home",
  "school",
+ "hospital",
];
```

Understanding the behavior of extra commas is important to understanding JavaScript as a language.

However, when writing your own code, you should explicitly declare the missing elements as `undefined`, or at least insert a comment to highlight its absence. Doing this increases your code's clarity and maintainability.

```
const myList = ["home", /* empty */, "school", /* empty */, ];
```

Boolean literals

The Boolean type has two literal values: `true` and `false`.

> **Note:** Do not confuse the primitive Boolean values `true` and `false` with the true and false values of the `Boolean` object.
>
> The Boolean object is a wrapper around the primitive Boolean data type. See `Boolean` for more information.

Numeric literals

JavaScript numeric literals include integer literals in different bases as well as floating-point literals in base-10.

Note that the language specification requires numeric literals to be unsigned. Nevertheless, code fragments like `-123.4` are fine, being interpreted as a unary `-` operator applied to the numeric literal `123.4`.

Integer literals

Integer and `BigInt` literals can be written in decimal (base 10), hexadecimal (base 16), octal (base 8) and binary (base 2).

- A *decimal* integer literal is a sequence of digits without a leading `0` (zero).
- A leading `0` (zero) on an integer literal, or a leading `0o` (or `0O`) indicates it is in *octal*. Octal integer literals can include only the digits `0` – `7`.
- A leading `0x` (or `0X`) indicates a *hexadecimal* integer literal. Hexadecimal integers can include digits (`0` – `9`) and the letters `a` – `f` and `A` – `F`. (The case of a character does not change its value. Therefore: `0xa` = `0xA` = `10` and `0xf` = `0xF` = `15`.)
- A leading `0b` (or `0B`) indicates a *binary* integer literal. Binary integer literals can only include the digits `0` and `1`.
- A trailing `n` suffix on an integer literal indicates a `BigInt` literal. The `BigInt` literal can use any of the above bases. Note that leading-zero octal syntax like `0123n` is not allowed, but `0o123n` is fine.

Some examples of integer literals are:

```
0, 117, 123456789123456789n            (decimal, base 10)
015, 0001, 0o777777777777n             (octal, base 8)
0x1123, 0x00111, 0x123456789ABCDEFn    (hexadecimal, "hex" or base 16)
0b11, 0b0011, 0b1110100101010101010101n   (binary, base 2)
```

For more information, see Numeric literals in the Lexical grammar reference.

Floating-point literals

A floating-point literal can have the following parts:

- An unsigned decimal integer,
- A decimal point (`.`),
- A fraction (another decimal number),
- An exponent.

The exponent part is an `e` or `E` followed by an integer, which can be signed (preceded by `+` or `-`). A floating-point literal must have at least one digit, and either a decimal point or `e` (or `E`).

More succinctly, the syntax is:

```
[digits].[digits][(E|e)[(+|-)]digits]
```

For example:

```
3.1415926
.123456789
3.1E+12
.1e-23
```

Object literals

An object literal is a list of zero or more pairs of property names and associated values of an object, enclosed in curly braces (`{}`).

> **Warning:** Do not use an object literal at the beginning of a statement! This will lead to an error (or not behave as you expect), because the `{` will be interpreted as the beginning of a block.

The following is an example of an object literal. The first element of the `car` object defines a property, `myCar`, and assigns to it a new string, `"Saturn"`; the second element, the `getCar` property, is immediately assigned the result of invoking the function `(carTypes("Honda"))`; the third element, the `special` property, uses an existing variable (`sales`).

```
const sales = "Toyota";

function carTypes(name) {
  return name === "Honda" ? name : `Sorry, we don't sell ${name}.`;
}

const car = { myCar: "Saturn", getCar: carTypes("Honda"), special: sales };

console.log(car.myCar); // Saturn
console.log(car.getCar); // Honda
console.log(car.special); // Toyota
```

Additionally, you can use a numeric or string literal for the name of a property or nest an object inside another. The following example uses these options.

```
const car = { manyCars: { a: "Saab", b: "Jeep" }, 7: "Mazda" };

console.log(car.manyCars.b); // Jeep
console.log(car[7]); // Mazda
```

Object property names can be any string, including the empty string. If the property name would not be a valid JavaScript identifier or number, it must be enclosed in quotes.

Property names that are not valid identifiers cannot be accessed as a dot (`.`) property.

```
const unusualPropertyNames = {
  "": "An empty string",
  "!": "Bang!",
};
console.log(unusualPropertyNames.""); // SyntaxError: Unexpected string
console.log(unusualPropertyNames.!); // SyntaxError: Unexpected token !
```

Instead, they must be accessed with the bracket notation (`[]`).

```
console.log(unusualPropertyNames[""]); // An empty string
console.log(unusualPropertyNames["!"]); // Bang!
```

Enhanced Object literals

Object literals support a range of shorthand syntaxes that include setting the prototype at construction, shorthand for `foo: foo` assignments, defining methods, making `super` calls, and computing property names with expressions.

Together, these also bring object literals and class declarations closer together, and allow object-based design to benefit from some of the same conveniences.

```
const theProtoObj = {};
const handler = {};
const obj = {
  // __proto__
  __proto__: theProtoObj,
  // Shorthand for 'handler: handler'
  handler,
  // Methods
  toString() {
    // Super calls
    return `d ${super.toString()}`;
  },
  // Computed (dynamic) property names
  ["prop_" + (() => 42)()]: 42,
};
```

RegExp literals

A regex literal (which is defined in detail later) is a pattern enclosed between slashes. The following is an example of a regex literal.

```
const re = /ab+c/;
```

String literals

A string literal is zero or more characters enclosed in double (`"`) or single (`'`) quotation marks. A string must be delimited by quotation marks of the same type (that is, either both single quotation marks, or both double quotation marks).

The following are examples of string literals:

```
'foo'
"bar"
'1234'
'one line \n another line'
"Joyo's cat"
```

You should use string literals unless you specifically need to use a `String` object. See `String` for details on `String` objects.

You can call any of the `String` object's methods on a string literal value. JavaScript automatically converts the string literal to a temporary String object, calls the method, then discards the temporary String object. You can also use the `length` property with a string literal:

```
// Will print the number of symbols in the string including whitespace.
console.log("Joyo's cat".length); // In this case, 10.
```

Template literals are also available. Template literals are enclosed by the back-tick (`` ` ``) (grave accent) character instead of double or single quotes.

Template literals provide syntactic sugar for constructing strings. (This is similar to string interpolation features in Perl, Python, and more.)

```
// Basic literal string creation
`In JavaScript '\n' is a line-feed.`;

// Multiline strings
`In JavaScript, template strings can run
 over multiple lines, but double and single
 quoted strings cannot.`;

// String interpolation
const name = "Lev",
  time = "today";
`Hello ${name}, how are you ${time}?`;
```

Tagged templates are a compact syntax for specifying a template literal along with a call to a "tag" function for parsing it. A tagged template is just a more succinct and semantic way to invoke a function that processes a string and a set of relevant values. The name of the template tag function precedes the template literal — as in the following example, where the template tag function is named `print`. The `print` function will interpolate the arguments and serialize any objects or arrays that may come up, avoiding the pesky `[object Object]`.

```
const formatArg = (arg) => {
  if (Array.isArray(arg)) {
    // Print a bulleted list
    return arg.map((part) => `- ${part}`).join("\n");
  }
  if (arg.toString === Object.prototype.toString) {
    // This object will be serialized to "[object Object]".
    // Let's print something nicer.
    return JSON.stringify(arg);
  }
  return arg;
};

const print = (segments, ...args) => {
  // For any well-formed template literal, there will always be N args and
  // (N+1) string segments.
  let message = segments[0];
  segments.slice(1).forEach((segment, index) => {
    message += formatArg(args[index]) + segment;
  });
  console.log(message);
};

const todos = [
  "Learn JavaScript",
  "Learn Web APIs",
  "Set up my website",
  "Profit!",
];

const progress = { javascript: 20, html: 50, css: 10 };

print`I need to do:
${todos}
My current progress is: ${progress}
`;

// I need to do:
// - Learn JavaScript
// - Learn Web APIs
// - Set up my website
// - Profit!
// My current progress is: {"javascript":20,"html":50,"css":10}
```

Since tagged template literals are just sugar of function calls, you can re-write the above as an equivalent function call:

```
print(["I need to do:\n", "\nMy current progress is: ", "\n"], todos, progress);
```

This may be reminiscent of the `console.log`-style interpolation:

```
console.log("I need to do:\n%o\nMy current progress is: %o\n", todos, progress);
```

You can see how the tagged template reads more naturally than a traditional "formatter" function, where the variables and the template itself have to be declared separately.

Using special characters in strings

In addition to ordinary characters, you can also include special characters in strings, as shown in the following example.

```
"one line \n another line";
```

The following table lists the special characters that you can use in JavaScript strings.

Character	Meaning
`\0`	Null Byte
`\b`	Backspace
`\f`	Form Feed
`\n`	New Line
`\r`	Carriage Return
`\t`	Tab
`\v`	Vertical tab
`\'`	Apostrophe or single quote
`\"`	Double quote
`\\`	Backslash character
`\XXX`	The character with the Latin-1 encoding specified by up to three octal digits `XXX` between `0` and `377`. For example, `\251` is the octal sequence for the copyright symbol.
`\xXX`	The character with the Latin-1 encoding specified by the two hexadecimal digits `XX` between `00` and `FF`. For example, `\xA9` is the hexadecimal sequence for the copyright symbol.
`\uXXXX`	The Unicode character specified by the four hexadecimal digits `XXXX`. For example, `\u00A9` is the Unicode sequence for the copyright symbol. See Unicode escape sequences.
`\u{XXXXX}`	Unicode code point escapes. For example, `\u{2F804}` is the same as the Unicode escapes `\uD87E\uDC04`.

Escaping characters

For characters not listed in the table, a preceding backslash is ignored, but this usage is deprecated and should be avoided.

You can insert a quotation mark inside a string by preceding it with a backslash. This is known as *escaping* the quotation mark. For example:

```
const quote = "He read \"The Cremation of Sam McGee\" by R.W. Service.";
console.log(quote);
```

The result of this would be:

```
He read "The Cremation of Sam McGee" by R.W. Service.
```

To include a literal backslash inside a string, you must escape the backslash character. For example, to assign the file path `c:\temp` to a string, use the following:

```
const home = "c:\\temp";
```

You can also escape line breaks by preceding them with backslash. The backslash and line break are both removed from the value of the string.

```
const str =
  "this string \
is broken \
across multiple \
lines.";
console.log(str); // this string is broken across multiple lines.
```

More information

This chapter focuses on basic syntax for declarations and types. To learn more about JavaScript's language constructs, see also the following chapters in this guide:

- Control flow and error handling guide
- Loops and iteration
- Functions
- Expressions and operators guide

In the next chapter, we will have a look at control flow constructs and error handling.

- Previous
- Next

Indexed collections

- Previous
- Next

This chapter introduces collections of data which are ordered by an index value. This includes arrays and array-like constructs such as `Array` objects and `TypedArray` objects.

An *array* is an ordered list of values that you refer to with a name and an index.

For example, consider an array called `emp`, which contains employees' names indexed by their numerical employee number. So `emp[0]` would be employee number zero, `emp[1]` employee number one, and so on.

JavaScript does not have an explicit array data type. However, you can use the predefined `Array` object and its methods to work with arrays in your applications. The `Array` object has methods for manipulating arrays in various ways, such as joining, reversing, and sorting them. It has a property for determining the array length and other properties for use with regular expressions.

We will be focusing on arrays in this article, but many of the same concepts apply to typed arrays as well, since arrays and typed arrays share many similar methods. For more information on typed arrays, see the typed array guide.

Creating an array

The following statements create equivalent arrays:

```
const arr1 = new Array(element0, element1, /* …, */ elementN);
const arr2 = Array(element0, element1, /* …, */ elementN);
const arr3 = [element0, element1, /* …, */ elementN];
```

`element0, element1, …, elementN` is a list of values for the array's elements. When these values are specified, the array is initialized with them as the array's elements. The array's `length` property is set to the number of arguments.

The bracket syntax is called an "array literal" or "array initializer." It's shorter than other forms of array creation, and so is generally preferred. See Array literals for details.

To create an array with non-zero length, but without any items, either of the following can be used:

```
// This...
const arr1 = new Array(arrayLength);

// … results in the same array as this
const arr2 = Array(arrayLength);

// This has exactly the same effect
const arr3 = [];
arr3.length = arrayLength;
```

> **Note:** In the above code, `arrayLength` must be a `Number`. Otherwise, an array with a single element (the provided value) will be created. Calling `arr.length` will return `arrayLength`, but the array doesn't contain any elements. A `for...in` loop will not find any property on the array.

In addition to a newly defined variable as shown above, arrays can also be assigned as a property of a new or an existing object:

```
const obj = {};
// …
obj.prop = [element0, element1, /* …, */ elementN];

// OR
const obj = { prop: [element0, element1, /* …, */ elementN] };
```

If you wish to initialize an array with a single element, and the element happens to be a `Number`, you must use the bracket syntax. When a single `Number` value is passed to the `Array()` constructor or function, it is interpreted as an `arrayLength`, not as a single element.

This creates an array with only one element: the number 42.

```
const arr = [42];
```

This creates an array with no elements and `arr.length` set to 42.

```
const arr = Array(42);
```

This is equivalent to:

```
const arr = [];
arr.length = 42;
```

Calling `Array(N)` results in a `RangeError`, if `N` is a non-whole number whose fractional portion is non-zero. The following example illustrates this behavior.

```
const arr = Array(9.3); // RangeError: Invalid array length
```

If your code needs to create arrays with single elements of an arbitrary data type, it is safer to use array literals. Alternatively, create an empty array first before adding the single element to it.

You can also use the `Array.of` static method to create arrays with single element.

```
const arr = Array.of(9.3); // arr contains only one element 9.3
```

Referring to array elements

Because elements are also properties, you can access them using property accessors. Suppose you define the following array:

```
const myArray = ["Wind", "Rain", "Fire"];
```

You can refer to the first element of the array as `myArray[0]`, the second element of the array as `myArray[1]`, etc. The index of the elements begins with zero.

> **Note:** You can also use property accessors to access other properties of the array, like with an object.
>
> ```
> const arr = ["one", "two", "three"];
> arr[2]; // three
> arr["length"]; // 3
> ```

Populating an array

You can populate an array by assigning values to its elements. For example:

```
const emp = [];
emp[0] = "Casey Jones";
emp[1] = "Phil Lesh";
emp[2] = "August West";
```

> **Note:** If you supply a non-integer value to the array operator in the code above, a property will be created in the object representing the array, instead of an array element.
>
> ```
> const arr = [];
> arr[3.4] = "Oranges";
> console.log(arr.length); // 0
> console.log(Object.hasOwn(arr, 3.4)); // true
> ```

You can also populate an array when you create it:

```
const myArray = new Array("Hello", myVar, 3.14159);
// OR
const myArray = ["Mango", "Apple", "Orange"];
```

Understanding length

At the implementation level, JavaScript's arrays actually store their elements as standard object properties, using the array index as the property name.

The `length` property is special. Its value is always a positive integer greater than the index of the last element if one exists. (In the example below, `'Dusty'` is indexed at `30`, so `cats.length` returns `30 + 1`).

Remember, JavaScript Array indexes are 0-based: they start at `0`, not `1`. This means that the `length` property will be one more than the highest index stored in the array:

```
const cats = [];
cats[30] = ["Dusty"];
console.log(cats.length); // 31
```

You can also assign to the `length` property.

Writing a value that is shorter than the number of stored items truncates the array. Writing `0` empties it entirely:

```
const cats = ["Dusty", "Misty", "Twiggy"];
console.log(cats.length); // 3

cats.length = 2;
console.log(cats); // [ 'Dusty', 'Misty' ] - Twiggy has been removed

cats.length = 0;
console.log(cats); // []; the cats array is empty

cats.length = 3;
console.log(cats); // [ <3 empty items> ]
```

Iterating over arrays

A common operation is to iterate over the values of an array, processing each one in some way, as follows:

```
const colors = ["red", "green", "blue"];
for (let i = 0; i < colors.length; i++) {
  console.log(colors[i]);
}
```

If you know that none of the elements in your array evaluate to `false` in a boolean context—if your array consists only of DOM nodes, for example—you can use a more efficient idiom:

```
const divs = document.getElementsByTagName("div");
for (let i = 0, div; (div = divs[i]); i++) {
  /* Process div in some way */
}
```

This avoids the overhead of checking the length of the array, and ensures that the `div` variable is reassigned to the current item each time around the loop for added convenience.

The `forEach()` method provides another way of iterating over an array:

```
const colors = ["red", "green", "blue"];
colors.forEach((color) => console.log(color));
// red
// green
// blue
```

The function passed to `forEach` is executed once for every item in the array, with the array item passed as the argument to the function. Unassigned values are not iterated in a `forEach` loop.

Note that the elements of an array that are omitted when the array is defined are not listed when iterating by `forEach`, but *are* listed when `undefined` has been manually assigned to the element:

```
const sparseArray = ["first", "second", , "fourth"];

sparseArray.forEach((element) => {
  console.log(element);
});
// Logs:
// first
// second
// fourth

if (sparseArray[2] === undefined) {
  console.log("sparseArray[2] is undefined"); // true
}

const nonsparseArray = ["first", "second", undefined, "fourth"];

nonsparseArray.forEach((element) => {
  console.log(element);
});
// Logs:
// first
// second
// undefined
// fourth
```

Since JavaScript array elements are saved as standard object properties, it is not advisable to iterate through JavaScript arrays using `for...in` loops, because normal elements and all enumerable properties will be listed.

Array methods

The `Array` object has the following methods:

The `concat()` method joins two or more arrays and returns a new array.

```
let myArray = ["1", "2", "3"];
myArray = myArray.concat("a", "b", "c");
// myArray is now ["1", "2", "3", "a", "b", "c"]
```

The `join()` method joins all elements of an array into a string.

```
const myArray = ["Wind", "Rain", "Fire"];
const list = myArray.join(" - "); // list is "Wind - Rain - Fire"
```

The `push()` method adds one or more elements to the end of an array and returns the resulting `length` of the array.

```
const myArray = ["1", "2"];
myArray.push("3"); // myArray is now ["1", "2", "3"]
```

The `pop()` method removes the last element from an array and returns that element.

```
const myArray = ["1", "2", "3"];
const last = myArray.pop();
// myArray is now ["1", "2"], last = "3"
```

The `shift()` method removes the first element from an array and returns that element.

```
const myArray = ["1", "2", "3"];
const first = myArray.shift();
// myArray is now ["2", "3"], first is "1"
```

The `unshift()` method adds one or more elements to the front of an array and returns the new length of the array.

```
const myArray = ["1", "2", "3"];
myArray.unshift("4", "5");
// myArray becomes ["4", "5", "1", "2", "3"]
```

The `slice()` method extracts a section of an array and returns a new array.

```
let myArray = ["a", "b", "c", "d", "e"];
myArray = myArray.slice(1, 4); // [ "b", "c", "d"]
// starts at index 1 and extracts all elements
// until index 3
```

The `at()` method returns the element at the specified index in the array, or `undefined` if the index is out of range. It's notably used for negative indices that access elements from the end of the array.

```
const myArray = ["a", "b", "c", "d", "e"];
myArray.at(-2); // "d", the second-last element of myArray
```

The `splice()` method removes elements from an array and (optionally) replaces them. It returns the items which were removed from the array.

```
const myArray = ["1", "2", "3", "4", "5"];
myArray.splice(1, 3, "a", "b", "c", "d");
// myArray is now ["1", "a", "b", "c", "d", "5"]
// This code started at index one (or where the "2" was),
// removed 3 elements there, and then inserted all consecutive
// elements in its place.
```

The `reverse()` method transposes the elements of an array, in place: the first array element becomes the last and the last becomes the first. It returns a reference to the array.

```
const myArray = ["1", "2", "3"];
myArray.reverse();
// transposes the array so that myArray = ["3", "2", "1"]
```

The `flat()` method returns a new array with all sub-array elements concatenated into it recursively up to the specified depth.

```
let myArray = [1, 2, [3, 4]];
myArray = myArray.flat();
// myArray is now [1, 2, 3, 4], since the [3, 4] subarray is flattened
```

The `sort()` method sorts the elements of an array in place, and returns a reference to the array.

```
const myArray = ["Wind", "Rain", "Fire"];
myArray.sort();
// sorts the array so that myArray = ["Fire", "Rain", "Wind"]
```

`sort()` can also take a callback function to determine how array elements are compared. The callback function is called with two arguments, which are two values from the array. The function compares these two values and returns a positive number, negative number, or zero, indicating the order of the two values. For instance, the following will sort the array by the last letter of a string:

```
const sortFn = (a, b) => {
  if (a[a.length - 1] < b[b.length - 1]) {
    return -1; // Negative number => a < b, a comes before b
  } else if (a[a.length - 1] > b[b.length - 1]) {
    return 1; // Positive number => a > b, a comes after b
  }
  return 0; // Zero => a = b, a and b keep their original order
};
myArray.sort(sortFn);
// sorts the array so that myArray = ["Wind","Fire","Rain"]
```

- if `a` is less than `b` by the sorting system, return `-1` (or any negative number)
- if `a` is greater than `b` by the sorting system, return `1` (or any positive number)
- if `a` and `b` are considered equivalent, return `0`.

The `indexOf()` method searches the array for `searchElement` and returns the index of the first match.

```
const a = ["a", "b", "a", "b", "a"];
console.log(a.indexOf("b")); // 1

// Now try again, starting from after the last match
console.log(a.indexOf("b", 2)); // 3
console.log(a.indexOf("z")); // -1, because 'z' was not found
```

The `lastIndexOf()` method works like `indexOf`, but starts at the end and searches backwards.

```
const a = ["a", "b", "c", "d", "a", "b"];
console.log(a.lastIndexOf("b")); // 5

// Now try again, starting from before the last match
console.log(a.lastIndexOf("b", 4)); // 1
console.log(a.lastIndexOf("z")); // -1
```

The `forEach()` method executes `callback` on every array item and returns `undefined`.

```
const a = ["a", "b", "c"];
a.forEach((element) => {
  console.log(element);
});
// Logs:
// a
// b
// c
```

The `forEach` method (and others below) that take a callback are known as *iterative methods*, because they iterate over the entire array in some fashion. Each one takes an optional second argument called `thisArg`. If provided, `thisArg` becomes the value of the `this` keyword inside the body of the callback function. If not provided, as with other cases where a function is invoked outside of an explicit object context, `this` will refer to the global object (`window`, `globalThis`, etc.) when the function is not strict, or `undefined` when the function is strict.

> **Note:** The `sort()` method introduced above is not an iterative method, because its callback function is only used for comparison and may not be called in any particular order based on element order. `sort()` does not accept the `thisArg` parameter either.

The `map()` method returns a new array of the return value from executing `callback` on every array item.

```
const a1 = ["a", "b", "c"];
const a2 = a1.map((item) => item.toUpperCase());
console.log(a2); // ['A', 'B', 'C']
```

The `flatMap()` method runs `map()` followed by a `flat()` of depth 1.

```
const a1 = ["a", "b", "c"];
const a2 = a1.flatMap((item) => [item.toUpperCase(), item.toLowerCase()]);
console.log(a2); // ['A', 'a', 'B', 'b', 'C', 'c']
```

The `filter()` method returns a new array containing the items for which `callback` returned `true`.

```
const a1 = ["a", 10, "b", 20, "c", 30];
const a2 = a1.filter((item) => typeof item === "number");
console.log(a2); // [10, 20, 30]
```

The `find()` method returns the first item for which `callback` returned `true`.

```
const a1 = ["a", 10, "b", 20, "c", 30];
const i = a1.find((item) => typeof item === "number");
console.log(i); // 10
```

The `findLast()` method returns the last item for which `callback` returned `true`.

```
const a1 = ["a", 10, "b", 20, "c", 30];
const i = a1.findLast((item) => typeof item === "number");
console.log(i); // 30
```

The `findIndex()` method returns the index of the first item for which `callback` returned `true`.

```
const a1 = ["a", 10, "b", 20, "c", 30];
const i = a1.findIndex((item) => typeof item === "number");
console.log(i); // 1
```

The `findLastIndex()` method returns the index of the last item for which `callback` returned `true`.

```
const a1 = ["a", 10, "b", 20, "c", 30];
const i = a1.findLastIndex((item) => typeof item === "number");
console.log(i); // 5
```

The `every()` method returns `true` if `callback` returns `true` for every item in the array.

```
function isNumber(value) {
  return typeof value === "number";
}
const a1 = [1, 2, 3];
console.log(a1.every(isNumber)); // true
const a2 = [1, "2", 3];
console.log(a2.every(isNumber)); // false
```

The `some()` method returns `true` if `callback` returns `true` for at least one item in the array.

```
function isNumber(value) {
  return typeof value === "number";
}
const a1 = [1, 2, 3];
console.log(a1.some(isNumber)); // true
const a2 = [1, "2", 3];
console.log(a2.some(isNumber)); // true
const a3 = ["1", "2", "3"];
console.log(a3.some(isNumber)); // false
```

The `reduce()` method applies `callback(accumulator, currentValue, currentIndex, array)` for each value in the array for the purpose of reducing the list of items down to a single value. The `reduce` function returns the final value returned by `callback` function.

If `initialValue` is specified, then `callback` is called with `initialValue` as the first parameter value and the value of the first item in the array as the second parameter value.

If `initialValue` is *not* specified, then `callback`'s first two parameter values will be the first and second elements of the array. On *every* subsequent call, the first parameter's value will be whatever `callback` returned on the previous call, and the second parameter's value will be the next value in the array.

If `callback` needs access to the index of the item being processed, or access to the entire array, they are available as optional parameters.

```
const a = [10, 20, 30];
const total = a.reduce(
  (accumulator, currentValue) => accumulator + currentValue,
  0,
);
console.log(total); // 60
```

The `reduceRight()` method works like `reduce()`, but starts with the last element.

`reduce` and `reduceRight` are the least obvious of the iterative array methods. They should be used for algorithms that combine two values recursively in order to reduce a sequence down to a single value.

Array transformations

You can transform back and forth between arrays and other data structures.

Grouping the elements of an array

The `Object.groupBy()` method can be used to group the elements of an array, using a test function that returns a string indicating the group of the current element.

Here we have an inventory array that contains "food" objects that have a `name` and a `type`.

```
const inventory = [
  { name: "asparagus", type: "vegetables" },
  { name: "bananas", type: "fruit" },
  { name: "goat", type: "meat" },
  { name: "cherries", type: "fruit" },
  { name: "fish", type: "meat" },
];
```

To use `Object.groupBy()`, you supply a callback function that is called with the current element, and optionally the current index and array, and returns a string indicating the group of the element.

The code below uses an arrow function to return the `type` of each array element (this uses object destructuring syntax for function arguments to unpack the `type` element from the passed object). The result is an object that has properties named after the unique strings returned by the callback. Each property is assigned an array containing the elements in the group.

```
const result = Object.groupBy(inventory, ({ type }) => type);
console.log(result);
// Logs
// {
//   vegetables: [{ name: 'asparagus', type: 'vegetables' }],
//   fruit: [
//     { name: 'bananas', type: 'fruit' },
//     { name: 'cherries', type: 'fruit' }
//   ],
//   meat: [
//     { name: 'goat', type: 'meat' },
//     { name: 'fish', type: 'meat' }
//   ]
// }
```

Note that the returned object references the *same* elements as the original array (not deep copies). Changing the internal structure of these elements will be reflected in both the original array and the returned object.

If you can't use a string as the key, for example, if the information to group is associated with an object that might change, then you can instead use `Map.groupBy()`. This is very similar to `Object.groupBy()` except that it groups the elements of the array into a `Map` that can use an arbitrary value (object or primitive) as a key.

Sparse arrays

Arrays can contain "empty slots", which are not the same as slots filled with the value `undefined`. Empty slots can be created in one of the following ways:

```
// Array constructor:
const a = Array(5); // [ <5 empty items> ]

// Consecutive commas in array literal:
const b = [1, 2, , , 5]; // [ 1, 2, <2 empty items>, 5 ]

// Directly setting a slot with index greater than array.length:
const c = [1, 2];
c[4] = 5; // [ 1, 2, <2 empty items>, 5 ]

// Elongating an array by directly setting .length:
const d = [1, 2];
d.length = 5; // [ 1, 2, <3 empty items> ]

// Deleting an element:
const e = [1, 2, 3, 4, 5];
delete e[2]; // [ 1, 2, <1 empty item>, 4, 5 ]
```

In some operations, empty slots behave as if they are filled with `undefined`.

```
const arr = [1, 2, , , 5]; // Create a sparse array

// Indexed access
console.log(arr[2]); // undefined

// For...of
for (const i of arr) {
  console.log(i);
}
// Logs: 1 2 undefined undefined 5

// Spreading
const another = [...arr]; // "another" is [ 1, 2, undefined, undefined, 5 ]
```

But in others (most notably array iteration methods), empty slots are skipped.

```
const mapped = arr.map((i) => i + 1); // [ 2, 3, <2 empty items>, 6 ]
arr.forEach((i) => console.log(i)); // 1 2 5
const filtered = arr.filter(() => true); // [ 1, 2, 5 ]
const hasFalsy = arr.some((k) => !k); // false

// Property enumeration
const keys = Object.keys(arr); // [ '0', '1', '4' ]
for (const key in arr) {
  console.log(key);
}
// Logs: '0' '1' '4'
// Spreading into an object uses property enumeration, not the array's iterator
const objectSpread = { ...arr }; // { '0': 1, '1': 2, '4': 5 }
```

For a complete list of how array methods behave with sparse arrays, see the `Array` reference page.

Multi-dimensional arrays

Arrays can be nested, meaning that an array can contain another array as an element. Using this characteristic of JavaScript arrays, multi-dimensional arrays can be created.

The following code creates a two-dimensional array.

```
const a = new Array(4);
for (let i = 0; i < 4; i++) {
  a[i] = new Array(4);
  for (let j = 0; j < 4; j++) {
    a[i][j] = `[${i}, ${j}]`;
  }
}
```

This example creates an array with the following rows:

```
Row 0: [0, 0] [0, 1] [0, 2] [0, 3]
Row 1: [1, 0] [1, 1] [1, 2] [1, 3]
Row 2: [2, 0] [2, 1] [2, 2] [2, 3]
Row 3: [3, 0] [3, 1] [3, 2] [3, 3]
```

Using arrays to store other properties

Arrays can also be used like objects, to store related information.

```
const arr = [1, 2, 3];
arr.property = "value";
console.log(arr.property); // "value"
```

For example, when an array is the result of a match between a regular expression and a string, the array returns properties and elements that provide information about the match. An array is the return value of `RegExp.prototype.exec()`, `String.prototype.match()`, and `String.prototype.split()`. For information on using arrays with regular expressions, see Regular Expressions.

Working with array-like objects

Some JavaScript objects, such as the `NodeList` returned by `document.getElementsByTagName()` or the `arguments` object made available within the body of a function, look and behave like arrays on the surface but do not share all of their methods. The `arguments` object provides a `length` attribute but does not implement array methods like `forEach()`.

Array methods cannot be called directly on array-like objects.

```
function printArguments() {
  arguments.forEach((item) => {
    console.log(item);
  }); // TypeError: arguments.forEach is not a function
}
```

But you can call them indirectly using `Function.prototype.call()`.

```
function printArguments() {
  Array.prototype.forEach.call(arguments, (item) => {
    console.log(item);
  });
}
```

Array prototype methods can be used on strings as well, since they provide sequential access to their characters in a similar way to arrays:

```
Array.prototype.forEach.call("a string", (chr) => {
  console.log(chr);
});
```

Inheritance and the prototype chain

In programming, *inheritance* refers to passing down characteristics from a parent to a child so that a new piece of code can reuse and build upon the features of an existing one. JavaScript implements inheritance by using objects. Each object has an internal link to another object called its *prototype*. That prototype object has a prototype of its own, and so on until an object is reached with `null` as its prototype. By definition, `null` has no prototype and acts as the final link in this **prototype chain**. It is possible to mutate any member of the prototype chain or even swap out the prototype at runtime, so concepts like static dispatching do not exist in JavaScript.

JavaScript is a bit confusing for developers experienced in class-based languages (like Java or C++), as it is dynamic and does not have static types. While this confusion is often considered to be one of JavaScript's weaknesses, the prototypal inheritance model itself is, in fact, more powerful than the classic model. It is, for example, fairly trivial to build a classic model on top of a prototypal model — which is how classes are implemented.

Although classes are now widely adopted and have become a new paradigm in JavaScript, classes do not bring a new inheritance pattern. While classes abstract most of the prototypal mechanism away, understanding how prototypes work under the hood is still useful.

Inheritance with the prototype chain

Inheriting properties

JavaScript objects are dynamic "bags" of properties (referred to as **own properties**). JavaScript objects have a link to a prototype object. When trying to access a property of an object, the property will not only be sought on the object, but also on the prototype of the object, the prototype of the prototype, and so on, until either a property with a matching name is found or the end of the prototype chain is reached.

> **Note:** Following the ECMAScript standard, the notation `someObject.[[Prototype]]` is used to designate the prototype of `someObject`. The `[[Prototype]]` internal slot can be accessed and modified with the `Object.getPrototypeOf()` and `Object.setPrototypeOf()` functions respectively. This is equivalent to the JavaScript accessor `__proto__` which is non-standard but de-facto implemented by many JavaScript engines. To prevent confusion while keeping it succinct, in our notation we will avoid using `obj.__proto__` but use `obj.[[Prototype]]` instead. This corresponds to `Object.getPrototypeOf(obj)`.
>
> It should not be confused with the `func.prototype` property of functions, which instead specifies the `[[Prototype]]` to be assigned to all *instances* of objects created by the given function when used as a constructor. We will discuss the `prototype` property of constructor functions in a later section.

There are several ways to specify the `[[Prototype]]` of an object, which are listed in a later section. For now, we will use the `__proto__` syntax for illustration. It's worth noting that the `{ __proto__: ... }` syntax is different from the `obj.__proto__` accessor: the former is standard and not deprecated.

In an object literal like `{ a: 1, b: 2, __proto__: c }`, the value `c` (which has to be either `null` or another object) will become the `[[Prototype]]` of the object represented by the literal, while the other keys like `a` and `b` will become the *own properties* of the object. This syntax reads very naturally, since `[[Prototype]]` is just an "internal property" of the object.

Here is what happens when trying to access a property:

```
const o = {
  a: 1,
  b: 2,
  // __proto__ sets the [[Prototype]]. It's specified here
  // as another object literal.
  __proto__: {
    b: 3,
    c: 4,
  },
};

// o.[[Prototype]] has properties b and c.
// o.[[Prototype]].[[Prototype]] is Object.prototype (we will explain
// what that means later).
// Finally, o.[[Prototype]].[[Prototype]].[[Prototype]] is null.
// This is the end of the prototype chain, as null,
// by definition, has no [[Prototype]].
// Thus, the full prototype chain looks like:
// { a: 1, b: 2 } ---> { b: 3, c: 4 } ---> Object.prototype ---> null

console.log(o.a); // 1
// Is there an 'a' own property on o? Yes, and its value is 1.

console.log(o.b); // 2
// Is there a 'b' own property on o? Yes, and its value is 2.
// The prototype also has a 'b' property, but it's not visited.
// This is called Property Shadowing

console.log(o.c); // 4
// Is there a 'c' own property on o? No, check its prototype.
// Is there a 'c' own property on o.[[Prototype]]? Yes, its value is 4.

console.log(o.d); // undefined
// Is there a 'd' own property on o? No, check its prototype.
// Is there a 'd' own property on o.[[Prototype]]? No, check its prototype.
// o.[[Prototype]].[[Prototype]] is Object.prototype and
// there is no 'd' property by default, check its prototype.
// o.[[Prototype]].[[Prototype]].[[Prototype]] is null, stop searching,
// no property found, return undefined.
```

Setting a property to an object creates an own property. The only exception to the getting and setting behavior rules is when it's intercepted by a getter or setter.

Similarly, you can create longer prototype chains, and a property will be sought on all of them.

```
const o = {
  a: 1,
  b: 2,
  // __proto__ sets the [[Prototype]]. It's specified here
  // as another object literal.
  __proto__: {
    b: 3,
    c: 4,
    __proto__: {
      d: 5,
    },
  },
};

// { a: 1, b: 2 } ---> { b: 3, c: 4 } ---> { d: 5 } ---> Object.prototype ---> null

console.log(o.d); // 5
```

Inheriting "methods"

JavaScript does not have "methods" in the form that class-based languages define them. In JavaScript, any function can be added to an object in the form of a property. An inherited function acts just as any other property, including property shadowing as shown above (in this case, a form of *method overriding*).

When an inherited function is executed, the value of `this` points to the inheriting object, not to the prototype object where the function is an own property.

```
const parent = {
  value: 2,
  method() {
    return this.value + 1;
  },
};

console.log(parent.method()); // 3
// When calling parent.method in this case, 'this' refers to parent
```

```
// child is an object that inherits from parent
const child = {
  __proto__: parent,
};
console.log(child.method()); // 3
// When child.method is called, 'this' refers to child.
// So when child inherits the method of parent,
// The property 'value' is sought on child. However, since child
// doesn't have an own property called 'value', the property is
// found on the [[Prototype]], which is parent.value.

child.value = 4; // assign the value 4 to the property 'value' on child.
// This shadows the 'value' property on parent.
// The child object now looks like:
// { value: 4, __proto__: { value: 2, method: [Function] } }
console.log(child.method()); // 5
// Since child now has the 'value' property, 'this.value' means
// child.value instead
```

Constructors

The power of prototypes is that we can reuse a set of properties if they should be present on every instance — especially for methods. Suppose we are to create a series of boxes, where each box is an object that contains a value which can be accessed through a `getValue` function. A naive implementation would be:

```
const boxes = [
  { value: 1, getValue() { return this.value; } },
  { value: 2, getValue() { return this.value; } },
  { value: 3, getValue() { return this.value; } },
];
```

This is subpar, because each instance has its own function property that does the same thing, which is redundant and unnecessary. Instead, we can move `getValue` to the `[[Prototype]]` of all boxes:

```
const boxPrototype = {
  getValue() {
    return this.value;
  },
};

const boxes = [
  { value: 1, __proto__: boxPrototype },
  { value: 2, __proto__: boxPrototype },
  { value: 3, __proto__: boxPrototype },
];
```

This way, all boxes' `getValue` method will refer to the same function, lowering memory usage. However, manually binding the `__proto__` for every object creation is still very inconvenient. This is when we would use a *constructor* function, which automatically sets the `[[Prototype]]` for every object manufactured. Constructors are functions called with `new`.

```
// A constructor function
function Box(value) {
  this.value = value;
}

// Properties all boxes created from the Box() constructor
// will have
Box.prototype.getValue = function () {
  return this.value;
};

const boxes = [new Box(1), new Box(2), new Box(3)];
```

We say that `new Box(1)` is an *instance* created from the `Box` constructor function. `Box.prototype` is not much different from the `boxPrototype` object we created previously — it's just a plain object. Every instance created from a constructor function will automatically have the constructor's `prototype` property as its `[[Prototype]]` — that is, `Object.getPrototypeOf(new Box()) === Box.prototype`. `Constructor.prototype` by default has one own property: `constructor`, which references the constructor function itself — that is, `Box.prototype.constructor === Box`. This allows one to access the original constructor from any instance.

> **Note:** If a non-primitive is returned from the constructor function, that value will become the result of the `new` expression. In this case the `[[Prototype]]` may not be correctly bound — but this should not happen much in practice.

The above constructor function can be rewritten in classes as:

```
class Box {
  constructor(value) {
    this.value = value;
  }

  // Methods are created on Box.prototype
  getValue() {
    return this.value;
```

```
  }
}
```

Classes are syntax sugar over constructor functions, which means you can still manipulate `Box.prototype` to change the behavior of all instances. However, because classes are designed to be an abstraction over the underlying prototype mechanism, we will use the more-lightweight constructor function syntax for this tutorial to fully demonstrate how prototypes work.

Because `Box.prototype` references the same object as the `[[Prototype]]` of all instances, we can change the behavior of all instances by mutating `Box.prototype`.

```
function Box(value) {
  this.value = value;
}
Box.prototype.getValue = function () {
  return this.value;
};
const box = new Box(1);

// Mutate Box.prototype after an instance has already been created
Box.prototype.getValue = function () {
  return this.value + 1;
};
box.getValue(); // 2
```

A corollary is, *re-assigning* `Constructor.prototype` (`Constructor.prototype = ...`) is a bad idea for two reasons:

- The `[[Prototype]]` of instances created before the reassignment is now referencing a different object from the `[[Prototype]]` of instances created after the reassignment — mutating one's `[[Prototype]]` no longer mutates the other.
- Unless you manually re-set the `constructor` property, the constructor function can no longer be traced from `instance.constructor`, which may break user expectation. Some built-in operations will read the `constructor` property as well, and if it is not set, they may not work as expected.

`Constructor.prototype` is only useful when constructing instances. It has nothing to do with `Constructor.[[Prototype]]`, which is the constructor function's *own* prototype, which is `Function.prototype` — that is, `Object.getPrototypeOf(Constructor) === Function.prototype`.

Implicit constructors of literals

Some literal syntaxes in JavaScript create instances that implicitly set the `[[Prototype]]`. For example:

```
// Object literals (without the `__proto__` key) automatically
// have `Object.prototype` as their `[[Prototype]]`
const object = { a: 1 };
Object.getPrototypeOf(object) === Object.prototype; // true

// Array literals automatically have `Array.prototype` as their `[[Prototype]]`
const array = [1, 2, 3];
Object.getPrototypeOf(array) === Array.prototype; // true

// RegExp literals automatically have `RegExp.prototype` as their `[[Prototype]]`
const regexp = /abc/;
Object.getPrototypeOf(regexp) === RegExp.prototype; // true
```

We can "de-sugar" them into their constructor form.

```
const array = new Array(1, 2, 3);
const regexp = new RegExp("abc");
```

For example, "array methods" like `map()` are simply methods defined on `Array.prototype`, which is why they are automatically available on all array instances.

> **Warning:** There is one misfeature that used to be prevalent — extending `Object.prototype` or one of the other built-in prototypes. An example of this misfeature is, defining `Array.prototype.myMethod = function () {...}` and then using `myMethod` on all array instances.
>
> This misfeature is called *monkey patching*. Doing monkey patching risks forward compatibility, because if the language adds this method in the future but with a different signature, your code will break. It has led to incidents like the SmooshGate, and can be a great nuisance for the language to advance since JavaScript tries to "not break the web".
>
> The **only** good reason for extending a built-in prototype is to backport the features of newer JavaScript engines, like `Array.prototype.forEach`.

It may be interesting to note that due to historical reasons, some built-in constructors' `prototype` property are instances themselves. For example, `Number.prototype` is a number 0, `Array.prototype` is an empty array, and `RegExp.prototype` is `/(?:)/`.

```
Number.prototype + 1; // 1
Array.prototype.map((x) => x + 1); // []
String.prototype + "a"; // "a"
RegExp.prototype.source; // "(?:)"
Function.prototype(); // Function.prototype is a no-op function by itself
```

However, this is not the case for user-defined constructors, nor for modern constructors like `Map`.

```
Map.prototype.get(1);
// Uncaught TypeError: get method called on incompatible Map.prototype
```

Building longer inheritance chains

The `Constructor.prototype` property will become the `[[Prototype]]` of the constructor's instances, as-is — including `Constructor.prototype`'s own `[[Prototype]]`. By default, `Constructor.prototype` is a *plain object* — that is, `Object.getPrototypeOf(Constructor.prototype) === Object.prototype`. The only exception is `Object.prototype` itself, whose `[[Prototype]]` is `null` — that is, `Object.getPrototypeOf(Object.prototype) === null`. Therefore, a typical constructor will build the following prototype chain:

```
function Constructor() {}

const obj = new Constructor();
// obj ---> Constructor.prototype ---> Object.prototype ---> null
```

To build longer prototype chains, we can set the `[[Prototype]]` of `Constructor.prototype` via the `Object.setPrototypeOf()` function.

```
function Base() {}
function Derived() {}
// Set the `[[Prototype]]` of `Derived.prototype`
// to `Base.prototype`
Object.setPrototypeOf(Derived.prototype, Base.prototype);

const obj = new Derived();
// obj ---> Derived.prototype ---> Base.prototype ---> Object.prototype ---> null
```

In class terms, this is equivalent to using the `extends` syntax.

```
class Base {}
class Derived extends Base {}

const obj = new Derived();
// obj ---> Derived.prototype ---> Base.prototype ---> Object.prototype ---> null
```

You may also see some legacy code using `Object.create()` to build the inheritance chain. However, because this reassigns the `prototype` property and removes the `constructor` property, it can be more error-prone, while performance gains may not be apparent if the constructors haven't created any instances yet.

```
function Base() {}
function Derived() {}
// Re-assigns `Derived.prototype` to a new object
// with `Base.prototype` as its `[[Prototype]]`
// DON'T DO THIS — use Object.setPrototypeOf to mutate it instead
Derived.prototype = Object.create(Base.prototype);
```

Inspecting prototypes: a deeper dive

Let's look at what happens behind the scenes in a bit more detail.

In JavaScript, as mentioned above, functions are able to have properties. All functions have a special property named `prototype`. Please note that the code below is free-standing (it is safe to assume there is no other JavaScript on the webpage other than the below code). For the best learning experience, it is highly recommended that you open a console, navigate to the "console" tab, copy-and-paste in the below JavaScript code, and run it by pressing the Enter/Return key. (The console is included in most web browser's Developer Tools. More information is available for Firefox Developer Tools, Chrome DevTools, and Edge DevTools.)

```
function doSomething() {}
console.log(doSomething.prototype);
// It does not matter how you declare the function; a
// function in JavaScript will always have a default
// prototype property — with one exception: an arrow
// function doesn't have a default prototype property:
const doSomethingFromArrowFunction = () => {};
console.log(doSomethingFromArrowFunction.prototype);
```

As seen above, `doSomething()` has a default `prototype` property, as demonstrated by the console. After running this code, the console should have displayed an object that looks similar to this.

```
{
  constructor: ƒ doSomething(),
  [[Prototype]]: {
    constructor: ƒ Object(),
    hasOwnProperty: ƒ hasOwnProperty(),
    isPrototypeOf: ƒ isPrototypeOf(),
    propertyIsEnumerable: ƒ propertyIsEnumerable(),
    toLocaleString: ƒ toLocaleString(),
    toString: ƒ toString(),
    valueOf: ƒ valueOf()
  }
}
```

> **Note:** The Chrome console uses `[[Prototype]]` to denote the object's prototype, following the spec's terms; Firefox uses `<prototype>`. For consistency we will use `[[Prototype]]`.

We can add properties to the prototype of `doSomething()`, as shown below.

```
function doSomething() {}
doSomething.prototype.foo = "bar";
console.log(doSomething.prototype);
```

This results in:

```
{
  foo: "bar",
  constructor: ƒ doSomething(),
  [[Prototype]]: {
    constructor: ƒ Object(),
    hasOwnProperty: ƒ hasOwnProperty(),
    isPrototypeOf: ƒ isPrototypeOf(),
    propertyIsEnumerable: ƒ propertyIsEnumerable(),
    toLocaleString: ƒ toLocaleString(),
    toString: ƒ toString(),
    valueOf: ƒ valueOf()
  }
}
```

We can now use the `new` operator to create an instance of `doSomething()` based on this prototype. To use the new operator, call the function normally except prefix it with `new`. Calling a function with the `new` operator returns an object that is an instance of the function. Properties can then be added onto this object.

Try the following code:

```
function doSomething() {}
doSomething.prototype.foo = "bar"; // add a property onto the prototype
const doSomeInstancing = new doSomething();
doSomeInstancing.prop = "some value"; // add a property onto the object
console.log(doSomeInstancing);
```

This results in an output similar to the following:

```
{
  prop: "some value",
  [[Prototype]]: {
    foo: "bar",
    constructor: ƒ doSomething(),
    [[Prototype]]: {
      constructor: ƒ Object(),
      hasOwnProperty: ƒ hasOwnProperty(),
      isPrototypeOf: ƒ isPrototypeOf(),
      propertyIsEnumerable: ƒ propertyIsEnumerable(),
      toLocaleString: ƒ toLocaleString(),
      toString: ƒ toString(),
      valueOf: ƒ valueOf()
    }
  }
}
```

As seen above, the `[[Prototype]]` of `doSomeInstancing` is `doSomething.prototype`. But, what does this do? When you access a property of `doSomeInstancing`, the runtime first looks to see if `doSomeInstancing` has that property.

If `doSomeInstancing` does not have the property, then the runtime looks for the property in `doSomeInstancing.[[Prototype]]` (a.k.a. `doSomething.prototype`). If `doSomeInstancing.[[Prototype]]` has the property being looked for, then that property on `doSomeInstancing.[[Prototype]]` is used.

Otherwise, if `doSomeInstancing.[[Prototype]]` does not have the property, then `doSomeInstancing.[[Prototype]].[[Prototype]]` is checked for the property. By default, the `[[Prototype]]` of any function's `prototype` property is `Object.prototype`. So, `doSomeInstancing.[[Prototype]].[[Prototype]]` (a.k.a. `doSomething.prototype.[[Prototype]]` (a.k.a. `Object.prototype`)) is then looked through for the property being searched for.

If the property is not found in `doSomeInstancing.[[Prototype]].[[Prototype]]`, then `doSomeInstancing.[[Prototype]].[[Prototype]].[[Prototype]]` is looked through. However, there is a problem: `doSomeInstancing.[[Prototype]].[[Prototype]].[[Prototype]]` does not exist, because `Object.prototype.[[Prototype]]` is `null`. Then, and only then, after the entire prototype chain of `[[Prototype]]`'s is looked through, the runtime asserts that the property does not exist and conclude that the value at the property is `undefined`.

Let's try entering some more code into the console:

```
function doSomething() {}
doSomething.prototype.foo = "bar";
const doSomeInstancing = new doSomething();
doSomeInstancing.prop = "some value";
console.log("doSomeInstancing.prop:     ", doSomeInstancing.prop);
console.log("doSomeInstancing.foo:      ", doSomeInstancing.foo);
console.log("doSomething.prop:          ", doSomething.prop);
console.log("doSomething.foo:           ", doSomething.foo);
console.log("doSomething.prototype.prop:", doSomething.prototype.prop);
console.log("doSomething.prototype.foo: ", doSomething.prototype.foo);
```

This results in the following:

```
doSomeInstancing.prop:      some value
doSomeInstancing.foo:       bar
```

```
doSomething.prop:           undefined
doSomething.foo:            undefined
doSomething.prototype.prop: undefined
doSomething.prototype.foo:  bar
```

Different ways of creating and mutating prototype chains

We have encountered many ways to create objects and change their prototype chains. We will systematically summarize the different ways, comparing each approach's pros and cons.

Objects created with syntax constructs

```
const o = { a: 1 };
// The newly created object o has Object.prototype as its [[Prototype]]
// Object.prototype has null as its [[Prototype]].
// o ---> Object.prototype ---> null

const b = ["yo", "sup", "?"];
// Arrays inherit from Array.prototype
// (which has methods indexOf, forEach, etc.)
// The prototype chain looks like:
// b ---> Array.prototype ---> Object.prototype ---> null

function f() {
  return 2;
}
// Functions inherit from Function.prototype
// (which has methods call, bind, etc.)
// f ---> Function.prototype ---> Object.prototype ---> null

const p = { b: 2, __proto__: o };
// It is possible to point the newly created object's [[Prototype]] to
// another object via the __proto__ literal property. (Not to be confused
// with Object.prototype.__proto__ accessors)
// p ---> o ---> Object.prototype ---> null
```

When using the `__proto__` key in object initializers, pointing the `__proto__` key to something that is not an object only fails silently without throwing an exception. Contrary to the `Object.prototype.__proto__` setter, `__proto__` in object literal initializers is standardized and optimized, and can even be more performant than `Object.create`. Declaring extra own properties on the object at creation is more ergonomic than `Object.create`.

With constructor functions

```
function Graph() {
  this.vertices = [];
  this.edges = [];
}

Graph.prototype.addVertex = function (v) {
  this.vertices.push(v);
};

const g = new Graph();
// g is an object with own properties 'vertices' and 'edges'.
// g.[[Prototype]] is the value of Graph.prototype when new Graph() is executed.
```

Constructor functions have been available since very early JavaScript. Therefore, it is very fast, very standard, and very JIT-optimizable. However, it's also hard to "do properly" because methods added this way are enumerable by default, which is inconsistent with the class syntax or how built-in methods behave. Doing longer inheritance chains is also error-prone, as previously demonstrated.

With Object.create()

Calling `Object.create()` creates a new object. The `[[Prototype]]` of this object is the first argument of the function:

```
const a = { a: 1 };
// a ---> Object.prototype ---> null

const b = Object.create(a);
// b ---> a ---> Object.prototype ---> null
console.log(b.a); // 1 (inherited)

const c = Object.create(b);
// c ---> b ---> a ---> Object.prototype ---> null

const d = Object.create(null);
// d ---> null (d is an object that has null directly as its prototype)
console.log(d.hasOwnProperty);
// undefined, because d doesn't inherit from Object.prototype
```

Similar to the `__proto__` key in object initializers, `Object.create()` allows directly setting the prototype of an object at creation time, which permits the runtime to further optimize the object. It also allows the creation of objects with `null` prototype, using `Object.create(null)`. The second parameter of `Object.create()` allows you to precisely specify the attributes of each property in the new object, which can be a double-edged sword:

- It allows you to create non-enumerable properties, etc., during object creation, which is not possible with object literals.

- It is much more verbose and error-prone than object literals.
- It may be slower than object literals, especially when creating many properties.

With classes

```
class Rectangle {
  constructor(height, width) {
    this.name = "Rectangle";
    this.height = height;
    this.width = width;
  }
}

class FilledRectangle extends Rectangle {
  constructor(height, width, color) {
    super(height, width);
    this.name = "Filled rectangle";
    this.color = color;
  }
}

const filledRectangle = new FilledRectangle(5, 10, "blue");
// filledRectangle ---> FilledRectangle.prototype ---> Rectangle.prototype ---> Object.prototype ---> null
```

Classes offer the highest readability and maintainability when defining complex inheritance structures. Private elements are a feature with no trivial replacement in prototypal inheritance. However, classes are less optimized than traditional constructor functions and are not supported in older environments.

With Object.setPrototypeOf()

While all methods above will set the prototype chain at object creation time, `Object.setPrototypeOf()` allows mutating the `[[Prototype]]` internal property of an existing object. It can even force a prototype on a prototype-less object created with `Object.create(null)` or remove the prototype of an object by setting it to `null`.

```
const obj = { a: 1 };
const anotherObj = { b: 2 };
Object.setPrototypeOf(obj, anotherObj);
// obj ---> anotherObj ---> Object.prototype ---> null
```

However, you should set the prototype during creation if possible, because setting the prototype dynamically disrupts all optimizations that engines have made to the prototype chain. It might cause some engines to recompile your code for de-optimization, to make it work according to the specs.

With the __proto__ accessor

All objects inherit the `Object.prototype.__proto__` setter, which can be used to set the `[[Prototype]]` of an existing object (if the `__proto__` key is not overridden on the object).

> **Warning:** `Object.prototype.__proto__` accessors are **non-standard** and deprecated. You should almost always use `Object.setPrototypeOf` instead.

```
const obj = {};
// DON'T USE THIS: for example only.
obj.__proto__ = { barProp: "bar val" };
obj.__proto__.__proto__ = { fooProp: "foo val" };
console.log(obj.fooProp);
console.log(obj.barProp);
```

Compared to `Object.setPrototypeOf`, setting `__proto__` to something that is not an object fails silently without throwing an exception. It also has slightly better browser support. However, it is non-standard and deprecated. You should almost always use `Object.setPrototypeOf` instead.

Performance

The lookup time for properties that are high up on the prototype chain can have a negative impact on the performance, and this may be significant in the code where performance is critical. Additionally, trying to access nonexistent properties will always traverse the full prototype chain.

Also, when iterating over the properties of an object, **every** enumerable property that is on the prototype chain will be enumerated. To check whether an object has a property defined on *itself* and not somewhere on its prototype chain, it is necessary to use the `hasOwnProperty` or `Object.hasOwn` methods. All objects, except those with `null` as `[[Prototype]]`, inherit `hasOwnProperty` from `Object.prototype` — unless it has been overridden further down the prototype chain. To give you a concrete example, let's take the above graph example code to illustrate it:

```
function Graph() {
  this.vertices = [];
  this.edges = [];
}

Graph.prototype.addVertex = function (v) {
  this.vertices.push(v);
};

const g = new Graph();
// g ---> Graph.prototype ---> Object.prototype ---> null

g.hasOwnProperty("vertices"); // true
Object.hasOwn(g, "vertices"); // true
```

```
g.hasOwnProperty("nope"); // false
Object.hasOwn(g, "nope"); // false

g.hasOwnProperty("addVertex"); // false
Object.hasOwn(g, "addVertex"); // false

Object.getPrototypeOf(g).hasOwnProperty("addVertex"); // true
```

Note: It is **not** enough to check whether a property is `undefined`. The property might very well exist, but its value just happens to be set to `undefined`.

Conclusion

JavaScript may be a bit confusing for developers coming from Java or C++, as it's all dynamic, all runtime, and it has no static types at all. Everything is either an object (instance) or a function (constructor), and even functions themselves are instances of the `Function` constructor. Even the "classes" as syntax constructs are just constructor functions at runtime.

All constructor functions in JavaScript have a special property called `prototype`, which works with the `new` operator. The reference to the prototype object is copied to the internal `[[Prototype]]` property of the new instance. For example, when you do `const a1 = new A()`, JavaScript (after creating the object in memory and before running function `A()` with `this` defined to it) sets `a1.[[Prototype]] = A.prototype`. When you then access properties of the instance, JavaScript first checks whether they exist on that object directly, and if not, it looks in `[[Prototype]]`. `[[Prototype]]` is looked at *recursively*, i.e., `a1.doSomething`, `Object.getPrototypeOf(a1).doSomething`, `Object.getPrototypeOf(Object.getPrototypeOf(a1)).doSomething` etc., until it's found or `Object.getPrototypeOf` returns `null`. This means that all properties defined on `prototype` are effectively shared by all instances, and you can even later change parts of `prototype` and have the changes appear in all existing instances.

If, in the example above, you do `const a1 = new A(); const a2 = new A();`, then `a1.doSomething` would actually refer to `Object.getPrototypeOf(a1).doSomething` — which is the same as the `A.prototype.doSomething` you defined, i.e., `Object.getPrototypeOf(a1).doSomething === Object.getPrototypeOf(a2).doSomething === A.prototype.doSomething`.

It is essential to understand the prototypal inheritance model before writing complex code that makes use of it. Also, be aware of the length of the prototype chains in your code and break them up if necessary to avoid possible performance problems. Further, the native prototypes should **never** be extended unless it is for the sake of compatibility with newer JavaScript features.

Internationalization

- Previous
- Next

The `Intl` object is the namespace for the ECMAScript Internationalization API, which provides a wide range of locale- and culture-sensitive data and operations.

Overview

The `Intl` object is very use-case driven. It provides a separate object for each use case that requires locale-specific logic. Currently, it provides the following functionalities:

- Getting information about a locale using `Intl.Locale`.
- Formatting data using `Intl.DateTimeFormat`, `Intl.DurationFormat`, `Intl.ListFormat`, `Intl.NumberFormat`, and `Intl.RelativeTimeFormat`.
- Collation (i.e., comparing strings for sorting or searching) using `Intl.Collator`.
- Selecting plural forms using `Intl.PluralRules`.
- Segmenting text into units such as words, sentences, or graphemes using `Intl.Segmenter`.
- Getting the displayed name for currencies, languages, scripts, regions, and time zones using `Intl.DisplayNames`.

Most `Intl` APIs share a similar design (`Intl.Locale` is the only exception). You start by constructing an instance with the desired locale and options. This defines a set of rules for the desired operation (formatting, collation, segmentation, etc.). Then, when you call the method on the instance, such as `format()`, `compare()`, or `segment()`, the object applies the specified rule to the passed data.

```
// 1. Construct a formatter object, specifying the locale and formatting options:
const price = new Intl.NumberFormat("en-US", {
  style: "currency",
  currency: "USD",
});

// 2. Use the `format` method of the formatter object to format a number:
console.log(price.format(5.259)); // $5.26
```

The general signature of the constructor is:

```
new Intl.SomeObject(locales, options)
```

`locales` Optional

> A string with a BCP 47 language tag or an `Intl.Locale` instance, or an array of such locale identifiers. The runtime's default locale is used when `undefined` is passed or when none of the specified locale identifiers is supported. For the general form and interpretation of the `locales` argument, see the parameter description on the `Intl` main page.

`options` Optional

> An object containing properties that customize specific aspects of the operation, which is key to understanding how to use each `Intl` object.

Locale information

Locales underlie all behaviors of `Intl`. A *locale* is a set of conventions, represented in the `Intl` API by the `Intl.Locale` object. All `Intl` constructors that accept language tags also accept `Intl.Locale` objects.

Each locale is primarily defined by four things: a `language`, a `script`, a `region`, and sometimes some `variants`. When connected together by `-` in that order, they form a BCP 47 language tag.

- The language is the most important part of the locale and is mandatory. When given a single language, like `en` or `fr`, there are algorithms to infer the rest of the information (see `Intl.Locale.prototype.maximize()`).
- However, you often want to specify the region as well, because conventions can differ drastically between regions that speak the same language. For example, the date format in the US is MM/DD/YYYY, whereas in the UK it is DD/MM/YYYY, so specifying `en-US` or `en-GB` is important.
- You can also specify a script. The script is the writing system, or the characters used to transcribe the language. In practice, the script is often unnecessary, because the language used in a certain region is only written in one script. However, there are exceptions such as the Serbian language, which can be written in both the Latin and Cyrillic scripts (`sr-Latn` and `sr-Cyrl`), or the Chinese language, which can be written in both the Simplified and Traditional scripts (`zh-Hans` and `zh-Hant`).
- The variants are rarely used. Usually, they denote different orthographies; for example, German has the `1901` and `1996` orthography variants, which are written as `de-1901` and `de-1996`.

```
// These two are equivalent when passed to other Intl APIs
const locale1 = new Intl.Locale("en-US");
const locale2 = new Intl.Locale("en-Latn-US");

console.log(locale1.language, locale1.script, locale1.region); // "en", undefined, "US"
console.log(locale2.language, locale2.script, locale2.region); // "en", "Latn", "US"
```

A locale also contains a set of conventions used by that particular culture:

Use case	Property	Description	Extension subtag
Date/time formatting	`calendar`	Used to group days into years, months, and weeks, and to assign names to them. For example, the `gregory` date "2022-01-01" becomes "28 Tevet 5782" in the `hebrew` calendar.	`ca`
	`hourCycle`	Decides if times are displayed in 12-hour or 24-hour format, and whether the smallest hour number is 0 or 1.	`hc`
Number formatting, including dates, times, durations, etc.	`numberingSystem`	Transforms numbers into a locale-specific notation. The regular `0123456789` system is called `latn` (Latin). Often, each script has a numbering system that is just a digit-by-digit translation, but some scripts have more than one numbering system, some may not typically write numbers in that script (for example, Chinese has its own `hanidec` numbering system, but most texts use the standard `latn` system), and others may require special conversion algorithms (for example, Roman numerals — `roman`).	`nu`
Collation	`collation`	Defines the generic collation algorithm. For example, if you use the German `phonebk` collation, then "ä" is treated as "ae", and will be sorted between "ad" and "af".	`co`
	`caseFirst`	Decides whether uppercase or lowercase letters should be sorted first, or if casing is ignored.	`kf`
	`numeric`	Decides whether numbers are sorted as numbers or as strings. For example, if true, "10" will be sorted after "2".	`kn`

You can explicitly specify these properties when constructing the `Intl.Locale` or passing language tags to other `Intl` constructors. There are two ways to do this — append them to the language tag or specify them as options.

- To append them to the language tag, you first append the string `-u` (meaning "Unicode extension"), then the extension subtag as given above, then the value.
- To specify them as options, you just add the property name as given above, together with its value, to the `options` object.

Using `Intl.DateTimeFormat` as an example, both of the following lines create a formatter that formats dates in the Hebrew calendar:

```
const df1 = new Intl.DateTimeFormat("en-US-u-ca-hebrew");
const df2 = new Intl.DateTimeFormat("en-US", { calendar: "hebrew" });
```

Unrecognized properties are ignored, so you can use the same syntax as above with `Intl.NumberFormat`, but it won't do anything different than just passing `en-US`, because number formatting doesn't use the `calendar` property.

It is tricky to get the default values of these locale conventions. `new Intl.Locale("en-US").calendar` returns `undefined`, because the `Locale` object only contains the information you passed to it. The default calendar is theoretically dependent on what API you are using the calendar with, so to get the default calendar of `en-US` as used by `Intl.DateTimeFormat`, you can use its `resolvedOptions()` method. The same goes for other properties.

```
const locale = new Intl.Locale("en-US");
console.log(locale.calendar); // undefined; it's not provided
console.log(new Intl.DateTimeFormat(locale).resolvedOptions().calendar); // "gregory"
```

`Intl.Locale` objects do two things simultaneously: they represent a parsed BCP 47 language tag (as demonstrated above), and they provide information about that locale. All of its properties, like `calendar`, are extracted from the input only, without querying any data source about default values. On the other hand, it has a group of methods for querying real-world information about the locale. For example, the `getCalendars()`, `getHourCycles()`, `getNumberingSystems()`, and `getCollations()` methods complement the `calendar`, `hourCycle`, `numberingSystem`, and `collation` properties, and each returns an array of preferred values for that property.

```
const locale = new Intl.Locale("ar-EG");
console.log(locale.getCalendars()); // ['gregory', 'coptic', 'islamic', 'islamic-civil', 'islamic-tbla']
```

`Intl.Locale` instances also contain other methods that expose useful information, such as `getTextInfo()`, `getTimeZones()`, and `getWeekInfo()`.

Figuring out the locale

A shared concern for internationalization is: how do I know what locale to use?

The most obvious answer is "what the user prefers." Browsers expose the user's language preferences through the `navigator.languages` property. This is an array of language identifiers that can be directly passed to the formatter constructor—more on this later. The user can configure this list in their browser settings. You can also pass an empty array or `undefined`, which both cause the browser's default locale to be used.

```
const numberFormatter = new Intl.NumberFormat(navigator.languages);
console.log(numberFormatter.format(1234567.89));

const numberFormatter2 = new Intl.NumberFormat([]);
```

However, this may not always provide the most desirable result. Strings formatted by `Intl` formatters represent a tiny fraction of text displayed on your site; most localized content is provided by you, the site developer. For example, suppose your site is only offered in two languages: English and French. If a Japanese user visits your site and expects to use your site in English, they will be baffled when they see the English text interleaved with numbers and dates in Japanese!

Usually, you don't want to use the browser's default language. Rather, you want to use the same language that the rest of your site is offered in. Suppose your site has a language switcher that stores the user's choice somewhere — you could directly use that.

```
// Suppose this can be changed by some site-wide control
const userSettings = {
  locale: "en-US",
  colorMode: "dark",
};
const numberFormatter = new Intl.NumberFormat(userSettings.locale);
console.log(numberFormatter.format(1234567.89));
```

If your site has a backend that dynamically selects the language based on the user's `Accept-Language` header and sends back different HTML based on that, you could also use the HTML element's `HTMLElement.lang` property: `new Intl.NumberFormat(document.documentElement.lang)`.

If your site is only offered in one language, you could also hardcode the locale in your code: `new Intl.NumberFormat("en-US")`.

As previously mentioned, you can also pass an array of locales to the constructor, representing a list of fallback choices. The first example using `navigator.languages` is an example of this: if the first user-configured locale is not supported for the particular operation, the next one is tried, and so on, until we find a requested locale for which the runtime has data. You can do this manually as well. In the example below, we specify a list of locales in decreasing order of specificity which all represent languages likely to be understood by a Hong Kong Chinese speaker, so the formatter picks the most specific one that it supports.

```
const numberFormatter = new Intl.NumberFormat([
  "yue-Hant",
  "zh-Hant-HK",
  "zh-Hant",
  "zh",
]);
```

There is no API for listing all supported locales, but there are a few methods for handling the locale list:

- `Intl.getCanonicalLocales()`: This function takes a list of locale identifiers and returns a list of canonicalized locale identifiers. This is useful for understanding the canonicalization process for each `Intl` constructor.
- The `supportedLocalesOf()` static method on each `Intl` object (like `Intl.DateTimeFormat.supportedLocalesOf()`): This method takes the same arguments as the constructor (`locales` and `options`) and returns a subset of the given locale tags that match the given data. This is useful for understanding which locales are supported by the runtime for a particular operation, for example, to show a language switcher containing only the supported languages.

Understanding the return value

The second shared concern for all objects is "what does the method return?" This is a hard question to answer beyond the structure or type of the returned value because there's no normative specification saying what *exactly* should be returned. Most of the time, the result of a method is consistent. However, the output may vary between implementations, even within the same locale — output variations are by design and allowed by the specification. It may also not be what you expect. For example, the string returned by `format()` may use non-breaking spaces or be surrounded by bidirectional control characters. You should not compare the results of any `Intl` method to hardcoded constants; they should only be displayed to users.

Of course, this answer seems unsatisfactory, because most developers do wish to control what the output looks like—at least, you don't want your user to be confused by nonsensical output. Here are some guidelines if you do want to conduct testing, whether automated or manual:

- Test all locales that your user may use. This is easier if you have a fixed set of supported locales (for example via a language switcher). If you are using whatever the user prefers, you may pick a few common ones for your users, but bear in mind that what the user sees could vary. You can usually mock user preference via the test runner's configuration or mocking the `Intl` constructors.
- Test on multiple JavaScript engines. The `Intl` API is directly implemented by the JavaScript engine, so for example you should expect Node.js and Chrome (which both use V8) to have the same output, while Firefox (which uses SpiderMonkey) may have a different output. Although all engines likely use the CLDR data, they usually postprocess it in different ways. Some browser build settings (for reducing the install size, for example) may also affect what locales and options are supported.
- Don't assume the output. This means you shouldn't write the output by hand, such as `expect(result).toBe("foo")`. Instead, use snapshot testing or copy the string value from the output of a test run.

Formatting data

A major use case of `Intl` is to output locale-specific texts representing structured data. This is similar to translation software, but instead of letting you translate arbitrary text, it takes data such as dates, numbers, and lists, and formats them according to locale-specific rules.

The `Intl.DateTimeFormat`, `Intl.DurationFormat`, `Intl.ListFormat`, `Intl.NumberFormat`, and `Intl.RelativeTimeFormat` objects each format one kind of data. Each instance provides two methods:

- `format()`: Takes a piece of data and returns a string using the formatting rule as determined by the locale and options.
- `formatToParts()`: Takes the same data and returns the same string, but broken down into parts, each part being an object with a `type` and a `value`. This is useful for more advanced use cases, such as interleaving the formatted text with other texts.

For example, here's a typical use of the `Intl.NumberFormat` object:

```
// 1. Construct a formatter object, specifying the locale and formatting options:
const price = new Intl.NumberFormat("en-US", {
  style: "currency",
  currency: "USD",
});

// 2. Use the `format` method of the formatter object to format a number:
console.log(price.format(5.259)); // $5.26

// Or, use the `formatToParts` method to get the formatted number
// broken down into parts:
console.table(price.formatToParts(5.259));
// |   | type       | value |
// | 0 | "currency" | "$"   |
// | 1 | "integer"  | "5"   |
// | 2 | "decimal"  | "."   |
// | 3 | "fraction" | "26"  |
```

You don't always have to construct a formatter object in order to format strings. For casual use, you can also directly call the `toLocaleString()` method on the data, passing the locale and options as arguments. The `toLocaleString()` method is implemented by `Temporal.PlainDate.prototype.toLocaleString()`, `Temporal.Duration.prototype.toLocaleString()`, `Number.prototype.toLocaleString()`, and so on. Read the documentation for the data you are formatting to see if it supports `toLocaleString()`, and what formatter options it corresponds to.

```
console.log(
  (5.259).toLocaleString("en-US", {
    style: "currency",
    currency: "USD",
  }),
); // $5.26
```

Note that `toLocaleString()` is potentially less efficient than using a formatter object, because every time `toLocaleString` is called, it has to perform a search in a big database of localization strings. When the method is called many times with the same arguments, it is better to create a formatter object and use its `format()` method, because a formatter object remembers the arguments passed to it and may decide to cache a slice of the database, so future `format` calls can search for localization strings within a more constrained context.

Date and time formatting

`Intl.DateTimeFormat` formats dates and times, as well as ranges of dates and times. The `DateTimeFormat` object takes date/time inputs in one of the following forms: `Date`, `Temporal.PlainDateTime`, `Temporal.PlainTime`, `Temporal.PlainDate`, `Temporal.PlainYearMonth`, or `Temporal.PlainMonthDay`.

> **Note:** You can't pass a `Temporal.ZonedDateTime` object directly, because the time zone is already fixed in the object. You should use `Temporal.ZonedDateTime.prototype.toLocaleString()` or convert it to a `Temporal.PlainDateTime` object first.

Common use cases of localized date and time formatting are as follows:

- Output the same date and time in another calendar system, such as the Islamic, Hebrew, or Chinese calendar.
- Output the same real-world time (instant) but in another time zone.
- Selectively output certain components of the date and time, such as only the year and month, and the specific representation of them (such as "Thursday" or "Thu").
- Output the date according to locale-specific conventions, such as MM/DD/YYYY as in the U.S., DD/MM/YYYY as in the U.K., or YYYY/MM/DD as in Japan.
- Output the time according to locale-specific conventions, such as 12-hour or 24-hour clock.

To decide what the formatted string looks like, you first choose the calendar (which affects the year, month, week, and day calculation) and time zone (which affects the exact time as well as possibly the date). This is done using the aforementioned `calendar` option (or the `-ca-` extension key in the locale identifier), and the `timeZone` option.

- `Date` objects represent a unique instant in the user's time zone and in the ISO 8601 calendar (as reported by methods like `Date.prototype.getHours()` and `Date.prototype.getMonth()`). They are converted to the given `calendar` and `timeZone` by preserving the instant, so the date and time components may change.
- The various `Temporal` objects already have a calendar built-in, so the `calendar` option must be consistent with the calendar of the object—unless the date's calendar is `"iso8601"`, in which case it is converted to the requested `calendar`. These objects don't have a time zone, so they are directly displayed in the given `timeZone` without conversion.

Here we demonstrate how the combination of `calendar` and `timeZone` configurations result in different representations of the same instant.

```
// Assume that the local time zone is UTC
const targetDate = new Date(2022, 0, 1); // 2022-01-01 midnight in the local time zone
const results = [];

for (const calendar of ["gregory", "hebrew"]) {
  for (const timeZone of ["America/New_York", "Asia/Tokyo"]) {
```

```
    const df = new Intl.DateTimeFormat("en-US", {
      calendar,
      timeZone,
      // More on these later
      dateStyle: "full",
      timeStyle: "full",
    });
    results.push({ calendar, timeZone, output: df.format(targetDate) });
  }
}

console.table(results);
```

The output looks like this:

calendar	timeZone	output
'gregory'	'America/New_York'	'Friday, December 31, 2021 at 7:00:00 PM Eastern Standard Time'
'gregory'	'Asia/Tokyo'	'Saturday, January 1, 2022 at 9:00:00 AM Japan Standard Time'
'hebrew'	'America/New_York'	'Friday, 27 Tevet 5782 at 7:00:00 PM Eastern Standard Time'
'hebrew'	'Asia/Tokyo'	'Saturday, 28 Tevet 5782 at 9:00:00 AM Japan Standard Time'

A date/time is comprised of the following components: `weekday`, `era`, `year`, `month`, `day`, `dayPeriod`, `hour`, `minute`, `second`, `fractionalSecondDigits`, and `timeZoneName`. Your next decision is what components to include in the output, and what forms they should take. You have two choices:

- You can manually configure each component, using options with the same name as the component. Only the components you specify will be included in the output, with the specified form.
- You can use the shortcuts `dateStyle` and `timeStyle`, which are predefined sets of components. They expand to a set of component options depending on the locale.

You should pick one of these two methods, because they are mutually exclusive. Using both methods simultaneously will result in an error.

Underlyingly, after requesting a combination of components, the `DateTimeFormat` object looks for a "template" that matches the requested components, so it only needs to fill in the values one by one. Not every combination of components has a predefined template. `DateTimeFormat` has a `formatMatcher` option that decides how to negotiate, by making components longer or shorter than requested, or by omitting or adding components. It gets quite technical, so you should read the `Intl.DateTimeFormat()` reference to better understand how it handles this.

Here, we demonstrate a few common ways to format the components:

```
const df1 = new Intl.DateTimeFormat("en-US", {
  // Include all components (usually)
  dateStyle: "full",
  timeStyle: "full",
});

const df2 = new Intl.DateTimeFormat("en-US", {
  // Display the calendar date
  era: "short",
  year: "numeric",
  month: "long",
  day: "numeric",
});

const df3 = new Intl.DateTimeFormat("en-US", {
  // Display a time like on a digital clock
  hour: "2-digit",
  minute: "2-digit",
  second: "2-digit",
  timeZoneName: "shortOffset",
});

const targetDate = new Date(2022, 0, 1, 12, 34, 56); // 2022-01-01 12:34:56 in the local time zone
console.log(df1.format(targetDate));
// Saturday, January 1, 2022 at 12:34:56 PM Coordinated Universal Time
// January 1, 2022 AD
// 12:34:56 PM GMT
```

There are other customization options. For example, you can use the `hourCycle` option to display the time in 12-hour or 24-hour and show midnight/noon as 12:00 or 0:00. You can also use the `numberingSystem` option to display any numbers in another numbering system.

Apart from `format()`, there's a second important method, `formatRange()`, which formats a range of dates or times. It takes two date-times of the same type, formats each one, joins them with a range separator (like the en-dash), and deduplicates the common parts.

```
const springBreak = {
  start: new Date(2023, 2, 10),
  end: new Date(2023, 2, 26),
};

const df = new Intl.DateTimeFormat("en-US", { dateStyle: "long" });
console.log(df.formatRange(springBreak.start, springBreak.end));
// March 10 – 26, 2023
```

Number formatting

Number formatting is done with the `Intl.NumberFormat` object. The `NumberFormat` object accepts inputs in the form of numbers, strings, or `BigInt` values. Passing a string or `BigInt` instead of a number allows you to format numbers that are too large or too small to be represented precisely as a JavaScript number.

Common use cases of localized number formatting are as follows:

- Output the number in another numbering system (script), such as Chinese, Arabic, or Roman.
- Output the number with locale-specific conventions, such as the decimal symbol ("." in English, but "," in many European cultures), or digit grouping (3 digits in English, but may be 4 or 2 in other cultures, and may use ",", " ", or ".").
- Output the number with exponential notation such as "3.7 million" or "2 thousand".
- Output the number as a currency, applying specific currency symbols and rounding rules. For example, monetary values less than one cent in the U.S. or less than one yen in Japan may not be meaningful to display.
- Output the number as a percentage, applying locale-specific conversion and formatting rules.
- Output the number with units, such as "meters" or "liters", with translated unit names.

To decide what the formatted string looks like, you first choose the numbering system (which affects the characters used for the digits). The purpose of a numbering system is already discussed in locale information. Another option you need to decide is the `style`, which sets the context for what the number represents, and potentially affects other options' default values. It is one of `"decimal"`, `"percent"`, `"currency"`, or `"unit"`. If you want to format currencies, then you also need to provide the `currency` option. If you want to format units, then you also need to provide the `unit` option.

```
const results = [];
for (const options of [
  { style: "decimal" }, // Format the number as a dimensionless decimal
  { style: "percent" }, // Format the number as a percentage; it is multiplied by 100
  { style: "currency", currency: "USD" }, // Format the number as a US dollar amount
  { style: "unit", unit: "meter" }, // Format the number as a length in meters
]) {
  const nf = new Intl.NumberFormat("en-US", options);
  results.push({ style: options.style, output: nf.format(1234567.89) });
}
console.table(results);
```

The output looks like:

style	output
'decimal'	'1,234,567.89'
'percent'	'123,456,789%'
'currency'	'$1,234,567.89'
'unit'	'1,234,567.89 m'

The next group of options all specify what the numeric part should look like. First, you may want to represent extremely large values in a more readable way. You can set the `notation` option to `"scientific"` or `"engineering"`, which both use the `1.23e+6` notation. The difference is that the latter uses multiples of 3 for the exponent, keeping the mantissa (the part before the `e` symbol) between 1 and 1000, while the former can use any integer for the exponent, keeping the mantissa between 1 and 10. You can also set `notation` to `"compact"` to use a more human-readable notation.

```
const results = [];
for (const options of [
  { notation: "scientific" },
  { notation: "engineering" },
  { notation: "compact", compactDisplay: "short" }, // "short" is default
  { notation: "compact", compactDisplay: "long" },
]) {
  const nf = new Intl.NumberFormat("en-US", options);
  results.push({
    notation: options.compactDisplay
      ? `${options.notation}-${options.compactDisplay}`
      : options.notation,
    output: nf.format(12000),
  });
}
console.table(results);
```

The output looks like:

notation	output
'scientific'	'1.2E4'
'engineering'	'12E3'
'compact-short'	'12K'
'compact-long'	'12 thousand'

Then, you may want to round the number (if you specified `notation`, then just the mantissa part), so you don't display a number that's too long. These are the digit options, which include:

- `minimumIntegerDigits`
- `minimumFractionDigits`
- `maximumFractionDigits`

- `minimumSignificantDigits`
- `maximumSignificantDigits`
- `roundingPriority`
- `roundingIncrement`
- `roundingMode`

The exact interaction of these options is quite complex and not worth covering here. You should read the digit options reference for more detail. Nevertheless, the general idea is straightforward: we first find the number of decimal places we want to keep, then we round excess decimal places off, either rounding down or up, depending on the value of the last digit.

```
const results = [];
for (const options of [
  { minimumFractionDigits: 4, maximumFractionDigits: 4 },
  { minimumSignificantDigits: 4, maximumSignificantDigits: 4 },
  { minimumFractionDigits: 0, maximumFractionDigits: 0, roundingMode: "floor" },
  {
    minimumFractionDigits: 0,
    maximumFractionDigits: 0,
    roundingMode: "floor",
    roundingIncrement: 10,
  },
]) {
  const nf = new Intl.NumberFormat("en-US", options);
  results.push({
    options,
    output: nf.format(1234.56789),
  });
}
console.table(results);
```

The output looks like this:

options	output
`{ minimumFractionDigits: 4, maximumFractionDigits: 4 }`	'1,234.5679'
`{ minimumSignificantDigits: 4, maximumSignificantDigits: 4 }`	'1,235'
`{ minimumFractionDigits: 0, maximumFractionDigits: 0, roundingMode: "floor" }`	'1,234'
`{ minimumFractionDigits: 0, maximumFractionDigits: 0, roundingMode: "floor", roundingIncrement: 10 }`	'1,230'

There are other customization options. For example, you can use the `useGrouping` and `signDisplay` options to customize whether and how to show the group separators (like "," in "1,234,567.89") and the sign. However, note that the characters used for the group separator, decimal point, and sign are locale-specific, so you can't customize them directly.

Apart from `format()`, there's a second important method, `formatRange()`, which formats a range of numbers. It takes two number representations, formats each one, joins them with a range separator (like the en-dash), and potentially deduplicates the common parts.

```
const heightRange = {
  min: 1.63,
  max: 1.95,
};

const nf = new Intl.NumberFormat("en-US", { style: "unit", unit: "meter" });
console.log(nf.formatRange(heightRange.min, heightRange.max));
// 1.63–1.95 m
```

List formatting

You may already have written code that does this:

```
const fruits = ["apple", "banana", "cherry"];
console.log(`I like ${fruits.join(", ")}.`);
// I like apple, banana, cherry.
```

This code is not internationalized. In some languages, the list separator is not a comma. In *most* languages (including English), you need a conjunction before the last item. But even just adding an "and" manually doesn't make it correct among all English speakers, because there's the debate of Oxford commas in English: "apple, banana, and cherry" vs. "apple, banana and cherry".

The `Intl.ListFormat` object solves this problem. It takes an array of strings and joins them in a locale-specific way such that the result represents a conjunction (and), disjunction (or), or a list of units.

```
const fruits = ["apple", "banana", "cherry"];
const lf = new Intl.ListFormat("en-US", { style: "long", type: "conjunction" });
console.log(`I like ${lf.format(fruits)}.`);
// I like apple, banana, and cherry.

const lf = new Intl.ListFormat("en-US", { style: "long", type: "disjunction" });
console.log(`I can give you ${lf.format(fruits)}.`);
// I can give you apple, banana, or cherry.
```

Check `Intl.ListFormat()` for more examples and options.

Relative time formatting

`Intl.RelativeTimeFormat` formats a time difference. The `RelativeTimeFormat` object takes relative times in the form of two arguments: a number (with any sign) and a time unit, such as `"day"`, `"hour"`, or `"minute"`.

It does several things at once:

- It localizes and pluralizes the time unit, such as "1 day" vs. "2 days", like in number formatting.
- It chooses the appropriate phrase for past and future times, such as "in 1 day" vs. "1 day ago".
- It may select a special phrase for some time units, such as "1 day ago" vs. "yesterday".

```
const rtf = new Intl.RelativeTimeFormat("en-US", { numeric: "auto" });
console.log(rtf.format(1, "day")); // tomorrow
console.log(rtf.format(2, "day")); // in 2 days
console.log(rtf.format(-1, "hour")); // 1 hour ago
```

Check `Intl.RelativeTimeFormat()` for more examples and options.

Duration formatting

`Intl.DurationFormat` provides duration formatting, such as "3 hours, 4 minutes, 5 seconds". It is not a primitive operation with its own formatter: it uses `Intl.NumberFormat` and `Intl.ListFormat` internally to format each duration component, then joins them with a list separator. The `DurationFormat` object takes durations in the form of a `Temporal.Duration` object, or a plain object with the same properties.

Apart from customizing the numbering system, the duration formatting options decides whether or not to show each component, and how long they should be.

```
console.log(
  new Intl.DurationFormat("en-US", {
    style: "long",
  }).format({ hours: 3, minutes: 4, seconds: 5 }),
);
// 3 hours, 4 minutes, and 5 seconds
```

Check `Intl.DurationFormat()` for more examples and options.

Collation

The `Intl.Collator` object is useful for comparing and sorting strings. It takes two strings and returns a number indicating their relative order, in the same way as the `compareFn` argument of the `Array.prototype.sort` method.

There are many reasons why you should not use JavaScript operators like `===` or `>` to compare user-facing strings:

- Irrelevant orthographic variants: For example, in English, "naïve" and "naive" are just alternative spellings of the same word and should be treated as equal.
- Ignoring case: Often, you want to ignore case when comparing strings. For example, "apple" and "Apple" should be treated as equal.
- Unicode code point order doesn't make sense: Comparison operators like `>` compare by Unicode code point order, which is not the same as the order of characters in a dictionary. For example, "ï" comes after "z" in code point order, but you would want it to be ordered next to "i" in a dictionary.
- Unicode normalization: The same character may have multiple representations in Unicode. For example, "ñ" can be represented as a single character or as "n" followed by a combining tilde. (See `String.prototype.normalize()`.) These should be treated as equal.
- Number comparison: Numbers in strings should be compared as numbers, not as strings. For example, you would want "test-10" to come after "test-2".

There are two distinct use cases for collation: **sorting** and **searching**. Sorting is when you have a list of strings and you want to order them according to some rule. Searching is when you have a list of strings and you want to find a string that matches a query. When searching, you should only pay attention to whether the comparison result is zero (equal) or not, not the sign of the result.

There are many different ways to sort, even within the same locale. For example, there are two different sort orders in German, *phonebook* and *dictionary*. Phonebook sort emphasizes sound — as if "ä", "ö", and so on were expanded to "ae", "oe", and so on before sorting.

```
const names = ["Hochberg", "Hönigswald", "Holzman"];

const germanPhonebook = new Intl.Collator("de-DE-u-co-phonebk");

// as if sorting ["Hochberg", "Hoenigswald", "Holzman"]:
console.log(names.sort(germanPhonebook.compare));
// ['Hochberg', 'Hönigswald', 'Holzman']
```

Some German words conjugate with extra umlauts, so in dictionaries it's sensible to order ignoring umlauts (except when ordering words differing *only* by umlauts: *schon* before *schön*).

```
const germanDictionary = new Intl.Collator("de-DE-u-co-dict");

// as if sorting ["Hochberg", "Honigswald", "Holzman"]:
console.log(names.sort(germanDictionary.compare).join(", "));
// "Hochberg, Holzman, Hönigswald"
```

Plural rules

The `Intl.PluralRules` object is useful for selecting the correct plural form of a word. It doesn't automatically pluralize words for you (for example, you can't pass it "apple" and expect "apples" back), but it tells you which plural form to use based on a number. You may already be doing this:

```
function formatMessage(n) {
  return `You have ${n} ${n === 1 ? "apple" : "apples"}.`;
```

```
}
```

But this is hard to generalize across languages, especially those with many plural forms. You can see `Intl.PluralRules` for a general introduction to plural rules. Here, we just demonstrate a few common use cases.

```
const prCard = new Intl.PluralRules("en-US");
const prOrd = new Intl.PluralRules("en-US", { type: "ordinal" });

const englishOrdinalSuffixes = {
  one: "st",
  two: "nd",
  few: "rd",
  other: "th",
};

const catPlural = {
  one: "cat",
  other: "cats",
};

function formatMessage(n1, n2) {
  return `The ${n1}${englishOrdinalSuffixes[prOrd.select(n1)]} U.S. president had ${n2} ${catPlural[prCard.select(n2)]}.`;
}

console.log(formatMessage(42, 1)); // The 42nd U.S. president had 1 cat.
console.log(formatMessage(45, 0)); // The 45th U.S. president had 0 cats.
```

Segmentation

The `Intl.Segmenter` object is useful for breaking a string into segments. Without `Intl`, you are already able to split a string by UTF-16 code units and Unicode code points:

```
const str = "USCNRUGBFR";
console.log(str.split(""));
// Array(20) ['\uD83C', '\uDDFA', '\uD83C', ...]
console.log([...str]);
// Array(10) ['U', 'S', 'C', 'N', 'R', 'U', 'G', 'B', 'F', 'R']
```

But as you can see, Unicode code points are not the same as what human users perceive as discrete characters. This often happens with emojis, where a single emoji can be represented by multiple code points. When the user interacts with text, a grapheme is the smallest unit of text they can manipulate, such as delete or select. The `Segmenter` object enables grapheme-level segmentation, which is useful for counting characters, measuring text width, and so on. It takes a string and returns an iterable segments object, each element of which has a `segment` property representing the text of the segment.

```
const segmenter = new Intl.Segmenter("en-US", { granularity: "grapheme" });
console.log([...segmenter.segment("USCNRUGBFR")].map((s) => s.segment));
// ['US', 'CN', 'RU', 'GB', 'FR']
```

The segmenter can also do higher-level segmentation, including word-level and sentence-level splitting. These use cases are necessarily language-specific. For example, the following is a very poor implementation of word-counting:

```
const wordCount = (str) => str.split(/\s+/).length;
console.log(wordCount("Hello, world!")); // 2
```

There are several problems with this: not all languages use spaces to separate words, not all spaces are word-separating, and not all words are separated by spaces. To solve this, use `Segmenter` with `granularity: "word"`. The result is the input string, split into segments of words and non-words. If you are counting words, you should filter out the non-words by checking each segment's `isWordLike` property.

```
const segmenter = new Intl.Segmenter("en-US", { granularity: "word" });
const str = "It can even split non-space-separated words";
console.table([...segmenter.segment(str)]);
// ┌─────────────┬───────┬─────────────┐
// │ segment     │ index │ isWordLike  │
// ├─────────────┼───────┼─────────────┤
// │ 'It'        │ 0     │ true        │
// │ ' '         │ 2     │ false       │
// │ 'can'       │ 3     │ true        │
// │ ' '         │ 6     │ false       │
// │ 'even'      │ 7     │ true        │
// │ ' '         │ 11    │ false       │
// │ 'split'     │ 12    │ true        │
// │ ' '         │ 17    │ false       │
// │ 'non'       │ 18    │ true        │
// │ '-'         │ 21    │ false       │
// │ 'space'     │ 22    │ true        │
// │ '-'         │ 27    │ false       │
// │ 'separated' │ 28    │ true        │
// │ ' '         │ 37    │ false       │
// │ 'words'     │ 38    │ true        │
// └─────────────┴───────┴─────────────┘

console.log(
  [...segmenter.segment(str)].filter((s) => s.isWordLike).map((s) => s.segment),
```

```
);
// ['It', 'can', 'even', 'split', 'non', 'space', 'separated', 'words']
```

Word segmentation works for character-based languages too. For example, in Chinese, several characters can represent a single word, but there's no space between them. The segmenter implements the same behavior as the browser's built-in word segmentation, triggered by double-clicking a word.

```
const segmenter = new Intl.Segmenter("zh-Hans", { granularity: "word" });
console.log([...segmenter.segment("我是这篇文档的作者")].map((s) => s.segment));
// ['我是', '这', '篇', '文', '档', '的', '作者']
```

Sentence segmentation is similarly complex. For example, in English, there are many punctuation marks that could mark the end of a sentence (".", "!", "?", and so on).

```
const segmenter = new Intl.Segmenter("en-US", { granularity: "sentence" });
console.log(
  [...segmenter.segment("I ate a sandwich. Then I went to bed.")].map(
    (s) => s.segment,
  ),
);
// ['I ate a sandwich. ', 'Then I went to bed.']
```

Note that the segmenter doesn't remove any characters. It just splits the string into segments, each of which is a sentence. You can then remove the punctuation marks if you want. Also, the current implementation of the segmenter doesn't support sentence segmentation suppressions (preventing sentence breaks after periods like "Mr." or "Approx."), but there's ongoing work to support this.

Display names

After introducing so many options and behaviors, you may wonder how to present them to the user. `Intl` comes with two useful APIs for building user interfaces: `Intl.supportedValuesOf()` and `Intl.DisplayNames`.

The `Intl.supportedValuesOf()` function returns an array of supported values for a given option. For example, you can use it to populate a dropdown list of supported calendars, from which users can select to display dates.

```
const supportedCal = Intl.supportedValuesOf("calendar");
console.log(supportedCal);
// ['buddhist', 'chinese', 'coptic', 'dangi', ...]
```

But often, these identifiers are not user-friendly. For example, you may want to show the calendars in the user's language, or unabbreviate them. The `Intl.DisplayNames` object is useful for this. It's like a formatter, but it's not template-based. Instead, it is a direct mapping from language-agnostic identifiers to localized names. It supports formatting languages, regions, scripts (the three subfields of a BCP 47 language tag), currency, calendar, and date-time fields.

Try the demo below:

```
<select id="lang"></select>
<select id="calendar"></select>
<output id="output"></output>
```

```
const langSelect = document.getElementById("lang");
const calSelect = document.getElementById("calendar");
const fieldset = document.querySelector("fieldset");
const output = document.getElementById("output");

// A few examples
const langs = [
  "en-US",
  "zh-Hans-CN",
  "ja-JP",
  "ar-EG",
  "ru-RU",
  "es-ES",
  "fr-FR",
  "de-DE",
  "hi-IN",
  "pt-BR",
  "bn-BD",
  "he-IL",
];
const calendars = Intl.supportedValuesOf("calendar");

for (const lang of langs) {
  const option = document.createElement("option");
  option.value = lang;
  option.textContent = new Intl.DisplayNames(lang, { type: "language" }).of(
    lang,
  );
  langSelect.appendChild(option);
}

function renderCalSelect() {
  const lang = langSelect.value;
  calSelect.innerHTML = "";
  const dn = new Intl.DisplayNames(lang, { type: "calendar" });
  const preferredCalendars = new Intl.Locale(lang).getCalendars?.() ?? [
    "gregory",
```

```
  ];
  for (const cal of [
    ...preferredCalendars,
    ...calendars.filter((c) => !preferredCalendars.includes(c)),
  ]) {
    const option = document.createElement("option");
    option.value = cal;
    option.textContent = dn.of(cal);
    calSelect.appendChild(option);
  }
}

function renderFieldInputs() {
  const lang = langSelect.value;
  fieldset.querySelectorAll("label").forEach((label) => label.remove());
  const dn = new Intl.DisplayNames(lang, { type: "dateTimeField" });
  for (const field of fields) {
    const label = document.createElement("label");
    label.textContent = dn.of(field);
    const input = document.createElement("input");
    input.type = "checkbox";
    input.value = field;
    label.appendChild(input);
    fieldset.appendChild(label);
  }
}

function renderTime() {
  const lang = langSelect.value;
  const cal = calSelect.value;
  const df = new Intl.DateTimeFormat(lang, {
    calendar: cal,
    dateStyle: "full",
    timeStyle: "full",
  });
  const now = new Date();
  const dn = new Intl.DisplayNames(lang, { type: "dateTimeField" });
  output.innerHTML = "";
  for (const component of df.formatToParts(now)) {
    const text = document.createElement("span");
    text.textContent = component.value;
    if (
      ![
        "era",
        "year",
        "quarter",
        "month",
        "weekOfYear",
        "weekday",
        "day",
        "dayPeriod",
        "hour",
        "minute",
        "second",
        "timeZoneName",
      ].includes(component.type)
    ) {
      output.appendChild(text);
      continue;
    }
    const title = dn.of(component.type);
    const field = document.createElement("ruby");
    field.appendChild(text);
    const rt = document.createElement("rt");
    rt.textContent = title;
    field.appendChild(rt);
    output.appendChild(field);
  }
}

renderCalSelect();
renderTime();
langSelect.addEventListener("change", renderCalSelect);
langSelect.addEventListener("change", renderTime);
calSelect.addEventListener("change", renderTime);
setInterval(renderTime, 500);
```

Introduction

- Previous
- Next

This chapter introduces JavaScript and discusses some of its fundamental concepts.

What you should already know

This guide assumes you have the following basic background:

- A general understanding of the Internet and the World Wide Web (WWW).
- Good working knowledge of HyperText Markup Language (HTML).
- Some programming experience. If you are new to programming, try one of the tutorials linked on the main page about JavaScript.

Where to find JavaScript information

The JavaScript documentation on MDN includes the following:

- Dynamic scripting with JavaScript provides structured JavaScript guides for beginners and introduces basic concepts of programming and the Internet.
- JavaScript Guide (this guide) provides an overview about the JavaScript language and its objects.
- JavaScript Reference provides detailed reference material for JavaScript.

What is JavaScript?

JavaScript is a cross-platform, object-oriented scripting language used to make webpages interactive (e.g., having complex animations, clickable buttons, popup menus, etc.). There are also more advanced server side versions of JavaScript such as Node.js, which allow you to add more functionality to a website than downloading files (such as realtime collaboration between multiple computers). Inside a host environment (for example, a web browser), JavaScript can be connected to the objects of its environment to provide programmatic control over them.

JavaScript contains a standard library of objects, such as `Array`, `Map`, and `Math`, and a core set of language elements such as operators, control structures, and statements. Core JavaScript can be extended for a variety of purposes by supplementing it with additional objects; for example:

- *Client-side JavaScript* extends the core language by supplying objects to control a browser and its *Document Object Model* (DOM). For example, client-side extensions allow an application to place elements on an HTML form and respond to user events such as mouse clicks, form input, and page navigation.
- *Server-side JavaScript* extends the core language by supplying objects relevant to running JavaScript on a server. For example, server-side extensions allow an application to communicate with a database, provide continuity of information from one invocation to another of the application, or perform file manipulations on a server.

This means that in the browser, JavaScript can change the way the webpage (DOM) looks. And, likewise, Node.js JavaScript on the server can respond to custom requests sent by code executed in the browser.

JavaScript and Java

JavaScript and Java are similar in some ways but fundamentally different in some others. The JavaScript language resembles Java but does not have Java's static typing and strong type checking. JavaScript follows most Java expression syntax, naming conventions and basic control-flow constructs which was the reason why it was renamed from LiveScript to JavaScript.

In contrast to Java's compile-time system of classes built by declarations, JavaScript supports a runtime system based on a small number of data types representing numeric, Boolean, and string values. JavaScript has a prototype-based object model instead of the more common class-based object model. The prototype-based model provides dynamic inheritance; that is, what is inherited can vary for individual objects. JavaScript also supports functions without any special declarative requirements. Functions can be properties of objects, executing as loosely typed methods.

JavaScript is a very free-form language compared to Java. You do not have to declare all variables, classes, and methods. You do not have to be concerned with whether methods are public, private, or protected, and you do not have to implement interfaces. Variables, parameters, and function return types are not explicitly typed.

Java is a class-based programming language designed for fast execution and type safety. Type safety means, for instance, that you can't cast a Java integer into an object reference or access private memory by corrupting the Java bytecode. Java's class-based model means that programs consist exclusively of classes and their methods. Java's class inheritance and strong typing generally require tightly coupled object hierarchies. These requirements make Java programming more complex than JavaScript programming.

In contrast, JavaScript descends in spirit from a line of smaller, dynamically typed languages such as HyperTalk and dBase. These scripting languages offer programming tools to a much wider audience because of their easier syntax, specialized built-in functionality, and minimal requirements for object creation.

JavaScript	Java
Object-oriented. No distinction between types of objects. Inheritance is through the prototype mechanism, and properties and methods can be added to any object dynamically.	Class-based. Objects are divided into classes and instances with all inheritance through the class hierarchy. Classes and instances cannot have properties or methods added dynamically.
Variable data types are not declared (dynamic typing, loosely typed).	Variable data types must be declared (static typing, strongly typed).
Cannot automatically write to hard disk.	Can automatically write to hard disk.

JavaScript and the ECMAScript specification

JavaScript is standardized at Ecma International — the European association for standardizing information and communication systems (ECMA was formerly an acronym for the European Computer Manufacturers Association) to deliver a standardized, international programming language based on JavaScript. This standardized version of JavaScript, called ECMAScript, behaves the same way in all applications that support the standard. Companies can use the open standard language to develop their implementation of JavaScript. The ECMAScript standard is documented in the ECMA-262 specification.

The ECMA-262 standard is also approved by the ISO (International Organization for Standardization) as ISO-16262. You can also find the specification on the Ecma International website. The ECMAScript specification does not describe the Document Object Model (DOM), which is standardized by the World Wide Web Consortium (W3C) and/or WHATWG (Web Hypertext Application Technology Working Group). The DOM defines the way in which HTML document objects are exposed to your script. To get a better idea about the different technologies that are used when programming with JavaScript, consult the article JavaScript technologies overview.

JavaScript documentation versus the ECMAScript specification

The ECMAScript specification is a set of requirements for implementing ECMAScript. It is useful if you want to implement standards-compliant language features in your ECMAScript implementation or engine (such as SpiderMonkey in Firefox, or V8 in Chrome).

The ECMAScript document is *not* intended to help script programmers. Use the JavaScript documentation for information when writing scripts.

The ECMAScript specification uses terminology and syntax that may be unfamiliar to a JavaScript programmer. Although the description of the language may differ in ECMAScript, the language itself remains the same. JavaScript supports all functionality outlined in the ECMAScript specification.

The JavaScript documentation describes aspects of the language that are appropriate for a JavaScript programmer.

Getting started with JavaScript

To get started with JavaScript, all you need is a modern web browser. Recent versions of Firefox, Chrome, Microsoft Edge, and Safari all support the features discussed in this guide.

A very useful tool for exploring JavaScript is the JavaScript Console (sometimes called the Web Console, or just the console): this is a tool which enables you to enter JavaScript and run it in the current page.

The screenshots here show the Firefox Web Console, but all modern browsers ship with a console that works in a similar way.

Opening the console

The exact instructions for opening the console vary from one browser to another:

- Opening the console in Firefox
- Opening the console in Chrome
- Opening the console in Microsoft Edge

Entering and running JavaScript

The console appears at the bottom of the browser window. Along the bottom of the console is an input line that you can use to enter JavaScript, and the output appears in the panel above:

The console works the exact same way as `eval`: the last expression entered is returned. For the sake of simplicity, it can be imagined that every time something is entered into the console, it is actually surrounded by `console.log` around `eval`, like so:

```
console.log(eval("3 + 5"));
```

Multi-line input in the console

By default, if you press `Enter` (or `Return`, depending on your keyboard) after entering a line of code, then the string you typed is executed. To enter multi-line input:

- If the string you typed was incomplete (for example, you typed `function foo() {`) then the console will treat `Enter` as a line break, and let you type another line.
- If you hold down `Shift` while pressing `Enter`, then the console will treat this as a line break, and let you type another line.
- In Firefox only, you can activate multi-line input mode, in which you can enter multiple lines in a mini-editor, then run the whole thing when you are ready.

To get started with writing JavaScript, open the console, copy the following code, and paste it in at the prompt:

```
(function () {
  "use strict";
  /* Start of your code */
  function greetMe(yourName) {
    alert(`Hello ${yourName}`);
  }

  greetMe("World");
  /* End of your code */
})();
```

Press `Enter` to watch it unfold in your browser!

What's next

In the following pages, this guide introduces you to the JavaScript syntax and language features, so that you will be able to write more complex applications.

But for now, remember to always include the `(function(){"use strict";` before your code, and add `})();` to the end of your code. The strict mode and IIFE articles explain what those do, but for now they can be thought of as doing the following:

1. Prevent semantics in JavaScript that trip up beginners.
2. Prevent code snippets executed in the console from interacting with one another (e.g., having something created in one console execution being used for a different console execution).

Iterators and generators

- Previous

- Next

Iterators and Generators bring the concept of iteration directly into the core language and provide a mechanism for customizing the behavior of `for...of` loops.

For details, see also:

- Iteration protocols
- `for...of`
- `function*` and `Generator`
- `yield` and `yield*`

Iterators

In JavaScript an **iterator** is an object which defines a sequence and potentially a return value upon its termination.

Specifically, an iterator is any object which implements the Iterator protocol by having a `next()` method that returns an object with two properties:

`value`

The next value in the iteration sequence.

`done`

This is `true` if the last value in the sequence has already been consumed. If `value` is present alongside `done`, it is the iterator's return value.

Once created, an iterator object can be iterated explicitly by repeatedly calling `next()`. Iterating over an iterator is said to consume the iterator, because it is generally only possible to do once. After a terminating value has been yielded additional calls to `next()` should continue to return `{done: true}`.

The most common iterator in JavaScript is the Array iterator, which returns each value in the associated array in sequence.

While it is easy to imagine that all iterators could be expressed as arrays, this is not true. Arrays must be allocated in their entirety, but iterators are consumed only as necessary. Because of this, iterators can express sequences of unlimited size, such as the range of integers between `0` and `Infinity`.

Here is an example which can do just that. It allows creation of a range iterator which defines a sequence of integers from `start` (inclusive) to `end` (exclusive) spaced `step` apart. Its final return value is the size of the sequence it created, tracked by the variable `iterationCount`.

```
function makeRangeIterator(start = 0, end = Infinity, step = 1) {
  let nextIndex = start;
  let iterationCount = 0;

  const rangeIterator = {
    next() {
      let result;
      if (nextIndex < end) {
        result = { value: nextIndex, done: false };
        nextIndex += step;
        iterationCount++;
        return result;
      }
      return { value: iterationCount, done: true };
    },
  };
  return rangeIterator;
}
```

Using the iterator then looks like this:

```
const iter = makeRangeIterator(1, 10, 2);

let result = iter.next();
while (!result.done) {
  console.log(result.value); // 1 3 5 7 9
  result = iter.next();
}

console.log("Iterated over sequence of size:", result.value); // [5 numbers returned, that took interval in between: 0 to 10]
```

> **Note:** It is not possible to know reflectively whether a particular object is an iterator. If you need to do this, use Iterables.

Generator functions

While custom iterators are a useful tool, their creation requires careful programming due to the need to explicitly maintain their internal state. **Generator functions** provide a powerful alternative: they allow you to define an iterative algorithm by writing a single function whose execution is not continuous. Generator functions are written using the `function*` syntax.

When called, generator functions do not initially execute their code. Instead, they return a special type of iterator, called a **Generator**. When a value is consumed by calling the generator's `next` method, the Generator function executes until it encounters the `yield` keyword.

The function can be called as many times as desired, and returns a new Generator each time. Each Generator may only be iterated once.

We can now adapt the example from above. The behavior of this code is identical, but the implementation is much easier to write and read.

```
function* makeRangeIterator(start = 0, end = Infinity, step = 1) {
  let iterationCount = 0;
  for (let i = start; i < end; i += step) {
    iterationCount++;
    yield i;
  }
  return iterationCount;
}
```

Iterables

An object is **iterable** if it defines its iteration behavior, such as what values are looped over in a `for...of` construct. Some built-in types, such as `Array` or `Map`, have a default iteration behavior, while other types (such as `Object`) do not.

In order to be **iterable**, an object must implement the `[Symbol.iterator]()` method. This means that the object (or one of the objects up its prototype chain) must have a property with a `Symbol.iterator` key.

It may be possible to iterate over an iterable more than once, or only once. It is up to the programmer to know which is the case.

Iterables which can iterate only once (such as Generators) customarily return `this` from their `[Symbol.iterator]()` method, whereas iterables which can be iterated many times must return a new iterator on each invocation of `[Symbol.iterator]()`.

```
function* makeIterator() {
  yield 1;
  yield 2;
}

const iter = makeIterator();

for (const itItem of iter) {
  console.log(itItem);
}

console.log(iter[Symbol.iterator]() === iter); // true

// This example shows us generator(iterator) is an iterable object,
// which has the [Symbol.iterator]() method return the `iter` (itself),
// and consequently, the `iter` object can iterate only _once_.

// If we change the [Symbol.iterator]() method of `iter` to a function/generator
// which returns a new iterator/generator object, `iter`
// can iterate many times

iter[Symbol.iterator] = function* () {
  yield 2;
  yield 1;
};
```

User-defined iterables

You can make your own iterables like this:

```
const myIterable = {
  *[Symbol.iterator]() {
    yield 1;
    yield 2;
    yield 3;
  },
};
```

User-defined iterables can be used in `for...of` loops or the spread syntax as usual.

```
for (const value of myIterable) {
  console.log(value);
}
// 1
// 2
// 3

[...myIterable]; // [1, 2, 3]
```

Built-in iterables

`String`, `Array`, `TypedArray`, `Map` and `Set` are all built-in iterables, because their prototype objects all have a `Symbol.iterator` method.

Syntaxes expecting iterables

Some statements and expressions expect iterables. For example: the `for...of` loops, spread syntax, `yield*`, and destructuring syntax.

```
for (const value of ["a", "b", "c"]) {
  console.log(value);
}
// "a"
```

```
// "b"
// "c"

[..."abc"];
// ["a", "b", "c"]

function* gen() {
  yield* ["a", "b", "c"];
}

gen().next();
// { value: "a", done: false }

[a, b, c] = new Set(["a", "b", "c"]);
a;
// "a"
```

Advanced generators

Generators compute their `yield`ed values *on demand*, which allows them to efficiently represent sequences that are expensive to compute (or even infinite sequences, as demonstrated above).

The `next()` method also accepts a value, which can be used to modify the internal state of the generator. A value passed to `next()` will be received by `yield`.

> **Note:** A value passed to the *first* invocation of `next()` is always ignored.

Here is the fibonacci generator using `next(x)` to restart the sequence:

```
function* fibonacci() {
  let current = 0;
  let next = 1;
  while (true) {
    const reset = yield current;
    [current, next] = [next, next + current];
    if (reset) {
      current = 0;
      next = 1;
    }
  }
}

const sequence = fibonacci();
console.log(sequence.next().value); // 0
console.log(sequence.next().value); // 1
console.log(sequence.next().value); // 1
console.log(sequence.next().value); // 2
console.log(sequence.next().value); // 3
console.log(sequence.next().value); // 5
console.log(sequence.next().value); // 8
console.log(sequence.next(true).value); // 0
console.log(sequence.next().value); // 1
console.log(sequence.next().value); // 1
console.log(sequence.next().value); // 2
```

You can force a generator to throw an exception by calling its `throw()` method and passing the exception value it should throw. This exception will be thrown from the current suspended context of the generator, as if the `yield` that is currently suspended were instead a `throw value` statement.

If the exception is not caught from within the generator, it will propagate up through the call to `throw()`, and subsequent calls to `next()` will result in the `done` property being `true`.

Generators have a `return()` method that returns the given value and finishes the generator itself.

Keyed collections

- Previous
- Next

This chapter introduces collections of data which are indexed by a key; `Map` and `Set` objects contain elements which are iterable in the order of insertion.

Maps

Map object

A `Map` object is a key/value map that can iterate its elements in insertion order.

The following code shows some basic operations with a `Map`. See also the `Map` reference page for more examples and the complete API. You can use a `for...of` loop to return an array of `[key, value]` for each iteration.

```
const sayings = new Map();
sayings.set("dog", "woof");
sayings.set("cat", "meow");
sayings.set("elephant", "toot");
sayings.size; // 3
sayings.get("dog"); // woof
sayings.get("fox"); // undefined
sayings.has("bird"); // false
sayings.delete("dog");
sayings.has("dog"); // false

for (const [key, value] of sayings) {
  console.log(`${key} goes ${value}`);
}
// "cat goes meow"
// "elephant goes toot"

sayings.clear();
sayings.size; // 0
```

Object and Map compared

Traditionally, objects have been used to map strings to values. Objects allow you to set keys to values, retrieve those values, delete keys, and detect whether something is stored at a key. `Map` objects, however, have a few more advantages that make them better maps.

- The keys of an `Object` are strings or symbols, whereas they can be of any value for a `Map`.
- You can get the `size` of a `Map` easily, while you have to manually keep track of size for an `Object`.
- The iteration of maps is in insertion order of the elements.
- An `Object` has a prototype, so there are default keys in the map. (This can be bypassed using `map = Object.create(null)`.)

These three tips can help you to decide whether to use a `Map` or an `Object`:

- Use maps over objects when keys are unknown until run time, especially if the keys come from external input.
- Maps support keys and values of any type and do not require keys to be serializable to strings or symbols.
- Use objects when the shape is known ahead of time and all keys are expressible as strings.

WeakMap object

A `WeakMap` is a collection of key/value pairs whose keys must be objects or non-registered symbols, with values of any arbitrary JavaScript type, and which does not create strong references to its keys. That is, an object's presence as a key in a `WeakMap` does not prevent the object from being garbage collected. Once an object used as a key has been collected, its corresponding values in any `WeakMap` become candidates for garbage collection as well — as long as they aren't strongly referred to elsewhere. The only primitive type that can be used as a `WeakMap` key is symbol — more specifically, non-registered symbols — because non-registered symbols are guaranteed to be unique and cannot be re-created.

The `WeakMap` API is essentially the same as the `Map` API. However, a `WeakMap` doesn't allow observing the liveness of its keys, which is why it doesn't allow enumeration. So there is no method to obtain a list of the keys in a `WeakMap`. If there were, the list would depend on the state of garbage collection, introducing non-determinism.

For more information and example code, see also "Why WeakMap?" on the `WeakMap` reference page.

One use case of `WeakMap` objects is to store private data for an object, or to hide implementation details. In the following example, the private data and methods belong inside the object and are stored in the `privates` object, which is a `WeakMap`. Everything exposed on the instance and prototype is public; everything else is inaccessible from the outside world because `privates` is not exported from the module.

```
const privates = new WeakMap();

export default function Public() {
  const me = {
    // Private data goes here
  };
  privates.set(this, me);
}

Public.prototype.method = function () {
  const me = privates.get(this);
  // Do stuff with private data in `me`
  // …
};
```

> **Note:** This use case can now be implemented with classes and private fields.

Sets

Set object

`Set` objects are collections of unique values. You can iterate its elements in insertion order. A value in a `Set` may only occur once; it is unique in the `Set`'s collection.

The following code shows some basic operations with a `Set`. See also the `Set` reference page for more examples and the complete API.

```
const mySet = new Set();
mySet.add(1);
mySet.add("some text");
```

```
mySet.add("foo");

mySet.has(1); // true
mySet.delete("foo");
mySet.size; // 2

for (const item of mySet) {
  console.log(item);
}
// 1
// "some text"
```

Converting between Array and Set

You can create an `Array` from a Set using `Array.from` or the spread syntax. Also, the `Set` constructor accepts an `Array` to convert in the other direction.

> **Note:** `Set` objects store *unique values*—so any duplicate elements from an Array are deleted when converting!

```
Array.from(mySet);
[...mySet2];

mySet2 = new Set([1, 2, 3, 4]);
```

Array and Set compared

Traditionally, a set of elements has been stored in arrays in JavaScript in a lot of situations. The `Set` object, however, has some advantages:

- Deleting Array elements by value (`arr.splice(arr.indexOf(val), 1)`) is very slow.
- `Set` objects let you delete elements by their value. With an array, you would have to `splice` based on an element's index.
- The value `NaN` cannot be found with `indexOf` in an array.
- `Set` objects store unique values. You don't have to manually keep track of duplicates.

WeakSet object

`WeakSet` objects are collections of garbage-collectable values, including objects and non-registered symbols. A value in the `WeakSet` may only occur once. It is unique in the `WeakSet`'s collection.

The main differences to the `Set` object are:

- In contrast to `Sets`, `WeakSets` are **collections of *objects or symbols only***, and not of arbitrary values of any type.
- The `WeakSet` is *weak*: References to objects in the collection are held weakly. If there is no other reference to an object stored in the `WeakSet`, they can be garbage collected. That also means that there is no list of current objects stored in the collection.
- `WeakSets` are not enumerable.

The use cases of `WeakSet` objects are limited. They will not leak memory, so it can be safe to use DOM elements as a key and mark them for tracking purposes, for example.

Key and value equality of Map and Set

Both the key equality of `Map` objects and the value equality of `Set` objects are based on the SameValueZero algorithm:

- Equality works like the identity comparison operator `===`.
- `-0` and `+0` are considered equal.
- `NaN` is considered equal to itself (contrary to `===`).

JavaScript language overview

JavaScript is a multi-paradigm, dynamic language with types and operators, standard built-in objects, and methods. Its syntax is based on the Java and C languages — many structures from those languages apply to JavaScript as well. JavaScript supports object-oriented programming with object prototypes and classes. It also supports functional programming since functions are first-class objects that can be easily created via expressions and passed around like any other object.

This page serves as a quick overview of various JavaScript language features, written for readers with background in other languages, such as C or Java.

Data types

Let's start off by looking at the building blocks of any language: the types. JavaScript programs manipulate values, and those values all belong to a type. JavaScript offers seven *primitive types*:

- Number: used for all number values (integer and floating point) except for *very* big integers.
- BigInt: used for arbitrarily large integers.
- String: used to store text.
- Boolean: `true` and `false` — usually used for conditional logic.
- Symbol: used for creating unique identifiers that won't collide.
- Undefined: indicating that a variable has not been assigned a value.
- Null: indicating a deliberate non-value.

Everything else is known as an Object. Common object types include:

- `Function`
- `Array`
- `Map`
- `RegExp`
- `Error`

Functions aren't special data structures in JavaScript — they are just a special type of object that can be called.

Numbers

JavaScript has two built-in numeric types: Number and BigInt.

The Number type is an IEEE 754 64-bit double-precision floating point value, which means integers can be safely represented between $-(2^{53} - 1)$ and $2^{53} - 1$ without loss of precision, and floating point numbers can be stored all the way up to 1.79×10^{308}. Within numbers, JavaScript does not distinguish between floating point numbers and integers.

```
console.log(3 / 2); // 1.5, not 1
```

So an *apparent integer* is in fact *implicitly a float*. Because of IEEE 754 encoding, sometimes floating point arithmetic can be imprecise.

```
console.log(0.1 + 0.2); // 0.30000000000000004
```

For operations that expect integers, such as bitwise operations, the number will be converted to a 32-bit integer.

Number literals can also have prefixes to indicate the base (binary, octal, decimal, or hexadecimal), or an exponent suffix.

```
console.log(0b111110111); // 503
console.log(0o767); // 503
console.log(0x1f7); // 503
console.log(5.03e2); // 503
```

The BigInt type is an arbitrary length integer. Its behavior is similar to C's integer types (e.g., division truncates to zero), except it can grow indefinitely. BigInts are specified with a number literal and an `n` suffix.

```
console.log(-3n / 2n); // -1n
```

The standard arithmetic operators are supported, including addition, subtraction, remainder arithmetic, etc. BigInts and numbers cannot be mixed in arithmetic operations.

The `Math` object provides standard mathematical functions and constants.

```
Math.sin(3.5);
const circumference = 2 * Math.PI * r;
```

There are three ways to convert a string to a number:

- `parseInt()`, which parses the string for an integer.
- `parseFloat()`, which parses the string for a floating-point number.
- The `Number()` function, which parses a string as if it's a number literal and supports many different number representations.

You can also use the unary plus `+` as a shorthand for `Number()`.

Number values also include `NaN` (short for "Not a Number") and `Infinity`. Many "invalid math" operations will return `NaN` — for example, if attempting to parse a non-numeric string, or using `Math.log()` on a negative value. Division by zero produces `Infinity` (positive or negative).

`NaN` is contagious: if you provide it as an operand to any mathematical operation, the result will also be `NaN`. `NaN` is the only value in JavaScript that's not equal to itself (per IEEE 754 specification).

Strings

Strings in JavaScript are sequences of Unicode characters. This should be welcome news to anyone who has had to deal with internationalization. More accurately, they are UTF-16 encoded.

```
console.log("Hello, world");
console.log("你好, 世界! "); // Nearly all Unicode characters can be written literally in string literals
```

Strings can be written with either single or double quotes — JavaScript does not have the distinction between characters and strings. If you want to represent a single character, you just use a string consisting of that single character.

```
console.log("Hello"[1] === "e"); // true
```

To find the length of a string (in code units), access its `length` property.

Strings have utility methods to manipulate the string and access information about the string. Because all primitives are immutable by design, these methods return new strings.

The `+` operator is overloaded for strings: when one of the operands is a string, it performs string concatenation instead of number addition. A special template literal syntax allows you to write strings with embedded expressions more succinctly. Unlike Python's f-strings or C#'s interpolated strings, template literals use backticks (not single or double quotes).

```
const age = 25;
console.log("I am " + age + " years old."); // String concatenation
console.log(`I am ${age} years old.`); // Template literal
```

Other types

JavaScript distinguishes between `null`, which indicates a deliberate non-value (and is only accessible through the `null` keyword), and `undefined`, which indicates absence of value. There are many ways to obtain `undefined`:

- A `return` statement with no value (`return;`) implicitly returns `undefined`.
- Accessing a nonexistent object property (`obj.iDontExist`) returns `undefined`.
- A variable declaration without initialization (`let x;`) will implicitly initialize the variable to `undefined`.

JavaScript has a Boolean type, with possible values `true` and `false` — both of which are keywords. Any value can be converted to a boolean according to the following rules:

1. `false`, `0`, empty strings (`""`), `NaN`, `null`, and `undefined` all become `false`.
2. All other values become `true`.

You can perform this conversion explicitly using the `Boolean()` function:

```
Boolean(""); // false
Boolean(234); // true
```

However, this is rarely necessary, as JavaScript will silently perform this conversion when it expects a boolean, such as in an `if` statement (see Control structures). For this reason, we sometimes speak of "truthy" and "falsy", meaning values that become `true` and `false`, respectively, when used in boolean contexts.

Boolean operations such as `&&` (logical *and*), `||` (logical *or*), and `!` (logical *not*) are supported; see Operators.

The Symbol type is often used to create unique identifiers. Every symbol created with the `Symbol()` function is guaranteed to be unique. In addition, there are registered symbols, which are shared constants, and well-known symbols, which are utilized by the language as "protocols" for certain operations. You can read more about them in the symbol reference.

Variables

Variables in JavaScript are declared using one of three keywords: `let`, `const`, or `var`.

`let` allows you to declare block-level variables. The declared variable is available from the *block* it is enclosed in.

```
let a;
let name = "Simon";

// myLetVariable is *not* visible out here

for (let myLetVariable = 0; myLetVariable < 5; myLetVariable++) {
  // myLetVariable is only visible in here
}

// myLetVariable is *not* visible out here
```

`const` allows you to declare variables whose values are never intended to change. The variable is available from the *block* it is declared in.

```
const Pi = 3.14; // Declare variable Pi
console.log(Pi); // 3.14
```

A variable declared with `const` cannot be reassigned.

```
const Pi = 3.14;
Pi = 1; // will throw an error because you cannot change a constant variable.
```

`const` declarations only prevent *reassignments* — they don't prevent *mutations* of the variable's value, if it's an object.

```
const obj = {};
obj.a = 1; // no error
console.log(obj); // { a: 1 }
```

`var` declarations can have surprising behaviors (for example, they are not block-scoped), and they are discouraged in modern JavaScript code.

If you declare a variable without assigning any value to it, its value is `undefined`. You can't declare a `const` variable without an initializer, because you can't change it later anyway.

`let` and `const` declared variables still occupy the entire scope they are defined in, and are in a region known as the temporal dead zone before the actual line of declaration. This has some interesting interactions with variable shadowing, which don't occur in other languages.

```
function foo(x, condition) {
  if (condition) {
    console.log(x);
    const x = 2;
    console.log(x);
  }
}
```

```
foo(1, true);
```

In most other languages, this would log "1" and "2", because before the `const x = 2` line, `x` should still refer to the parameter `x` in the upper scope. In JavaScript, because each declaration occupies the entire scope, this would throw an error on the first `console.log`: "Cannot access 'x' before initialization". For more information, see the reference page of `let`.

JavaScript is *dynamically typed*. Types (as described in the previous section) are only associated with values, but not with variables. For `let`-declared variables, you can always change its type through reassignment.

```
let a = 1;
a = "foo";
```

Operators

JavaScript's numeric operators include `+`, `-`, `*`, `/`, `%` (remainder), and `**` (exponentiation). Values are assigned using `=`. Each binary operator also has a compound assignment counterpart such as `+=` and `-=`, which extend out to `x = x operator y`.

```
x += 5;
x = x + 5;
```

You can use `++` and `--` to increment and decrement respectively. These can be used as a prefix or postfix operators.

The `+` operator also does string concatenation:

```
"hello" + " world"; // "hello world"
```

If you add a string to a number (or other value) everything is converted into a string first. This might trip you up:

```
"3" + 4 + 5; // "345"
3 + 4 + "5"; // "75"
```

Adding an empty string to something is a useful way of converting it to a string itself.

Comparisons in JavaScript can be made using `<`, `>`, `<=` and `>=`, which work for both strings and numbers. For equality, the double-equals operator performs type coercion if you give it different types, with sometimes interesting results. On the other hand, the triple-equals operator does not attempt type coercion, and is usually preferred.

```
123 == "123"; // true
1 == true; // true

123 === "123"; // false
1 === true; // false
```

The double-equals and triple-equals also have their inequality counterparts: `!=` and `!==`.

JavaScript also has bitwise operators and logical operators. Notably, logical operators don't work with boolean values only — they work by the "truthiness" of the value.

```
const a = 0 && "Hello"; // 0 because 0 is "falsy"
const b = "Hello" || "world"; // "Hello" because both "Hello" and "world" are "truthy"
```

The `&&` and `||` operators use short-circuit logic, which means whether they will execute their second operand is dependent on the first. This is useful for checking for null objects before accessing their attributes:

```
const name = o && o.getName();
```

Or for caching values (when falsy values are invalid):

```
const name = cachedName || (cachedName = getName());
```

For a comprehensive list of operators, see the guide page or reference section. You may be especially interested in the operator precedence.

Grammar

JavaScript grammar is very similar to the C family. There are a few points worth mentioning:

- Identifiers can have Unicode characters, but they cannot be one of the reserved words.
- Comments are commonly `//` or `/* */`, while many other scripting languages like Perl, Python, and Bash use `#`.
- Semicolons are optional in JavaScript — the language automatically inserts them when needed. However, there are certain caveats to watch out for, since unlike Python, semicolons are still part of the syntax.

For an in-depth look at the JavaScript grammar, see the reference page for lexical grammar.

Control structures

JavaScript has a similar set of control structures to other languages in the C family. Conditional statements are supported by `if` and `else`; you can chain them together:

```
let name = "kittens";
if (name === "puppies") {
  name += " woof";
} else if (name === "kittens") {
  name += " meow";
} else {
  name += "!";
}
name === "kittens meow";
```

JavaScript doesn't have `elif`, and `else if` is really just an `else` branch comprised of a single `if` statement.

JavaScript has `while` loops and `do...while` loops. The first is good for basic looping; the second is for loops where you wish to ensure that the body of the loop is executed at least once:

```
while (true) {
  // an infinite loop!
}

let input;
do {
  input = get_input();
} while (inputIsNotValid(input));
```

JavaScript's `for` loop is the same as that in C and Java: it lets you provide the control information for your loop on a single line.

```
for (let i = 0; i < 5; i++) {
  // Will execute 5 times
}
```

JavaScript also contains two other prominent for loops: `for...of`, which iterates over iterables, most notably arrays, and `for...in`, which visits all enumerable properties of an object.

```
for (const value of array) {
  // do something with value
}

for (const property in object) {
  // do something with object property
}
```

The `switch` statement can be used for multiple branches based on equality checking.

```
switch (action) {
  case "draw":
    drawIt();
    break;
  case "eat":
    eatIt();
    break;
  default:
    doNothing();
}
```

Similar to C, case clauses are conceptually the same as labels, so if you don't add a `break` statement, execution will "fall through" to the next level. However, they are not actually jump tables — any expression can be part of the `case` clause, not just string or number literals, and they would be evaluated one-by-one until one equals the value being matched. Comparison takes place between the two using the `===` operator.

Unlike some languages like Rust, control-flow structures are statements in JavaScript, meaning you can't assign them to a variable, like `const a = if (x) { 1 } else { 2 }`.

JavaScript errors are handled using the `try...catch` statement.

```
try {
  buildMySite("./website");
} catch (e) {
  console.error("Building site failed:", e);
}
```

Errors can be thrown using the `throw` statement. Many built-in operations may throw as well.

```
function buildMySite(siteDirectory) {
  if (!pathExists(siteDirectory)) {
    throw new Error("Site directory does not exist");
  }
}
```

In general, you can't tell the type of the error you just caught, because anything can be thrown from a `throw` statement. However, you can usually assume it's an `Error` instance, as is the example above. There are some subclasses of `Error` built-in, like `TypeError` and `RangeError`, that you can use to provide extra semantics about the error. There's no conditional catch in JavaScript — if you only want to handle one type of error, you need to catch everything, identify the type of error using `instanceof`, and then rethrow the other cases.

```
try {
  buildMySite("./website");
} catch (e) {
  if (e instanceof RangeError) {
    console.error("Seems like a parameter is out of range:", e);
    console.log("Retrying...");
    buildMySite("./website");
  } else {
    // Don't know how to handle other error types; throw them so
    // something else up in the call stack may catch and handle it
    throw e;
  }
}
```

If an error is uncaught by any `try...catch` in the call stack, the program will exit.

For a comprehensive list of control flow statements, see the reference section.

Objects

JavaScript objects can be thought of as collections of key-value pairs. As such, they are similar to:

- Dictionaries in Python.
- Hashes in Perl and Ruby.
- Hash tables in C and C++.
- HashMaps in Java.
- Associative arrays in PHP.

JavaScript objects are hashes. Unlike objects in statically typed languages, objects in JavaScript do not have fixed shapes — properties can be added, deleted, re-ordered, mutated, or dynamically queried at any time. Object keys are always strings or symbols — even array indices, which are canonically integers, are actually strings under the hood.

Objects are usually created using the literal syntax:

```
const obj = {
  name: "Carrot",
  for: "Max",
  details: {
    color: "orange",
    size: 12,
  },
};
```

Object properties can be accessed using dot (`.`) or square brackets (`[]`). When using the dot notation, the key must be a valid identifier. Square brackets, on the other hand, allow indexing the object with a dynamic key value.

```
// Dot notation
obj.name = "Simon";
const name = obj.name;

// Bracket notation
obj["name"] = "Simon";
const name = obj["name"];

// Can use a variable to define a key
const userName = prompt("what is your key?");
obj[userName] = prompt("what is its value?");
```

Property access can be chained together:

```
obj.details.color; // orange
obj["details"]["size"]; // 12
```

Objects are always references, so unless something is explicitly copying the object, mutations to an object would be visible to the outside.

```
const obj = {};
function doSomething(o) {
  o.x = 1;
}
doSomething(obj);
console.log(obj.x); // 1
```

This also means two separately created objects will never be equal (`!==`), because they are different references. If you hold two references of the same object, mutating one would be observable through the other.

```
const me = {};
const stillMe = me;
me.x = 1;
console.log(stillMe.x); // 1
```

For more on objects and prototypes, see the `Object` reference page. For more information on the object initializer syntax, see its reference page.

This page has omitted all details about object prototypes and inheritance because you can usually achieve inheritance with classes without touching the underlying mechanism (which you may have heard to be abstruse). To learn about them, see Inheritance and the prototype chain.

Arrays

Arrays in JavaScript are actually a special type of object. They work very much like regular objects (numerical properties can naturally be accessed only using `[]` syntax) but they have one magic property called `length`. This is always one more than the highest index in the array.

Arrays are usually created with array literals:

```
const a = ["dog", "cat", "hen"];
a.length; // 3
```

JavaScript arrays are still objects — you can assign any properties to them, including arbitrary number indices. The only "magic" is that `length` will be automatically updated when you set a particular index.

```
const a = ["dog", "cat", "hen"];
a[100] = "fox";
console.log(a.length); // 101
console.log(a); // ['dog', 'cat', 'hen', empty × 97, 'fox']
```

The array we got above is called a *sparse array* because there are uninhabited slots in the middle, and will cause the engine to deoptimize it from an array to a hash table. Make sure your array is densely populated!

Out-of-bounds indexing doesn't throw. If you query a non-existent array index, you'll get a value of `undefined` in return:

```
const a = ["dog", "cat", "hen"];
console.log(typeof a[90]); // undefined
```

Arrays can have any elements and can grow or shrink arbitrarily.

```
const arr = [1, "foo", true];
arr.push({});
// arr = [1, "foo", true, {}]
```

Arrays can be iterated with the `for` loop, as you can in other C-like languages:

```
for (let i = 0; i < a.length; i++) {
  // Do something with a[i]
}
```

Or, since arrays are iterable, you can use the `for...of` loop, which is synonymous to C++/Java's `for (int x : arr)` syntax:

```
for (const currentValue of a) {
  // Do something with currentValue
}
```

Arrays come with a plethora of array methods. Many of them would iterate the array — for example, `map()` would apply a callback to every array element, and return a new array:

```
const babies = ["dog", "cat", "hen"].map((name) => `baby ${name}`);
// babies = ['baby dog', 'baby cat', 'baby hen']
```

Functions

Along with objects, functions are the core component in understanding JavaScript. The most basic function declaration looks like this:

```
function add(x, y) {
  const total = x + y;
  return total;
}
```

A JavaScript function can take 0 or more parameters. The function body can contain as many statements as you like and can declare its own variables which are local to that function. The `return` statement can be used to return a value at any time, terminating the function. If no return statement is used (or an empty return with no value), JavaScript returns `undefined`.

Functions can be called with more or fewer parameters than it specifies. If you call a function without passing the parameters it expects, they will be set to `undefined`. If you pass more parameters than it expects, the function will ignore the extra parameters.

```
add(); // NaN
// Equivalent to add(undefined, undefined)

add(2, 3, 4); // 5
// added the first two; 4 was ignored
```

There are a number of other parameter syntaxes available. For example, the rest parameter syntax allows collecting all the extra parameters passed by the caller into an array, similar to Python's `*args`. (Since JS doesn't have named parameters on the language level, there's no `**kwargs`.)

```
function avg(...args) {
  let sum = 0;
  for (const item of args) {
    sum += item;
  }
  return sum / args.length;
}

avg(2, 3, 4, 5); // 3.5
```

In the above code, the variable `args` holds all the values that were passed into the function.

The rest parameter will store all arguments *after* where it's declared, but not before. In other words, `function avg(firstValue, ...args)` will store the first value passed into the function in the `firstValue` variable and the remaining arguments in `args`.

If a function accepts a list of arguments and you already hold them in an array, you can use the spread syntax in the function call to *spread* the array as a list of elements. For instance: `avg(...numbers)`.

We mentioned that JavaScript doesn't have named parameters. It's possible, though, to implement them using object destructuring, which allows objects to be conveniently packed and unpacked.

```
// Note the { } braces: this is destructuring an object
function area({ width, height }) {
  return width * height;
}

// The { } braces here create a new object
console.log(area({ width: 2, height: 3 }));
```

There's also the *default parameter* syntax, which allows omitted parameters (or those passed as `undefined`) to have a default value.

```
function avg(firstValue, secondValue, thirdValue = 0) {
  return (firstValue + secondValue + thirdValue) / 3;
}

avg(1, 2); // 1, instead of NaN
```

Anonymous functions

JavaScript lets you create anonymous functions — that is, functions without names. In practice, anonymous functions are typically used as arguments to other functions, immediately assigned to a variable that can be used to invoke the function, or returned from another function.

```
// Note that there's no function name before the parentheses
const avg = function (...args) {
  let sum = 0;
  for (const item of args) {
    sum += item;
  }
  return sum / args.length;
};
```

That makes the anonymous function invocable by calling `avg()` with some arguments — that is, it's semantically equivalent to declaring the function using the `function avg() {}` declaration syntax.

There's another way to define anonymous functions — using an arrow function expression.

```
// Note that there's no function name before the parentheses
const avg = (...args) => {
  let sum = 0;
  for (const item of args) {
    sum += item;
  }
  return sum / args.length;
};

// You can omit the `return` when simply returning an expression
const sum = (a, b, c) => a + b + c;
```

Arrow functions are not semantically equivalent to function expressions — for more information, see its reference page.

There's another way that anonymous functions can be useful: it can be simultaneously declared and invoked in a single expression, called an Immediately invoked function expression (IIFE):

```
(function () {
  // …
})();
```

For use-cases of IIFEs, you can read emulating private methods with closures.

Recursive functions

JavaScript allows you to call functions recursively. This is particularly useful for dealing with tree structures, such as those found in the browser DOM.

```
function countChars(elm) {
  if (elm.nodeType === 3) {
    // TEXT_NODE
    return elm.nodeValue.length;
  }
  let count = 0;
  for (let i = 0, child; (child = elm.childNodes[i]); i++) {
    count += countChars(child);
  }
  return count;
}
```

Function expressions can be named as well, which allows them to be recursive.

```
const charsInBody = (function counter(elm) {
  if (elm.nodeType === 3) {
    // TEXT_NODE
    return elm.nodeValue.length;
  }
  let count = 0;
  for (let i = 0, child; (child = elm.childNodes[i]); i++) {
    count += counter(child);
  }
  return count;
})(document.body);
```

The name provided to a function expression as above is only available to the function's own scope. This allows more optimizations to be done by the engine and results in more readable code. The name also shows up in the debugger and some stack traces, which can save you time when debugging.

If you are used to functional programming, beware of the performance implications of recursion in JavaScript. Although the language specification specifies tail-call optimization, only JavaScriptCore (used by Safari) has implemented it, due to the difficulty of recovering stack traces and debuggability. For deep recursion, consider using iteration instead to avoid stack overflow.

Functions are first-class objects

JavaScript functions are first-class objects. This means that they can be assigned to variables, passed as arguments to other functions, and returned from other functions. In addition, JavaScript supports closures out-of-the-box without explicit capturing, allowing you to conveniently apply functional programming styles.

```
// Function returning function
const add = (x) => (y) => x + y;
// Function accepting function
const babies = ["dog", "cat", "hen"].map((name) => `baby ${name}`);
```

Note that JavaScript functions are themselves objects — like everything else in JavaScript — and you can add or change properties on them just like we've seen earlier in the Objects section.

Inner functions

JavaScript function declarations are allowed inside other functions. An important detail of nested functions in JavaScript is that they can access variables in their parent function's scope:

```
function parentFunc() {
  const a = 1;

  function nestedFunc() {
    const b = 4; // parentFunc can't use this
    return a + b;
  }
  return nestedFunc(); // 5
}
```

This provides a great deal of utility in writing more maintainable code. If a called function relies on one or two other functions that are not useful to any other part of your code, you can nest those utility functions inside it. This keeps the number of functions that are in the global scope down.

This is also a great counter to the lure of global variables. When writing complex code, it is often tempting to use global variables to share values between multiple functions, which leads to code that is hard to maintain. Nested functions can share variables in their parent, so you can use that mechanism to couple functions together without polluting your global namespace.

Classes

JavaScript offers the class syntax that's very similar to languages like Java.

```
class Person {
  constructor(name) {
    this.name = name;
  }
  sayHello() {
    return `Hello, I'm ${this.name}!`;
  }
}
```

```
const p = new Person("Maria");
console.log(p.sayHello());
```

JavaScript classes are just functions that must be instantiated with the `new` operator. Every time a class is instantiated, it returns an object containing the methods and properties that the class specified. Classes don't enforce any code organization — for example, you can have functions returning classes, or you can have multiple classes per file. Here's an example of how ad hoc the creation of a class can be: it's just an expression returned from an arrow function. This pattern is called a mixin.

```
const withAuthentication = (cls) =>
  class extends cls {
    authenticate() {
      // …
    }
  };

class Admin extends withAuthentication(Person) {
  // …
}
```

Static properties are created by prepending `static`. Private fields and methods are created by prepending a hash `#` (not `private`). The hash is an integral part of the element's name, and distinguishes it from a regular string-keyed property. (Think about `#` as _ in Python.) Unlike most other languages, there's absolutely no way to read a private element outside the class body — not even in derived classes.

For a detailed guide on various class features, you can read the guide page.

Asynchronous programming

JavaScript is single-threaded by nature. There's no paralleling; only concurrency. Asynchronous programming is powered by an event loop, which allows a set of tasks to be queued and polled for completion.

There are three idiomatic ways to write asynchronous code in JavaScript:

- Callback-based (such as `setTimeout()`)
- `Promise`-based
- `async`/`await`, which is a syntactic sugar for Promises

For example, here's what a file-read operation might look like in JavaScript:

```
// Callback-based
fs.readFile(filename, (err, content) => {
  // This callback is invoked when the file is read, which could be after a while
  if (err) {
    throw err;
  }
  console.log(content);
});
// Code here will be executed while the file is waiting to be read

// Promise-based
fs.readFile(filename)
  .then((content) => {
    // What to do when the file is read
    console.log(content);
  })
  .catch((err) => {
    throw err;
  });
// Code here will be executed while the file is waiting to be read

// Async/await
async function readFile(filename) {
  const content = await fs.readFile(filename);
  console.log(content);
}
```

The core language doesn't specify any asynchronous programming features, but it's crucial when interacting with the external environment — from asking user permissions, to fetching data, to reading files. Keeping the potentially long-running operations async ensures that other processes can still run while this one waits — for example, the browser will not freeze while waiting for the user to click a button to grant permission.

If you have an async value, it's not possible to get its value synchronously. For example, if you have a promise, you can only access the eventual result via the `then()` method. Similarly, `await` can only be used in an async context, which is usually an async function or a module. Promises are *never blocking* — only the logic depending on the promise's result will be deferred; everything else continues to execute in the meantime. If you are a functional programmer, you may recognize promises as monads which can be mapped with `then()` (however, they are not *proper* monads because they auto-flatten; i.e., you can't have a `Promise<Promise<T>>`).

In fact, the single-threaded model has made Node.js a popular choice for server-side programming due to its non-blocking IO, making handling a large number of database or file-system requests very performant. However, CPU-bound (computationally intensive) tasks that are pure JavaScript will still block the main thread. To achieve real paralleling, you may need to use workers.

To learn more about asynchronous programming, you can read about using promises or follow the asynchronous JavaScript tutorial.

Modules

JavaScript also specifies a module system supported by most runtimes. A module is usually a file, identified by its file path or URL. You can use the `import` and `export` statements to exchange data between modules:

```
import { foo } from "./foo.js";

// Unexported variables are local to the module
const b = 2;

export const a = 1;
```

Unlike Haskell, Python, Java, etc., JavaScript module resolution is entirely host-defined — it's usually based on URLs or file paths, so relative file paths "just work" and are relative to the current module's path instead of some project root path.

However, the JavaScript language doesn't offer standard library modules — all core functionalities are powered by global variables like `Math` and `Intl` instead. This is due to the long history of JavaScript lacking a module system, and the fact that opting into the module system involves some changes to the runtime setup.

Different runtimes may use different module systems. For example, Node.js uses the package manager npm and is mostly file-system based, while Deno and browsers are fully URL-based and modules can be resolved from HTTP URLs.

For more information, see the modules guide page.

Language and runtime

Throughout this page, we've constantly mentioned that certain features are *language-level* while others are *runtime-level*.

JavaScript is a general-purpose scripting language. The core language specification focuses on pure computational logic. It doesn't deal with any input/output — in fact, without extra runtime-level APIs (most notably `console.log()`), a JavaScript program's behavior is entirely unobservable.

A runtime, or a host, is something that feeds data to the JavaScript engine (the interpreter), provides extra global properties, and provides hooks for the engine to interact with the outside world. Module resolution, reading data, printing messages, sending network requests, etc. are all runtime-level operations. Since its inception, JavaScript has been adopted in various environments, such as browsers (which provide APIs like DOM), Node.js (which provides APIs like file system access), etc. JavaScript has been successfully integrated in web (which was its primary purpose), mobile apps, desktop apps, server-side apps, serverless, embedded systems, and more. While you learn about JavaScript core features, it's also important to understand host-provided features in order to put the knowledge to use. For example, you can read about all web platform APIs, which are implemented by browsers, and sometimes non-browsers.

Further exploration

This page offers a very basic insight into how various JavaScript features compare with other languages. If you want to learn more about the language itself and the nuances of each feature, you can read the JavaScript guide and the JavaScript reference.

There are some essential parts of the language that we have omitted due to space and complexity, but you can explore on your own:

- Inheritance and the prototype chain
- Closures
- Regular expressions
- Iteration

Loops and iteration

- Previous
- Next

Loops offer a quick and easy way to do something repeatedly. This chapter of the JavaScript Guide introduces the different iteration statements available to JavaScript.

You can think of a loop as a computerized version of the game where you tell someone to take *X* steps in one direction, then *Y* steps in another. For example, the idea "Go five steps to the east" could be expressed this way as a loop:

```
for (let step = 0; step < 5; step++) {
  // Runs 5 times, with values of step 0 through 4.
  console.log("Walking east one step");
}
```

There are many different kinds of loops, but they all essentially do the same thing: they repeat an action some number of times. (Note that it's possible that number could be zero!)

The various loop mechanisms offer different ways to determine the start and end points of the loop. There are various situations that are more easily served by one type of loop over the others.

The statements for loops provided in JavaScript are:

- for statement
- do...while statement
- while statement
- labeled statement
- break statement
- continue statement
- for...in statement
- for...of statement

for statement

A `for` loop repeats until a specified condition evaluates to false. The JavaScript `for` loop is similar to the Java and C `for` loop.

A `for` statement looks as follows:

```
for (initialization; condition; afterthought)
  statement
```

When a `for` loop executes, the following occurs:

1. The initializing expression `initialization`, if any, is executed. This expression usually initializes one or more loop counters, but the syntax allows an expression of any degree of complexity. This expression can also declare variables.
2. The `condition` expression is evaluated. If the value of `condition` is true, the loop statements execute. Otherwise, the `for` loop terminates. (If the `condition` expression is omitted entirely, the condition is assumed to be true.)
3. The `statement` executes. To execute multiple statements, use a block statement (`{ }`) to group those statements.
4. If present, the update expression `afterthought` is executed.
5. Control returns to Step 2.

Example

In the example below, the function contains a `for` statement that counts the number of selected options in a scrolling list (a `<select>` element that allows multiple selections).

HTML

```
<form name="selectForm">
  <label for="musicTypes"
    >Choose some music types, then click the button below:</label
  >
  <select id="musicTypes" name="musicTypes" multiple>
    <option selected>R&amp;B</option>
    <option>Jazz</option>
    <option>Blues</option>
    <option>New Age</option>
    <option>Classical</option>
    <option>Opera</option>
  </select>
  <button id="btn" type="button">How many are selected?</button>
</form>
```

JavaScript

Here, the `for` statement declares the variable `i` and initializes it to `0`. It checks that `i` is less than the number of options in the `<select>` element, performs the succeeding `if` statement, and increments `i` by 1 after each pass through the loop.

```
function countSelected(selectObject) {
  let numberSelected = 0;
  for (let i = 0; i < selectObject.options.length; i++) {
    if (selectObject.options[i].selected) {
      numberSelected++;
    }
  }
  return numberSelected;
}

const btn = document.getElementById("btn");

btn.addEventListener("click", () => {
  const musicTypes = document.selectForm.musicTypes;
  console.log(`You have selected ${countSelected(musicTypes)} option(s).`);
});
```

do...while statement

The `do...while` statement repeats until a specified condition evaluates to false.

A `do...while` statement looks as follows:

```
do
  statement
while (condition);
```

`statement` is always executed once before the condition is checked. (To execute multiple statements, use a block statement (`{ }`) to group those statements.)

If `condition` is `true`, the statement executes again. At the end of every execution, the condition is checked. When the condition is `false`, execution stops, and control passes to the statement following `do...while`.

Example

In the following example, the `do` loop iterates at least once and reiterates until `i` is no longer less than `5`.

```
let i = 0;
do {
  i += 1;
  console.log(i);
} while (i < 5);
```

while statement

A `while` statement executes its statements as long as a specified condition evaluates to `true`. A `while` statement looks as follows:

```
while (condition)
  statement
```

If the `condition` becomes `false`, `statement` within the loop stops executing and control passes to the statement following the loop.

The condition test occurs *before* `statement` in the loop is executed. If the condition returns `true`, `statement` is executed and the `condition` is tested again. If the condition returns `false`, execution stops, and control is passed to the statement following `while`.

To execute multiple statements, use a block statement (`{ }`) to group those statements.

Example 1

The following `while` loop iterates as long as `n` is less than `3`:

```
let n = 0;
let x = 0;
while (n < 3) {
  n++;
  x += n;
}
```

With each iteration, the loop increments `n` and adds that value to `x`. Therefore, `x` and `n` take on the following values:

- After the first pass: `n = 1` and `x = 1`
- After the second pass: `n = 2` and `x = 3`
- After the third pass: `n = 3` and `x = 6`

After completing the third pass, the condition `n < 3` is no longer `true`, so the loop terminates.

Example 2

Avoid infinite loops. Make sure the condition in a loop eventually becomes `false`—otherwise, the loop will never terminate! The statements in the following `while` loop execute forever because the condition never becomes `false`:

```
// Infinite loops are bad!
while (true) {
  console.log("Hello, world!");
}
```

labeled statement

A `label` provides a statement with an identifier that lets you refer to it elsewhere in your program. For example, you can use a label to identify a loop, and then use the `break` or `continue` statements to indicate whether a program should interrupt the loop or continue its execution.

The syntax of the labeled statement looks like the following:

```
label:
  statement
```

The value of `label` may be any JavaScript identifier that is not a reserved word. The `statement` that you identify with a label may be any statement. For examples of using labeled statements, see the examples of `break` and `continue` below.

break statement

Use the `break` statement to terminate a loop, `switch`, or in conjunction with a labeled statement.

- When you use `break` without a label, it terminates the innermost enclosing `while`, `do-while`, `for`, or `switch` immediately and transfers control to the following statement.
- When you use `break` with a label, it terminates the specified labeled statement.

The syntax of the `break` statement looks like this:

```
break;
break label;
```

1. The first form of the syntax terminates the innermost enclosing loop or `switch`.
2. The second form of the syntax terminates the specified enclosing labeled statement.

Example 1

The following example iterates through the elements in an array until it finds the index of an element whose value is `theValue`:

```
for (let i = 0; i < a.length; i++) {
  if (a[i] === theValue) {
    break;
  }
}
```

Example 2: Breaking to a label

```
let x = 0;
let z = 0;
labelCancelLoops: while (true) {
  console.log("Outer loops:", x);
  x += 1;
  z = 1;
  while (true) {
    console.log("Inner loops:", z);
    z += 1;
    if (z === 10 && x === 10) {
      break labelCancelLoops;
    } else if (z === 10) {
      break;
    }
  }
}
```

continue statement

The `continue` statement can be used to restart a `while`, `do-while`, `for`, or `label` statement.

- When you use `continue` without a label, it terminates the current iteration of the innermost enclosing `while`, `do-while`, or `for` statement and continues execution of the loop with the next iteration. In contrast to the `break` statement, `continue` does not terminate the execution of the loop entirely. In a `while` loop, it jumps back to the condition. In a `for` loop, it jumps to the `increment-expression`.
- When you use `continue` with a label, it applies to the looping statement identified with that label.

The syntax of the `continue` statement looks like the following:

```
continue;
continue label;
```

Example 1

The following example shows a `while` loop with a `continue` statement that executes when the value of `i` is `3`. Thus, `n` takes on the values `1`, `3`, `7`, and `12`.

```
let i = 0;
let n = 0;
while (i < 5) {
  i++;
  if (i === 3) {
    continue;
  }
  n += i;
  console.log(n);
}
// Logs:
// 1 3 7 12
```

If you comment out the `continue;`, the loop would run till the end and you would see `1,3,6,10,15`.

Example 2

A statement labeled `checkIandJ` contains a statement labeled `checkJ`. If `continue` is encountered, the program terminates the current iteration of `checkJ` and begins the next iteration. Each time `continue` is encountered, `checkJ` reiterates until its condition returns `false`. When `false` is returned, the remainder of the `checkIandJ` statement is completed, and `checkIandJ` reiterates until its condition returns `false`. When `false` is returned, the program continues at the statement following `checkIandJ`.

If `continue` had a label of `checkIandJ`, the program would continue at the top of the `checkIandJ` statement.

```
let i = 0;
let j = 10;
checkIandJ: while (i < 4) {
  console.log(i);
  i += 1;
  checkJ: while (j > 4) {
    console.log(j);
    j -= 1;
    if (j % 2 === 0) {
      continue;
    }
    console.log(j, "is odd.");
  }
  console.log("i =", i);
  console.log("j =", j);
}
```

for...in statement

The `for...in` statement iterates a specified variable over all the enumerable properties of an object. For each distinct property, JavaScript executes the specified statements. A `for...in` statement looks as follows:

```
for (variable in object)
  statement
```

Example

The following function takes as its argument an object and the object's name. It then iterates over all the object's properties and returns a string that lists the property names and their values.

```
function dumpProps(obj, objName) {
  let result = "";
  for (const i in obj) {
    result += `${objName}.${i} = ${obj[i]}<br>`;
  }
  result += "<hr>";
  return result;
}
```

For an object `car` with properties `make` and `model`, `result` would be:

```
car.make = Ford
car.model = Mustang
```

Arrays

Although it may be tempting to use this as a way to iterate over `Array` elements, the `for...in` statement will return the name of your user-defined properties in addition to the numeric indexes.

Therefore, it is better to use a traditional `for` loop with a numeric index when iterating over arrays, because the `for...in` statement iterates over user-defined properties in addition to the array elements, if you modify the Array object (such as adding custom properties or methods).

for...of statement

The `for...of` statement creates a loop Iterating over iterable objects (including `Array`, `Map`, `Set`, `arguments` object and so on), invoking a custom iteration hook with statements to be executed for the value of each distinct property.

```
for (variable of iterable)
  statement
```

The following example shows the difference between a `for...of` loop and a `for...in` loop. While `for...in` iterates over property names, `for...of` iterates over property values:

```
const arr = [3, 5, 7];
arr.foo = "hello";

for (const i in arr) {
  console.log(i);
}
// "0" "1" "2" "foo"

for (const i of arr) {
  console.log(i);
}
// Logs: 3 5 7
```

The `for...of` and `for...in` statements can also be used with destructuring. For example, you can simultaneously loop over the keys and values of an object using `Object.entries()`.

```
const obj = { foo: 1, bar: 2 };

for (const [key, val] of Object.entries(obj)) {
  console.log(key, val);
}
// "foo" 1
// "bar" 2
```

Memory management

Low-level languages like C, have manual memory management primitives such as `malloc()` and `free()`. In contrast, JavaScript automatically allocates memory when objects are created and frees it when they are not used anymore (*garbage collection*). This automaticity is a potential source of confusion: it can give developers the false impression that they don't need to worry about memory management.

Memory life cycle

Regardless of the programming language, the memory life cycle is pretty much always the same:

1. Allocate the memory you need
2. Use the allocated memory (read, write)

3. Release the allocated memory when it is not needed anymore

The second part is explicit in all languages. The first and last parts are explicit in low-level languages but are mostly implicit in high-level languages like JavaScript.

Allocation in JavaScript

Value initialization

In order to not bother the programmer with allocations, JavaScript will automatically allocate memory when values are initially declared.

```
const n = 123; // allocates memory for a number
const s = "string"; // allocates memory for a string

const o = {
  a: 1,
  b: null,
}; // allocates memory for an object and contained values

// (like object) allocates memory for the array and
// contained values
const a = [1, null, "str2"];

function f(a) {
  return a + 2;
} // allocates a function (which is a callable object)

// function expressions also allocate an object
someElement.addEventListener("click", () => {
  someElement.style.backgroundColor = "blue";
});
```

Allocation via function calls

Some function calls result in object allocation.

```
const d = new Date(); // allocates a Date object

const e = document.createElement("div"); // allocates a DOM element
```

Some methods allocate new values or objects:

```
const s = "string";
const s2 = s.substring(0, 3); // s2 is a new string
// Since strings are immutable values,
// JavaScript may decide to not allocate memory,
// but just store the [0, 3] range.

const a = ["yeah yeah", "no no"];
const a2 = ["generation", "no no"];
const a3 = a.concat(a2);
// new array with 4 elements being
// the concatenation of a and a2 elements.
```

Using values

Using values basically means reading and writing in allocated memory. This can be done by reading or writing the value of a variable or an object property or even passing an argument to a function.

Release when the memory is not needed anymore

The majority of memory management issues occur at this phase. The most difficult aspect of this stage is determining when the allocated memory is no longer needed.

Low-level languages require the developer to manually determine at which point in the program the allocated memory is no longer needed and to release it.

Some high-level languages, such as JavaScript, utilize a form of automatic memory management known as garbage collection (GC). The purpose of a garbage collector is to monitor memory allocation and determine when a block of allocated memory is no longer needed and reclaim it. This automatic process is an approximation since the general problem of determining whether or not a specific piece of memory is still needed is undecidable.

Garbage collection

As stated above, the general problem of automatically finding whether some memory "is not needed anymore" is undecidable. As a consequence, garbage collectors implement a restriction of a solution to the general problem. This section will explain the concepts that are necessary for understanding the main garbage collection algorithms and their respective limitations.

References

The main concept that garbage collection algorithms rely on is the concept of *reference*. Within the context of memory management, an object is said to reference another object if the former has access to the latter (either implicitly or explicitly). For instance, a JavaScript object has a reference to its prototype (implicit reference) and to its properties values (explicit reference).

In this context, the notion of an "object" is extended to something broader than regular JavaScript objects and also contain function scopes (or the global lexical scope).

Reference-counting garbage collection

> **Note:** No modern JavaScript engine uses reference-counting for garbage collection anymore.

This is the most naïve garbage collection algorithm. This algorithm reduces the problem from determining whether or not an object is still needed to determining if an object still has any other objects referencing it. An object is said to be "garbage", or collectible if there are zero references pointing to it.

For example:

```
let x = {
  a: {
    b: 2,
  },
};
// 2 objects are created. One is referenced by the other as one of its properties.
// The other is referenced by virtue of being assigned to the 'x' variable.
// Obviously, none can be garbage-collected.

let y = x;
// The 'y' variable is the second thing that has a reference to the object.

x = 1;
// Now, the object that was originally in 'x' has a unique reference
// embodied by the 'y' variable.

let z = y.a;
// Reference to 'a' property of the object.
// This object now has 2 references: one as a property,
// the other as the 'z' variable.

y = "mozilla";
// The object that was originally in 'x' has now zero
// references to it. It can be garbage-collected.
// However its 'a' property is still referenced by
// the 'z' variable, so it cannot be freed.

z = null;
// The 'a' property of the object originally in x
// has zero references to it. It can be garbage collected.
```

There is a limitation when it comes to circular references. In the following example, two objects are created with properties that reference one another, thus creating a cycle. They will go out of scope after the function call has completed. At that point they become unneeded and their allocated memory should be reclaimed. However, the reference-counting algorithm will not consider them reclaimable since each of the two objects has at least one reference pointing to them, resulting in neither of them being marked for garbage collection. Circular references are a common cause of memory leaks.

```
function f() {
  const x = {};
  const y = {};
  x.a = y; // x references y
  y.a = x; // y references x

  return "azerty";
}

f();
```

Mark-and-sweep algorithm

This algorithm reduces the definition of "an object is no longer needed" to "an object is unreachable".

This algorithm assumes the knowledge of a set of objects called *roots*. In JavaScript, the root is the global object. Periodically, the garbage collector will start from these roots, find all objects that are referenced from these roots, then all objects referenced from these, etc. Starting from the roots, the garbage collector will thus find all *reachable* objects and collect all non-reachable objects.

This algorithm is an improvement over the previous one since an object having zero references is effectively unreachable. The opposite does not hold true as we have seen with circular references.

Currently, all modern engines ship a mark-and-sweep garbage collector. All improvements made in the field of JavaScript garbage collection (generational/incremental/concurrent/parallel garbage collection) over the last few years are implementation improvements of this algorithm, but not improvements over the garbage collection algorithm itself nor its reduction of the definition of when "an object is no longer needed".

The immediate benefit of this approach is that cycles are no longer a problem. In the first example above, after the function call returns, the two objects are no longer referenced by any resource that is reachable from the global object. Consequently, they will be found unreachable by the garbage collector and have their allocated memory reclaimed.

However, the inability to manually control garbage collection remains. There are times when it would be convenient to manually decide when and what memory is released. In order to release the memory of an object, it needs to be made explicitly unreachable. It is also not possible to programmatically trigger garbage collection in JavaScript — and will likely never be within the core language, although engines may expose APIs behind opt-in flags.

Configuring an engine's memory model

JavaScript engines typically offer flags that expose the memory model. For example, Node.js offers additional options and tools that expose the underlying V8 mechanisms for configuring and debugging memory issues. This configuration may not be available in browsers, and even less so for web pages (via HTTP headers, etc.).

The max amount of available heap memory can be increased with a flag:

```
node --max-old-space-size=6000 index.js
```

We can also expose the garbage collector for debugging memory issues using a flag and the Chrome Debugger:

```
node --expose-gc --inspect index.js
```

Data structures aiding memory management

Although JavaScript does not directly expose the garbage collector API, the language offers several data structures that indirectly observe garbage collection and can be used to manage memory usage.

WeakMaps and WeakSets

`WeakMap` and `WeakSet` are data structures whose APIs closely mirror their non-weak counterparts: `Map` and `Set`. `WeakMap` allows you to maintain a collection of key-value pairs, while `WeakSet` allows you to maintain a collection of unique values, both with performant addition, deletion, and querying.

`WeakMap` and `WeakSet` got the name from the concept of *weakly held* values. If `x` is weakly held by `y`, it means that although you can access the value of `x` via `y`, the mark-and-sweep algorithm won't consider `x` as reachable if nothing else *strongly holds* to it. Most data structures, except the ones discussed here, strongly hold to the objects passed in so that you can retrieve them at any time. The keys of `WeakMap` and `WeakSet` can be garbage-collected (for `WeakMap` objects, the values would then be eligible for garbage collection as well) as long as nothing else in the program is referencing the key. This is ensured by two characteristics:

- `WeakMap` and `WeakSet` can only store objects or symbols. This is because only objects are garbage collected — primitive values can always be forged (that is, `1 === 1` but `{} !== {}`), making them stay in the collection forever. Registered symbols (like `Symbol.for("key")`) can also be forged and thus are not garbage collectable, but symbols created with `Symbol("key")` are garbage collectable. Well-known symbols like `Symbol.iterator` come in a fixed set and are unique throughout the lifetime of the program, similar to intrinsic objects such as `Array.prototype`, so they are also allowed as keys.
- `WeakMap` and `WeakSet` are not iterable. This prevents you from using `Array.from(map.keys()).length` to observe the liveliness of objects, or get hold of an arbitrary key which should otherwise be eligible for garbage collection. (Garbage collection should be as invisible as possible.)

In typical explanations of `WeakMap` and `WeakSet` (such as the one above), it's often implied that the key is garbage-collected first, freeing the value for garbage collection as well. However, consider the case of the value referencing the key:

```
const wm = new WeakMap();
const key = {};
wm.set(key, { key });
// Now `key` cannot be garbage collected,
// because the value holds a reference to the key,
// and the value is strongly held in the map!
```

If `key` is stored as an actual reference, it would create a cyclic reference and make both the key and value ineligible for garbage collection, even when nothing else references `key` — because if `key` is garbage collected, it means that at some particular instant, `value.key` would point to a non-existent address, which is not legal. To fix this, the entries of `WeakMap` and `WeakSet` aren't actual references, but ephemerons, an enhancement to the mark-and-sweep mechanism. Barros et al. offers a good summary of the algorithm (page 4). To quote a paragraph:

> Ephemerons are a refinement of weak pairs where neither the key nor the value can be classified as weak or strong. The connectivity of the key determines the connectivity of the value, but the connectivity of the value does not affect the connectivity of the key. [...] when the garbage collection offers support to ephemerons, it occurs in three phases instead of two (mark and sweep).

As a rough mental model, think of a `WeakMap` as the following implementation:

> **Warning:** This is not a polyfill, nor is it anywhere close to how it's implemented in the engine (which hooks into the garbage collection mechanism).

```
class MyWeakMap {
  #marker = Symbol("MyWeakMapData");
  get(key) {
    return key[this.#marker];
  }
  set(key, value) {
    key[this.#marker] = value;
  }
  has(key) {
    return this.#marker in key;
  }
  delete(key) {
    delete key[this.#marker];
  }
}
```

As you can see, the `MyWeakMap` never actually holds a collection of keys. It simply adds metadata to each object being passed in. The object is then garbage-collectable via mark-and-sweep. Therefore, it's not possible to iterate over the keys in a `WeakMap`, nor clear the `WeakMap` (as that also relies on the knowledge of the entire key collection).

For more information on their APIs, see the keyed collections guide.

WeakRefs and FinalizationRegistry

> **Note:** `WeakRef` and `FinalizationRegistry` offer direct introspection into the garbage collection machinery. Avoid using them where possible because the runtime semantics are almost completely unguaranteed.

All variables with an object as value are references to that object. However, such references are *strong* — their existence would prevent the garbage collector from marking the object as eligible for collection. A `WeakRef` is a *weak reference* to an object that allows the object to be garbage collected, while still retaining the ability to read the object's content during its lifetime.

One use case for `WeakRef` is a cache system which maps string URLs to large objects. We cannot use a `WeakMap` for this purpose, because `WeakMap` objects have their *keys* weakly held, but not their *values* — if you access a key, you would always deterministically get the value (since having access to the key means it's still alive). Here, we are okay to get `undefined` for a key (if the corresponding value is no longer alive) since we can just re-compute it, but we don't want unreachable objects to stay in the cache. In this case, we can use a normal `Map`, but with each value being a `WeakRef` of the object instead of the actual object value.

```
function cached(getter) {
  // A Map from string URLs to WeakRefs of results
  const cache = new Map();
  return async (key) => {
    if (cache.has(key)) {
      const dereferencedValue = cache.get(key).deref();
      if (dereferencedValue !== undefined) {
        return dereferencedValue;
      }
    }
    const value = await getter(key);
    cache.set(key, new WeakRef(value));
    return value;
  };
}

const getImage = cached((url) => fetch(url).then((res) => res.blob()));
```

`FinalizationRegistry` provides an even stronger mechanism to observe garbage collection. It allows you to register objects and be notified when they are garbage collected. For example, for the cache system exemplified above, even when the blobs themselves are free for collection, the `WeakRef` objects that hold them are not — and over time, the `Map` may accumulate a lot of useless entries. Using a `FinalizationRegistry` allows one to perform cleanup in this case.

```
function cached(getter) {
  // A Map from string URLs to WeakRefs of results
  const cache = new Map();
  // Every time after a value is garbage collected, the callback is
  // called with the key in the cache as argument, allowing us to remove
  // the cache entry
  const registry = new FinalizationRegistry((key) => {
    // Note: it's important to test that the WeakRef is indeed empty.
    // Otherwise, the callback may be called after a new object has been
    // added with this key, and that new, alive object gets deleted
    if (!cache.get(key)?.deref()) {
      cache.delete(key);
    }
  });
  return async (key) => {
    if (cache.has(key)) {
      return cache.get(key).deref();
    }
    const value = await getter(key);
    cache.set(key, new WeakRef(value));
    registry.register(value, key);
    return value;
  };
}

const getImage = cached((url) => fetch(url).then((res) => res.blob()));
```

Due to performance and security concerns, there is no guarantee of when the callback will be called, or if it will be called at all. It should only be used for cleanup — and non-critical cleanup. There are other ways for more deterministic resource management, such as `try...finally`, which will always execute the `finally` block. `WeakRef` and `FinalizationRegistry` exist solely for optimization of memory usage in long-running programs.

For more information on the API of `WeakRef` and `FinalizationRegistry`, see their reference pages.

Meta programming

The `Proxy` and `Reflect` objects allow you to intercept and define custom behavior for fundamental language operations (e.g., property lookup, assignment, enumeration, function invocation, etc.). With the help of these two objects you are able to program at the meta level of JavaScript.

Proxies

`Proxy` objects allow you to intercept certain operations and to implement custom behaviors.

For example, getting a property on an object:

```
const handler = {
  get(target, name) {
    return name in target ? target[name] : 42;
  },
};

const p = new Proxy({}, handler);
p.a = 1;
console.log(p.a, p.b); // 1, 42
```

The `Proxy` object defines a `target` (an empty object here) and a `handler` object, in which a `get` *trap* is implemented. Here, an object that is proxied will not return `undefined` when getting undefined properties, but will instead return the number `42`.

Additional examples are available on the `Proxy` reference page.

Terminology

The following terms are used when talking about the functionality of proxies.

handler

Placeholder object which contains traps.

traps

The methods that provide property access. (This is analogous to the concept of *traps* in operating systems.)

target

Object which the proxy virtualizes. It is often used as storage backend for the proxy. Invariants (semantics that remain unchanged) regarding object non-extensibility or non-configurable properties are verified against the target.

invariants

Semantics that remain unchanged when implementing custom operations are called *invariants*. If you violate the invariants of a handler, a `TypeError` will be thrown.

Handlers and traps

The following table summarizes the available traps available to `Proxy` objects. See the reference pages for detailed explanations and examples.

Handler / trap	Interceptions

`handler.getPrototypeOf()`	`Object.getPrototypeOf()`
	`Reflect.getPrototypeOf()`
	`__proto__`
	`Object.prototype.isPrototypeOf()`
	`instanceof`

`handler.setPrototypeOf()`	`Object.setPrototypeOf()` `Reflect.setPrototypeOf()`
`handler.isExtensible()`	`Object.isExtensible()` `Reflect.isExtensible()`
`handler.preventExtensions()`	`Object.preventExtensions()` `Reflect.preventExtensions()`
`handler.getOwnPropertyDescriptor()`	`Object.getOwnPropertyDescriptor()` `Reflect.getOwnPropertyDescriptor()`
`handler.defineProperty()`	`Object.defineProperty()` `Reflect.defineProperty()`

`handler.has()`	Property query
	`foo in proxy`
	Inherited property query
	`foo in Object.create(proxy)`
	`Reflect.has()`

`handler.get()`	Property access
	`proxy[foo]`
	`proxy.bar`
	Inherited property access
	`Object.create(proxy)[foo]`
	`Reflect.get()`

`handler.set()`	Property assignment
	`proxy[foo] = bar`
	`proxy.foo = bar`
	Inherited property assignment

Handler / trap	Interceptions
	`Object.create(proxy)[foo] = bar` `Reflect.set()`

`handler.deleteProperty()`	Property deletion
	`delete proxy[foo]`
	`delete proxy.foo`
	`Reflect.deleteProperty()`

`handler.ownKeys()`	`Object.getOwnPropertyNames()`
	`Object.getOwnPropertySymbols()`
	`Object.keys()`
	`Reflect.ownKeys()`

`handler.apply()`	`proxy(..args)`
	`Function.prototype.apply()` and `Function.prototype.call()`
	`Reflect.apply()`

`handler.construct()`	`new proxy(...args)` `Reflect.construct()`

Revocable <code>Proxy</code>

The `Proxy.revocable()` method is used to create a revocable `Proxy` object. This means that the proxy can be revoked via the function `revoke` and switches the proxy off.

Afterwards, any operation on the proxy leads to a `TypeError`.

```
const revocable = Proxy.revocable(
  {},
  {
    get(target, name) {
      return `[[${name}]]`;
    },
  },
);
const proxy = revocable.proxy;
console.log(proxy.foo); // "[[foo]]"

revocable.revoke();

console.log(proxy.foo); // TypeError: Cannot perform 'get' on a proxy that has been revoked
proxy.foo = 1; // TypeError: Cannot perform 'set' on a proxy that has been revoked
delete proxy.foo; // TypeError: Cannot perform 'deleteProperty' on a proxy that has been revoked
console.log(typeof proxy); // "object", typeof doesn't trigger any trap
```

Reflection

`Reflect` is a built-in object that provides methods for interceptable JavaScript operations. The methods are the same as those of the proxy handler's.

`Reflect` is not a function object.

`Reflect` helps with forwarding default operations from the handler to the `target`.

With `Reflect.has()` for example, you get the `in` operator as a function:

```
Reflect.has(Object, "assign"); // true
```

A better apply() function

Before `Reflect`, you typically use the `Function.prototype.apply()` method to call a function with a given `this` value and `arguments` provided as an array (or an array-like object).

```
Function.prototype.apply.call(Math.floor, undefined, [1.75]);
```

With `Reflect.apply` this becomes less verbose and easier to understand:

```
Reflect.apply(Math.floor, undefined, [1.75]);
// 1

Reflect.apply(String.fromCharCode, undefined, [104, 101, 108, 108, 111]);
// "hello"

Reflect.apply(RegExp.prototype.exec, /ab/, ["confabulation"]).index;
// 4

Reflect.apply("".charAt, "ponies", [3]);
// "i"
```

Checking if property definition has been successful

With `Object.defineProperty`, which returns an object if successful, or throws a `TypeError` otherwise, you would use a `try...catch` block to catch any error that occurred while defining a property. Because `Reflect.defineProperty()` returns a Boolean success status, you can just use an `if...else` block here:

```
if (Reflect.defineProperty(target, property, attributes)) {
  // success
} else {
  // failure
}
```

JavaScript modules

- Previous

This guide gives you all you need to get started with JavaScript module syntax.

A background on modules

JavaScript programs started off pretty small — most of its usage in the early days was to do isolated scripting tasks, providing a bit of interactivity to your web pages where needed, so large scripts were generally not needed. Fast forward a few years and we now have complete applications being run in browsers with a lot of JavaScript, as well as JavaScript being used in other contexts (Node.js, for example).

Complex projects necessitate a mechanism for splitting JavaScript programs into separate modules that can be imported when needed. Node.js has had this ability for a long time, and there are a number of JavaScript libraries and frameworks that enable module usage (for example, other CommonJS and AMD-based module systems like RequireJS, webpack, and Babel).

All modern browsers support module features natively without needing transpilation. It can only be a good thing — browsers can optimize loading of modules, making it more efficient than having to use a library and do all of that extra client-side processing and extra round trips. It does not obsolete bundlers like webpack, though — bundlers still do a good job at partitioning code into reasonably sized chunks, and are able to do other optimizations like minification, dead code elimination, and tree-shaking.

Introducing an example

To demonstrate usage of modules, we've created a set of examples that you can find on GitHub. These examples demonstrate a set of modules that create a `<canvas>` element on a webpage, and then draw (and report information about) different shapes on the canvas.

These are fairly trivial, but have been kept deliberately simple to demonstrate modules clearly.

> **Note:** If you want to download the examples and run them locally, you'll need to run them through a local web server.

Basic example structure

In our first example (see basic-modules) we have a file structure as follows:

```
index.html
main.js
modules/
    canvas.js
    square.js
```

> **Note:** All of the examples in this guide have basically the same structure; the above should start getting pretty familiar.

The modules directory's two modules are described below:

- `canvas.js` — contains functions related to setting up the canvas:
  - `create()` — creates a canvas with a specified `width` and `height` inside a wrapper `<div>` with a specified ID, which is itself appended inside a specified parent element. Returns an object containing the canvas's 2D context and the wrapper's ID.
  - `createReportList()` — creates an unordered list appended inside a specified wrapper element, which can be used to output report data into. Returns the list's ID.
- `square.js` — contains:
  - `name` — a constant containing the string 'square'.
  - `draw()` — draws a square on a specified canvas, with a specified size, position, and color. Returns an object containing the square's size, position, and color.
  - `reportArea()` — writes a square's area to a specific report list, given its length.
  - `reportPerimeter()` — writes a square's perimeter to a specific report list, given its length.

Aside — .mjs versus .js

Throughout this article, we've used `.js` extensions for our module files, but in other resources you may see the `.mjs` extension used instead. V8's documentation recommends this, for example. The reasons given are:

- It is good for clarity, i.e., it makes it clear which files are modules, and which are regular JavaScript.
- It ensures that your module files are parsed as a module by runtimes such as Node.js, and build tools such as Babel.

However, we decided to keep using `.js`, at least for the moment. To get modules to work correctly in a browser, you need to make sure that your server is serving them with a `Content-Type` header that contains a JavaScript MIME type such as `text/javascript`. If you don't, you'll get a strict MIME type checking error along the

lines of "The server responded with a non-JavaScript MIME type" and the browser won't run your JavaScript. Most servers already set the correct type for `.js` files, but not yet for `.mjs` files. Servers that already serve `.mjs` files correctly include GitHub Pages and `http-server` for Node.js.

This is OK if you are using such an environment already, or if you aren't but you know what you are doing and have access (i.e., you can configure your server to set the correct `Content-Type` for `.mjs` files). It could however cause confusion if you don't control the server you are serving files from, or are publishing files for public use, as we are here.

For learning and portability purposes, we decided to keep to `.js`.

If you really value the clarity of using `.mjs` for modules versus using `.js` for "normal" JavaScript files, but don't want to run into the problem described above, you could always use `.mjs` during development and convert them to `.js` during your build step.

It is also worth noting that:

- Some tools may never support `.mjs`.
- The `<script type="module">` attribute is used to denote when a module is being pointed to, as described in Applying the module to your HTML.

Exporting module features

The first thing you do to get access to module features is export them. This is done using the `export` statement.

The easiest way to use it is to place it in front of any items you want exported out of the module, for example:

```
export const name = "square";

export function draw(ctx, length, x, y, color) {
  ctx.fillStyle = color;
  ctx.fillRect(x, y, length, length);

  return { length, x, y, color };
}
```

You can export functions, `var`, `let`, `const`, and — as we'll see later — classes. They need to be top-level items: for example, you can't use `export` inside a function.

A more convenient way of exporting all the items you want to export is to use a single export statement at the end of your module file, followed by a comma-separated list of the features you want to export wrapped in curly braces. For example:

```
export { name, draw, reportArea, reportPerimeter };
```

Importing features into your script

Once you've exported some features out of your module, you need to import them into your script to be able to use them. The simplest way to do this is as follows:

```
import { name, draw, reportArea, reportPerimeter } from "./modules/square.js";
```

You use the `import` statement, followed by a comma-separated list of the features you want to import wrapped in curly braces, followed by the keyword `from`, followed by the *module specifier*.

The *module specifier* provides a string that the JavaScript environment can resolve to a path to the module file. In a browser, this could be a path relative to the site root, which for our `basic-modules` example would be `/js-examples/module-examples/basic-modules`. However, here we are instead using the dot (`.`) syntax to mean "the current location", followed by the relative path to the file we are trying to find. This is much better than writing out the entire absolute path each time, as relative paths are shorter and make the URL portable — the example will still work if you move it to a different location in the site hierarchy.

So for example:

```
/js-examples/module-examples/basic-modules/modules/square.js
```

becomes

```
./modules/square.js
```

You can see such lines in action in `main.js`.

> **Note:** In some module systems, you can use a module specifier like `modules/square` that isn't a relative or absolute path, and that doesn't have a file extension. This kind of specifier can be used in a browser environment if you first define an import map.

Once you've imported the features into your script, you can use them just like they were defined inside the same file. The following is found in `main.js`, below the import lines:

```
const myCanvas = create("myCanvas", document.body, 480, 320);
const reportList = createReportList(myCanvas.id);

const square = draw(myCanvas.ctx, 50, 50, 100, "blue");
reportArea(square.length, reportList);
reportPerimeter(square.length, reportList);
```

> **Note:** The imported values are read-only views of the features that were exported. Similar to `const` variables, you cannot re-assign the variable that was imported,

> but you can still modify properties of object values. The value can only be re-assigned by the module exporting it. See the `import` reference for an example.

Importing modules using import maps

Above we saw how a browser can import a module using a module specifier that is either an absolute URL, or a relative URL that is resolved using the base URL of the document:

```
import { name as circleName } from "https://example.com/shapes/circle.js";
import { name as squareName, draw } from "./shapes/square.js";
```

Import maps allow developers to instead specify almost any text they want in the module specifier when importing a module; the map provides a corresponding value that will replace the text when the module URL is resolved.

For example, the `imports` key in the import map below defines a "module specifier map" JSON object where the property names can be used as module specifiers, and the corresponding values will be substituted when the browser resolves the module URL. The values must be absolute or relative URLs. Relative URLs are resolved to absolute URL addresses using the base URL of the document containing the import map.

```
<script type="importmap">
  {
    "imports": {
      "shapes": "./shapes/square.js",
      "shapes/square": "./modules/shapes/square.js",
      "https://example.com/shapes/square.js": "./shapes/square.js",
      "https://example.com/shapes/": "/shapes/square/",
      "../shapes/square": "./shapes/square.js"
    }
  }
</script>
```

The import map is defined using a JSON object inside a `<script>` element with the `type` attribute set to `importmap`. Note that an import map only applies to the document — the specification does not cover how to apply an import map in a worker or worklet context.

With this map you can now use the property names above as module specifiers. If there is no trailing forward slash on the module specifier key then the whole module specifier key is matched and substituted. For example, below we match bare module names, and remap a URL to another path.

```
// Bare module names as module specifiers
import { name as squareNameOne } from "shapes";
import { name as squareNameTwo } from "shapes/square";

// Remap a URL to another URL
import { name as squareNameThree } from "https://example.com/shapes/square.js";
```

If the module specifier has a trailing forward slash then the value must have one as well, and the key is matched as a "path prefix". This allows remapping of whole classes of URLs.

```
// Remap a URL as a prefix ( https://example.com/shapes/)
import { name as squareNameFour } from "https://example.com/shapes/moduleshapes/square.js";
```

It is possible for multiple keys in an import map to be valid matches for a module specifier. For example, a module specifier of `shapes/circle/` could match the module specifier keys `shapes/` and `shapes/circle/`. In this case the browser will select the most specific (longest) matching module specifier key.

Import maps allow modules to be imported using bare module names (as in Node.js), and can also simulate importing modules from packages, both with and without file extensions. While not shown above, they also allow particular versions of a library to be imported, based on the path of the script that is importing the module. Generally they let developers write more ergonomic import code, and make it easier to manage the different versions and dependencies of modules used by a site. This can reduce the effort required to use the same JavaScript libraries in both browser and server.

The following sections expand on the various features outlined above.

Feature detection

You can check support for import maps using the `HTMLScriptElement.supports()` static method (which is itself broadly supported):

```
if (HTMLScriptElement.supports?.("importmap")) {
  console.log("Browser supports import maps.");
}
```

Importing modules as bare names

In some JavaScript environments, such as Node.js, you can use bare names for the module specifier. This works because the environment can resolve module names to a standard location in the file system. For example, you might use the following syntax to import the "square" module.

```
import { name, draw, reportArea, reportPerimeter } from "square";
```

To use bare names on a browser you need an import map, which provides the information needed by the browser to resolve module specifiers to URLs (JavaScript will throw a `TypeError` if it attempts to import a module specifier that can't be resolved to a module location).

Below you can see a map that defines a `square` module specifier key, which in this case maps to a relative address value.

```
<script type="importmap">
  {
    "imports": {
      "square": "./shapes/square.js"
    }
  }
</script>
```

With this map we can now use a bare name when we import the module:

```
import { name as squareName, draw } from "square";
```

Remapping module paths

Module specifier map entries, where both the specifier key and its associated value have a trailing forward slash (`/`), can be used as a path-prefix. This allows the remapping of a whole set of import URLs from one location to another. It can also be used to emulate working with "packages and modules", such as you might see in the Node ecosystem.

> **Note:** The trailing `/` indicates that the module specifier key can be substituted as *part* of a module specifier. If this is not present, the browser will only match (and substitute) the whole module specifier key.

Packages of modules

The following JSON import map definition maps `lodash` as a bare name, and the module specifier prefix `lodash/` to the path `/node_modules/lodash-es/` (resolved to the document base URL):

```
{
  "imports": {
    "lodash": "/node_modules/lodash-es/lodash.js",
    "lodash/": "/node_modules/lodash-es/"
  }
}
```

With this mapping you can import both the whole "package", using the bare name, and modules within it (using the path mapping):

```
import _ from "lodash";
import fp from "lodash/fp.js";
```

It is possible to import `fp` above without the `.js` file extension, but you would need to create a bare module specifier key for that file, such as `lodash/fp`, rather than using the path. This may be reasonable for just one module, but scales poorly if you wish to import many modules.

General URL remapping

A module specifier key doesn't have to be a path — it can also be an absolute URL (or a URL-like relative path like `./`, `../`, `/`). This may be useful if you want to remap a module that has absolute paths to a resource with your own local resources.

```
{
  "imports": {
    "https://www.unpkg.com/moment/": "/node_modules/moment/"
  }
}
```

Scoped modules for version management

Ecosystems like Node use package managers such as npm to manage modules and their dependencies. The package manager ensures that each module is separated from other modules and their dependencies. As a result, while a complex application might include the same module multiple times with several different versions in different parts of the module graph, users do not need to think about this complexity.

> **Note:** You can also achieve version management using relative paths, but this is subpar because, among other things, this forces a particular structure on your project, and prevents you from using bare module names.

Import maps similarly allow you to have multiple versions of dependencies in your application and refer to them using the same module specifier. You implement this with the `scopes` key, which allows you to provide module specifier maps that will be used depending on the path of the script performing the import. The example below demonstrates this.

```
{
  "imports": {
    "cool-module": "/node_modules/cool-module/index.js"
  },
  "scopes": {
    "/node_modules/dependency/": {
      "cool-module": "/node_modules/some/other/location/cool-module/index.js"
    }
  }
}
```

With this mapping, if a script with a URL that contains `/node_modules/dependency/` imports `cool-module`, the version in `/node_modules/some/other/location/cool-module/index.js` will be used. The map in `imports` is used as a fallback if there is no matching scope in the scoped map, or the matching scopes don't contain a matching specifier. For example, if `cool-module` is imported from a script with a non-matching scope path, then the module specifier map in `imports` will be used instead, mapping to the version in `/node_modules/cool-module/index.js`.

Note that the path used to select a scope does not affect how the address is resolved. The value in the mapped path does not have to match the scopes path, and relative paths are still resolved to the base URL of the script that contains the import map.

Just as for module specifier maps, you can have many scope keys, and these may contain overlapping paths. If multiple scopes match the referrer URL, then the most specific scope path is checked first (the longest scope key) for a matching specifier. The browsers will fall back to the next most specific matching scoped path if there is no matching specifier, and so on. If there is no matching specifier in any of the matching scopes, the browser checks for a match in the module specifier map in the `imports` key.

Improve caching by mapping away hashed filenames

Script files used by websites often have hashed filenames to simplify caching. The downside of this approach is that if a module changes, any modules that import it using its hashed filename will also need to be updated/regenerated. This potentially results in a cascade of updates, which is wasteful of network resources.

Import maps provide a convenient solution to this problem. Rather than depending on specific hashed filenames, applications and scripts instead depend on an un-hashed version of the module name (address). An import map like the one below then provides a mapping to the actual script file.

```
{
  "imports": {
    "main_script": "/node/srcs/application-fg7744e1b.js",
    "dependency_script": "/node/srcs/dependency-3qn7e4b1q.js"
  }
}
```

If `dependency_script` changes, then its hash contained in the file name changes as well. In this case, we only need to update the import map to reflect the changed name of the module. We don't have to update the source of any JavaScript code that depends on it, because the specifier in the import statement does not change.

Loading non-JavaScript resources

One exciting feature that a unified module architecture brings is the ability to load non-JavaScript resources as modules. For example, you can import JSON as a JavaScript object, or import CSS as a `CSSStyleSheet` object.

You must explicitly declare what kind of resource you are importing. By default, the browser assumes that the resource is JavaScript, and will throw an error if the resolved resource is something else. To import JSON, CSS, or other types of resource, use the import attributes syntax:

```
import colors from "./colors.json" with { type: "json" };
import styles from "./styles.css" with { type: "css" };
```

Browsers will also perform validation on the module type, and fail if, for example, `./data.json` does not resolve to a JSON file. This ensures that you don't accidentally execute code when you just intend to import data. Once imported successfully, you can now use the imported value as a normal JavaScript object or `CSSStyleSheet` object.

```
console.log(colors.map((color) => color.value));
document.adoptedStyleSheets = [styles];
```

Applying the module to your HTML

Now we just need to apply the `main.js` module to our HTML page. This is very similar to how we apply a regular script to a page, with a few notable differences.

First of all, you need to include `type="module"` in the `<script>` element, to declare this script as a module. To import the `main.js` script, we use this:

```
<script type="module" src="https://developer.mozilla.org/en-US/docs/Web/JavaScript/Guide/Modules/main.js"></script>
```

You can also embed the module's script directly into the HTML file by placing the JavaScript code within the body of the `<script>` element:

```
<script type="module">
  /* JavaScript module code here */
</script>
```

You can only use `import` and `export` statements inside modules, not regular scripts. An error will be thrown if your `<script>` element doesn't have the `type="module"` attribute and attempts to import other modules. For example:

```
<script>
  import _ from "lodash"; // SyntaxError: import declarations may only appear at top level of a module
  // …
</script>
<script src="https://developer.mozilla.org/en-US/docs/Web/JavaScript/Guide/Modules/a-module-using-import-statements.js"></script>
<!-- SyntaxError: import declarations may only appear at top level of a module -->
```

You should generally define all your modules in separate files. Modules declared inline in HTML can only import other modules, but anything they export will not be accessible by other modules (because they don't have a URL).

> **Note:** Modules and their dependencies can be preloaded by specifying them in `<link>` elements with `rel="modulepreload"`. This can significantly reduce load time when the modules are used.

Other differences between modules and classic scripts

- You need to pay attention to local testing — if you try to load the HTML file locally (i.e., with a `file://` URL), you'll run into CORS errors due to JavaScript module security requirements. You need to do your testing through a server.
- Also, note that you might get different behavior from sections of script defined inside modules as opposed to in classic scripts. This is because modules use strict mode automatically.
- There is no need to use the `defer` attribute (see `<script>` attributes) when loading a module script; modules are deferred automatically.
- Modules are only executed once, even if they have been referenced in multiple `<script>` tags.
- Last but not least, let's make this clear — module features are imported into the scope of a single script — they aren't available in the global scope. Therefore, you will only be able to access imported features in the script they are imported into, and you won't be able to access them from the JavaScript console, for example. You'll still get syntax errors shown in the DevTools, but you'll not be able to use some of the debugging techniques you might have expected to use.

Module-defined variables are scoped to the module unless explicitly attached to the global object. On the other hand, globally-defined variables are available within the module. For example, given the following code:

```
<!doctype html>
<html lang="en-US">
  <head>
    <meta charset="UTF-8" />
    <title>Example page</title>
    <link rel="stylesheet" href="" />
  </head>
  <body>
    <div id="main"></div>
    <script>
      // A var statement creates a global variable.
      var text = "Hello";
    </script>
    <script type="module" src="https://developer.mozilla.org/en-US/docs/Web/JavaScript/Guide/Modules/./render.js"></script>
  </body>
</html>
```

```
/* render.js */
document.getElementById("main").innerText = text;
```

The page would still render `Hello`, because the global variables `text` and `document` are available in the module. (Also note from this example that a module doesn't necessarily need an import/export statement — the only thing needed is for the entry point to have `type="module"`.)

Default exports versus named exports

The functionality we've exported so far has been comprised of **named exports** — each item (be it a function, `const`, etc.) has been referred to by its name upon export, and that name has been used to refer to it on import as well.

There is also a type of export called the **default export** — this is designed to make it easy to have a default function provided by a module, and also helps JavaScript modules to interoperate with existing CommonJS and AMD module systems (as explained nicely in ES6 In Depth: Modules by Jason Orendorff; search for "Default exports").

Let's look at an example as we explain how it works. In our basic-modules `square.js` you can find a function called `randomSquare()` that creates a square with a random color, size, and position. We want to export this as our default, so at the bottom of the file we write this:

```
export default randomSquare;
```

Note the lack of curly braces.

We could instead prepend `export default` onto the function and define it as an anonymous function, like this:

```
export default function (ctx) {
  // …
}
```

Over in our `main.js` file, we import the default function using this line:

```
import randomSquare from "./modules/square.js";
```

Again, note the lack of curly braces. This is because there is only one default export allowed per module, and we know that `randomSquare` is it. The above line is basically shorthand for:

```
import { default as randomSquare } from "./modules/square.js";
```

> **Note:** The as syntax for renaming exported items is explained below in the Renaming imports and exports section.

Avoiding naming conflicts

So far, our canvas shape drawing modules seem to be working OK. But what happens if we try to add a module that deals with drawing another shape, like a circle or triangle? These shapes would probably have associated functions like `draw()`, `reportArea()`, etc. too; if we tried to import different functions of the same name into the same top-level module file, we'd end up with conflicts and errors.

Fortunately there are a number of ways to get around this. We'll look at these in the following sections.

Renaming imports and exports

Inside your `import` and `export` statement's curly braces, you can use the keyword `as` along with a new feature name, to change the identifying name you will use for a feature inside the top-level module.

So for example, both of the following would do the same job, albeit in a slightly different way:

```
// -- module.js --
export { function1 as newFunctionName, function2 as anotherNewFunctionName };

// -- main.js --
import { newFunctionName, anotherNewFunctionName } from "./modules/module.js";
```

```
// -- module.js --
export { function1, function2 };

// -- main.js --
import {
  function1 as newFunctionName,
  function2 as anotherNewFunctionName,
} from "./modules/module.js";
```

Let's look at a real example. In our renaming directory you'll see the same module system as in the previous example, except that we've added `circle.js` and `triangle.js` modules to draw and report on circles and triangles.

Inside each of these modules, we've got features with the same names being exported, and therefore each has the same `export` statement at the bottom:

```
export { name, draw, reportArea, reportPerimeter };
```

When importing these into `main.js`, if we tried to use

```
import { name, draw, reportArea, reportPerimeter } from "./modules/square.js";
import { name, draw, reportArea, reportPerimeter } from "./modules/circle.js";
import { name, draw, reportArea, reportPerimeter } from "./modules/triangle.js";
```

The browser would throw an error such as "SyntaxError: redeclaration of import name" (Firefox).

Instead we need to rename the imports so that they are unique:

```
import {
  name as squareName,
  draw as drawSquare,
  reportArea as reportSquareArea,
  reportPerimeter as reportSquarePerimeter,
} from "./modules/square.js";

import {
  name as circleName,
  draw as drawCircle,
  reportArea as reportCircleArea,
  reportPerimeter as reportCirclePerimeter,
} from "./modules/circle.js";

import {
  name as triangleName,
  draw as drawTriangle,
  reportArea as reportTriangleArea,
  reportPerimeter as reportTrianglePerimeter,
} from "./modules/triangle.js";
```

Note that you could solve the problem in the module files instead, e.g.

```
// in square.js
export {
  name as squareName,
  draw as drawSquare,
  reportArea as reportSquareArea,
  reportPerimeter as reportSquarePerimeter,
};
```

```
// in main.js
import {
  squareName,
  drawSquare,
  reportSquareArea,
  reportSquarePerimeter,
} from "./modules/square.js";
```

And it would work just the same. What style you use is up to you, however it arguably makes more sense to leave your module code alone, and make the changes in the imports. This especially makes sense when you are importing from third party modules that you don't have any control over.

Creating a module object

The above method works OK, but it's a little messy and long-winded. An even better solution is to import each module's features inside a module object. The following syntax form does that:

```
import * as Module from "./modules/module.js";
```

This grabs all the exports available inside `module.js`, and makes them available as members of an object `Module`, effectively giving it its own namespace. So for example:

```
Module.function1();
Module.function2();
```

Again, let's look at a real example. If you go to our module-objects directory, you'll see the same example again, but rewritten to take advantage of this new syntax. In the modules, the exports are all in the following simple form:

```
export { name, draw, reportArea, reportPerimeter };
```

The imports on the other hand look like this:

```
import * as Canvas from "./modules/canvas.js";

import * as Square from "./modules/square.js";
import * as Circle from "./modules/circle.js";
import * as Triangle from "./modules/triangle.js";
```

In each case, you can now access the module's imports underneath the specified object name, for example:

```
const square = Square.draw(myCanvas.ctx, 50, 50, 100, "blue");
Square.reportArea(square.length, reportList);
Square.reportPerimeter(square.length, reportList);
```

So you can now write the code just the same as before (as long as you include the object names where needed), and the imports are much neater.

Modules and classes

As we hinted at earlier, you can also export and import classes; this is another option for avoiding conflicts in your code, and is especially useful if you've already got your module code written in an object-oriented style.

You can see an example of our shape drawing module rewritten with ES classes in our classes directory. As an example, the `square.js` file now contains all its functionality in a single class:

```
class Square {
  constructor(ctx, listId, length, x, y, color) {
    // …
  }

  draw() {
    // …
  }

  // …
}
```

which we then export:

```
export { Square };
```

Over in `main.js`, we import it like this:

```
import { Square } from "./modules/square.js";
```

And then use the class to draw our square:

```
const square = new Square(myCanvas.ctx, myCanvas.listId, 50, 50, 100, "blue");
square.draw();
square.reportArea();
square.reportPerimeter();
```

Aggregating modules

There will be times where you'll want to aggregate modules together. You might have multiple levels of dependencies, where you want to simplify things, combining several submodules into one parent module. This is possible using export syntax of the following forms in the parent module:

```
export * from "x.js";
export { name } from "x.js";
```

For an example, see our module-aggregation directory. In this example (based on our earlier classes example) we've got an extra module called `shapes.js`, which aggregates all the functionality from `circle.js`, `square.js`, and `triangle.js` together. We've also moved our submodules inside a subdirectory inside the `modules` directory called `shapes`. So the module structure in this example is:

```
modules/
  canvas.js
  shapes.js
  shapes/
    circle.js
    square.js
    triangle.js
```

In each of the submodules, the export is of the same form, e.g.

```
export { Square };
```

Next up comes the aggregation part. Inside `shapes.js`, we include the following lines:

```
export { Square } from "./shapes/square.js";
export { Triangle } from "./shapes/triangle.js";
export { Circle } from "./shapes/circle.js";
```

These grab the exports from the individual submodules and effectively make them available from the `shapes.js` module.

> **Note:** The exports referenced in `shapes.js` basically get redirected through the file and don't really exist there, so you won't be able to write any useful related code inside the same file.

So now in the `main.js` file, we can get access to all three module classes by replacing

```
import { Square } from "./modules/square.js";
import { Circle } from "./modules/circle.js";
import { Triangle } from "./modules/triangle.js";
```

with the following single line:

```
import { Square, Circle, Triangle } from "./modules/shapes.js";
```

Dynamic module loading

A recent addition to JavaScript modules functionality is dynamic module loading. This allows you to dynamically load modules only when they are needed, rather than having to load everything up front. This has some obvious performance advantages; let's read on and see how it works.

This new functionality allows you to call `import()` as a function, passing it the path to the module as a parameter. It returns a `Promise`, which fulfills with a module object (see Creating a module object) giving you access to that object's exports. For example:

```
import("./modules/myModule.js").then((module) => {
  // Do something with the module.
});
```

> **Note:** Dynamic import is permitted in the browser main thread, and in shared and dedicated workers. However `import()` will throw if called in a service worker or worklet.

Let's look at an example. In the dynamic-module-imports directory we've got another example based on our classes example. This time however we are not drawing anything on the canvas when the example loads. Instead, we include three buttons — "Circle", "Square", and "Triangle" — that, when pressed, dynamically load the required module and then use it to draw the associated shape.

In this example we've only made changes to our `index.html` and `main.js` files — the module exports remain the same as before.

Over in `main.js` we've grabbed a reference to each button using a `document.querySelector()` call, for example:

```
const squareBtn = document.querySelector(".square");
```

We then attach an event listener to each button so that when pressed, the relevant module is dynamically loaded and used to draw the shape:

```
squareBtn.addEventListener("click", () => {
  import("./modules/square.js").then((Module) => {
    const square = new Module.Square(
      myCanvas.ctx,
      myCanvas.listId,
      50,
      50,
      100,
      "blue",
    );
    square.draw();
    square.reportArea();
    square.reportPerimeter();
  });
});
```

Note that, because the promise fulfillment returns a module object, the class is then made a subfeature of the object, hence we now need to access the constructor with `Module.` prepended to it, e.g., `Module.Square( /* … */ )`.

Another advantage of dynamic imports is that they are always available, even in script environments. Therefore, if you have an existing `<script>` tag in your HTML that doesn't have `type="module"`, you can still reuse code distributed as modules by dynamically importing it.

```
<script>
  import("./modules/square.js").then((module) => {
    // Do something with the module.
  });
  // Other code that operates on the global scope and is not
  // ready to be refactored into modules yet.
  var btn = document.querySelector(".square");
</script>
```

Top level await

Top level await is a feature available within modules. This means the `await` keyword can be used. It allows modules to act as big asynchronous functions meaning code can be evaluated before use in parent modules, but without blocking sibling modules from loading.

Let's take a look at an example. You can find all the files and code described in this section within the `top-level-await` directory, which extends from the previous examples.

Firstly we'll declare our color palette in a separate `colors.json` file:

```
{
  "yellow": "#F4D03F",
  "green": "#52BE80",
  "blue": "#5499C7",
  "red": "#CD6155",
  "orange": "#F39C12"
}
```

Then we'll create a module called `getColors.js` which uses a fetch request to load the `colors.json` file and return the data as an object.

```
// fetch request
const colors = fetch("../data/colors.json").then((response) => response.json());

export default await colors;
```

Notice the last export line here.

We're using the keyword `await` before specifying the constant `colors` to export. This means any other modules which include this one will wait until `colors` has been downloaded and parsed before using it.

Let's include this module in our `main.js` file:

```
import colors from "./modules/getColors.js";
import { Canvas } from "./modules/canvas.js";

const circleBtn = document.querySelector(".circle");

// …
```

We'll use `colors` instead of the previously used strings when calling our shape functions:

```
const square = new Module.Square(
  myCanvas.ctx,
  myCanvas.listId,
  50,
  50,
  100,
  colors.blue,
);

const circle = new Module.Circle(
  myCanvas.ctx,
  myCanvas.listId,
  75,
  200,
  100,
  colors.green,
);

const triangle = new Module.Triangle(
  myCanvas.ctx,
  myCanvas.listId,
  100,
  75,
  190,
  colors.yellow,
);
```

This is useful because the code within `main.js` won't execute until the code in `getColors.js` has run. However it won't block other modules being loaded. For instance our `canvas.js` module will continue to load while `colors` is being fetched.

Import declarations are hoisted

Import declarations are hoisted. In this case, it means that the imported values are available in the module's code even before the place that declares them, and that the imported module's side effects are produced before the rest of the module's code starts running.

So for example, in `main.js`, importing `Canvas` in the middle of the code would still work:

```
// …
const myCanvas = new Canvas("myCanvas", document.body, 480, 320);
myCanvas.create();
import { Canvas } from "./modules/canvas.js";
myCanvas.createReportList();
// …
```

Still, it is considered good practice to put all your imports at the top of the code, which makes it easier to analyze dependencies.

Cyclic imports

Modules can import other modules, and those modules can import other modules, and so on. This forms a directed graph called the "dependency graph". In an ideal world, this graph is acyclic. In this case, the graph can be evaluated using a depth-first traversal.

However, cycles are often inevitable. Cyclic import arises if module `a` imports module `b`, but `b` directly or indirectly depends on `a`. For example:

```
// -- a.js --
import { b } from "./b.js";

// -- b.js --
import { a } from "./a.js";

// Cycle:
// a.js ——> b.js
//  ^         |
//  └─────────┘
```

Cyclic imports don't always fail. The imported variable's value is only retrieved when the variable is actually used (hence allowing live bindings), and only if the variable remains uninitialized at that time will a `ReferenceError` be thrown.

```
// -- a.js --
import { b } from "./b.js";

setTimeout(() => {
  console.log(b); // 1
}, 10);

export const a = 2;

// -- b.js --
import { a } from "./a.js";

setTimeout(() => {
  console.log(a); // 2
}, 10);

export const b = 1;
```

In this example, both `a` and `b` are used asynchronously. Therefore, at the time the module is evaluated, neither `b` nor `a` is actually read, so the rest of the code is executed as normal, and the two `export` declarations produce the values of `a` and `b`. Then, after the timeout, both `a` and `b` are available, so the two `console.log` statements also execute as normal.

If you change the code to use `a` synchronously, the module evaluation fails:

```
// -- a.js (entry module) --
import { b } from "./b.js";

export const a = 2;

// -- b.js --
import { a } from "./a.js";

console.log(a); // ReferenceError: Cannot access 'a' before initialization
export const b = 1;
```

This is because when JavaScript evaluates `a.js`, it needs to first evaluate `b.js`, the dependency of `a.js`. However, `b.js` uses `a`, which is not yet available.

On the other hand, if you change the code to use `b` synchronously but `a` asynchronously, the module evaluation succeeds:

```
// -- a.js (entry module) --
import { b } from "./b.js";

console.log(b); // 1
```

```
export const a = 2;

// -- b.js --
import { a } from "./a.js";

setTimeout(() => {
  console.log(a); // 2
}, 10);
export const b = 1;
```

This is because the evaluation of `b.js` completes normally, so the value of `b` is available when `a.js` is evaluated.

You should usually avoid cyclic imports in your project, because they make your code more error-prone. Some common cycle-elimination techniques are:

- Merge the two modules into one.
- Move the shared code into a third module.
- Move some code from one module to the other.

However, cyclic imports can also occur if the libraries depend on each other, which is harder to fix.

Authoring "isomorphic" modules

The introduction of modules encourages the JavaScript ecosystem to distribute and reuse code in a modular fashion. However, that doesn't necessarily mean a piece of JavaScript code can run in every environment. Suppose you discovered a module that generates SHA hashes of your user's password. Can you use it in the browser front end? Can you use it on your Node.js server? The answer is: it depends.

Modules still have access to global variables, as demonstrated previously. If the module references globals like `window`, it can run in the browser, but will throw an error in your Node.js server, because `window` is not available there. Similarly, if the code requires access to `process` to be functional, it can only be used in Node.js.

In order to maximize the reusability of a module, it is often advised to make the code "isomorphic" — that is, exhibits the same behavior in every runtime. This is commonly achieved in three ways:

- Separate your modules into "core" and "binding". For the "core", focus on pure JavaScript logic like computing the hash, without any DOM, network, filesystem access, and expose utility functions. For the "binding" part, you can read from and write to the global context. For example, the "browser binding" may choose to read the value from an input box, while the "Node binding" may read it from `process.env`, but values read from either place will be piped to the same core function and handled in the same way. The core can be imported in every environment and used in the same way, while only the binding, which is usually lightweight, needs to be platform-specific.
- Detect whether a particular global exists before using it. For example, if you test that `typeof window === "undefined"`, you know that you are probably in a Node.js environment, and should not read DOM.

  ```
  // myModule.js
  let password;
  if (typeof process !== "undefined") {
    // We are running in Node.js; read it from `process.env`
    password = process.env.PASSWORD;
  } else if (typeof window !== "undefined") {
    // We are running in the browser; read it from the input box
    password = document.getElementById("password").value;
  }
  ```

  This is preferable if the two branches actually end up with the same behavior ("isomorphic"). If it's impossible to provide the same functionality, or if doing so involves loading significant amounts of code while a large part remains unused, better use different "bindings" instead.
- Use a polyfill to provide a fallback for missing features. For example, if you want to use the `fetch` function, which is only supported in Node.js since v18, you can use a similar API, like the one provided by `node-fetch`. You can do so conditionally through dynamic imports:

  ```
  // myModule.js
  if (typeof fetch === "undefined") {
    // We are running in Node.js; use node-fetch
    globalThis.fetch = (await import("node-fetch")).default;
  }
  // …
  ```

  The `globalThis` variable is a global object that is available in every environment and is useful if you want to read or create global variables within modules.

These practices are not unique to modules. Still, with the trend of code reusability and modularization, you are encouraged to make your code cross-platform so that it can be enjoyed by as many people as possible. Runtimes like Node.js are also actively implementing web APIs where possible to improve interoperability with the web.

Troubleshooting

Here are a few tips that may help you if you are having trouble getting your modules to work. Feel free to add to the list if you discover more!

- We mentioned this before, but to reiterate: `.mjs` files need to be loaded with a MIME-type of `text/javascript` (or another JavaScript-compatible MIME-type, but `text/javascript` is recommended), otherwise you'll get a strict MIME type checking error like "The server responded with a non-JavaScript MIME type".
- If you try to load the HTML file locally (i.e., with a `file://` URL), you'll run into CORS errors due to JavaScript module security requirements. You need to do your testing through a server. GitHub pages is ideal as it also serves `.mjs` files with the correct MIME type.
- Because `.mjs` is a non-standard file extension, some operating systems might not recognize it, or try to replace it with something else. For example, we found that macOS was silently adding on `.js` to the end of `.mjs` files and then automatically hiding the file extension. So all of our files were actually coming out as `x.mjs.js`. Once we turned off automatically hiding file extensions, and trained it to accept `.mjs`, it was OK.

Numbers and strings

- Previous
- Next

This chapter introduces the two most fundamental data types in JavaScript: numbers and strings. We will introduce their underlying representations, and functions used to work with and perform calculations on them.

Numbers

In JavaScript, numbers are implemented in double-precision 64-bit binary format IEEE 754 (i.e., a number between ±2^−1022 and ±2^+1023, or about ±10^−308 to ±10^+308, with a numeric precision of 53 bits). Integer values up to ±2^53 − 1 can be represented exactly.

In addition to being able to represent floating-point numbers, the number type has three symbolic values: `Infinity`, `-Infinity`, and `NaN` (not-a-number).

See also JavaScript data types and structures for context with other primitive types in JavaScript.

You can use four types of number literals: decimal, binary, octal, and hexadecimal.

Decimal numbers

```
1234567890
42
```

Decimal literals can start with a zero (`0`) followed by another decimal digit, but if all digits after the leading `0` are smaller than 8, the number is interpreted as an octal number. This is considered a legacy syntax, and number literals prefixed with `0`, whether interpreted as octal or decimal, cause a syntax error in strict mode — so, use the `0o` prefix instead.

```
0888 // 888 parsed as decimal
0777 // parsed as octal, 511 in decimal
```

Binary numbers

Binary number syntax uses a leading zero followed by a lowercase or uppercase Latin letter "B" (`0b` or `0B`). If the digits after the `0b` are not 0 or 1, the following `SyntaxError` is thrown: "Missing binary digits after 0b".

```
0b10000000000000000000000000000000 // 2147483648
0b01111111100000000000000000000000 // 2139095040
0B00000000011111111111111111111111 // 8388607
```

Octal numbers

The standard syntax for octal numbers is to prefix them with `0o`. For example:

```
0O755 // 493
0o644 // 420
```

There's also a legacy syntax for octal numbers — by prefixing the octal number with a zero: `0644 === 420` and `"\045" === "%"`. If the digits after the `0` are outside the range 0 through 7, the number will be interpreted as a decimal number.

```
const n = 0755; // 493
const m = 0644; // 420
```

Strict mode forbids this octal syntax.

Hexadecimal numbers

Hexadecimal number syntax uses a leading zero followed by a lowercase or uppercase Latin letter "X" (`0x` or `0X`). If the digits after 0x are outside the range (0123456789ABCDEF), the following `SyntaxError` is thrown: "Identifier starts immediately after numeric literal".

```
0xFFFFFFFFFFFFF // 4503599627370495
0xabcdef123456  // 188900967593046
0XA             // 10
```

Exponentiation

```
0e-5   // 0
0e+5   // 0
5e1    // 50
175e-2 // 1.75
1e3    // 1000
```

```
1e-3   // 0.001
1E3    // 1000
```

Numeric separators

For all literal syntaxes shown above, an underscore (_) can be inserted between digits to improve readability.

```
1_000_000_000_000
1_050.95
0b1010_0001_1000_0101
0o2_2_5_6
0xA0_B0_C0
1_000_000_000_000_000_000_000n
```

See the lexical grammar reference for more details about number literals.

Number object

The built-in `Number` object has properties for numerical constants, such as maximum value, not-a-number, and infinity. You cannot change the values of these properties and you use them as follows:

```
const biggestNum = Number.MAX_VALUE;
const smallestNum = Number.MIN_VALUE;
const infiniteNum = Number.POSITIVE_INFINITY;
const negInfiniteNum = Number.NEGATIVE_INFINITY;
const notANum = Number.NaN;
```

You always refer to a property of the predefined `Number` object as shown above, and not as a property of a `Number` object you create yourself.

The following table summarizes the `Number` object's properties.

Property	Description
`Number.MAX_VALUE`	The largest positive representable number (`1.7976931348623157e+308`)
`Number.MIN_VALUE`	The smallest positive representable number (`5e-324`)
`Number.NaN`	Special "not a number" value
`Number.NEGATIVE_INFINITY`	Special negative infinite value; returned on overflow
`Number.POSITIVE_INFINITY`	Special positive infinite value; returned on overflow
`Number.EPSILON`	Difference between `1` and the smallest value greater than `1` that can be represented as a `Number` (`2.220446049250313e-16`)
`Number.MIN_SAFE_INTEGER`	Minimum safe integer in JavaScript (−2^53 + 1, or `-9007199254740991`)
`Number.MAX_SAFE_INTEGER`	Maximum safe integer in JavaScript (+2^53 − 1, or `+9007199254740991`)

Method	Description
`Number.parseFloat()`	Parses a string argument and returns a floating point number. Same as the global `parseFloat()` function.
`Number.parseInt()`	Parses a string argument and returns an integer of the specified radix or base. Same as the global `parseInt()` function.
`Number.isFinite()`	Determines whether the passed value is a finite number.
`Number.isInteger()`	Determines whether the passed value is an integer.
`Number.isNaN()`	Determines whether the passed value is `NaN`. More robust version of the original global `isNaN()`.
`Number.isSafeInteger()`	Determines whether the provided value is a number that is a *safe integer*.

The `Number` prototype provides methods for retrieving information from `Number` objects in various formats. The following table summarizes the methods of `Number.prototype`.

Method	Description
`toExponential()`	Returns a string representing the number in exponential notation.
`toFixed()`	Returns a string representing the number in fixed-point notation.
`toPrecision()`	Returns a string representing the number to a specified precision in fixed-point notation.

Math object

The built-in `Math` object has properties and methods for mathematical constants and functions. For example, the `Math` object's `PI` property has the value of pi (3.141...), which you would use in an application as

```
Math.PI;
```

Similarly, standard mathematical functions are methods of `Math`. These include trigonometric, logarithmic, exponential, and other functions. For example, if you want to use the trigonometric function sine, you would write

```
Math.sin(1.56);
```

Note that all trigonometric methods of `Math` take arguments in radians.

The following table summarizes the `Math` object's methods.

Methods of `Math`

Method	Description
`abs()`	Absolute value
`sin()`, `cos()`, `tan()`	Standard trigonometric functions; with the argument in radians.
`asin()`, `acos()`, `atan()`, `atan2()`	Inverse trigonometric functions; return values in radians.
`sinh()`, `cosh()`, `tanh()`	Hyperbolic functions; argument in hyperbolic angle.
`asinh()`, `acosh()`, `atanh()`	Inverse hyperbolic functions; return values in hyperbolic angle.
`pow()`, `exp()`, `expm1()`, `log()`, `log10()`, `log1p()`, `log2()`	Exponential and logarithmic functions.
`floor()`, `ceil()`	Returns the largest/smallest integer less/greater than or equal to an argument.
`min()`, `max()`	Returns the minimum or maximum (respectively) value of a comma separated list of numbers as arguments.
`random()`	Returns a random number between 0 and 1.
`round()`, `fround()`, `trunc()`,	Rounding and truncation functions.
`sqrt()`, `cbrt()`, `hypot()`	Square root, cube root, Square root of the sum of square arguments.
`sign()`	The sign of a number, indicating whether the number is positive, negative or zero.
`clz32()`, `imul()`	Number of leading zero bits in the 32-bit binary representation. The result of the C-like 32-bit multiplication of the two arguments.

Unlike many other objects, you never create a `Math` object of your own. You always use the built-in `Math` object.

BigInts

One shortcoming of number values is they only have 64 bits. In practice, due to using IEEE 754 encoding, they cannot represent any integer larger than `Number.MAX_SAFE_INTEGER` (which is 2^{53} - 1) accurately. To solve the need of encoding binary data and to interoperate with other languages that offer wide integers like `i64` (64-bit integers) and `i128` (128-bit integers), JavaScript also offers another data type to represent *arbitrarily large integers*: `BigInt`.

A BigInt can be defined as an integer literal suffixed by `n`:

```
const b1 = 123n;
// Can be arbitrarily large.
const b2 = -1234567890987654321n;
```

BigInts can also be constructed from number values or string values using the `BigInt` constructor.

```
const b1 = BigInt(123);
// Using a string prevents loss of precision, since long number
// literals don't represent what they seem like.
const b2 = BigInt("-1234567890987654321");
```

Conceptually, a BigInt is just an arbitrarily long sequence of bits which encodes an integer. You can safely do any arithmetic operations without losing precision or over-/underflowing.

```
const integer = 12 ** 34; // 4.9222352429520264e+36; only has limited precision
const bigint = 12n ** 34n; // 4922235242952026704037113243122008064n
```

Compared to numbers, BigInt values yield higher precision when representing large *integers*; however, they cannot represent *floating-point numbers*. For example, division would round to zero:

```
const bigintDiv = 5n / 2n; // 2n, because there's no 2.5 in BigInt
```

`Math` functions cannot be used on BigInt values; they only work with numbers.

Choosing between BigInt and number depends on your use-case and your input's range. The precision of numbers should be able to accommodate most day-to-day tasks already, and BigInts are most suitable for handling binary data.

Read more about what you can do with BigInt values in the Expressions and Operators section, or the BigInt reference.

Strings

JavaScript's String type is used to represent textual data. It is a set of "elements" of 16-bit unsigned integer values (UTF-16 code units). Each element in the String occupies a position in the String. The first element is at index 0, the next at index 1, and so on. The length of a String is the number of elements in it. You can create strings using string literals or string objects.

String literals

You can declare strings in source code using either single or double quotes:

```
'foo'
"bar"
```

Within a string literal, most characters can be entered literally. The only exceptions are the backslash (`\`, which starts an escape sequence), the quote character being used to enclose the string, which terminates the string, and the newline character, which is a syntax error if not preceded by a backslash.

More advanced strings can be created using escape sequences:

Hexadecimal escape sequences

The number after `\x` is interpreted as a hexadecimal number.

```
"\xA9" // "©"
```

Unicode escape sequences

The Unicode escape sequences require at least four hexadecimal digits following `\u`.

```
"\u00A9" // "©"
```

Unicode code point escapes

With Unicode code point escapes, any character can be escaped using hexadecimal numbers so that it is possible to use Unicode code points up to `0x10FFFF`. With the four-digit Unicode escapes it is often necessary to write the surrogate halves separately to achieve the same result.

See also `String.fromCodePoint()` or `String.prototype.codePointAt()`.

```
"\u{2F804}"

// the same with simple Unicode escapes
"\uD87E\uDC04"
```

String object

You can call methods directly on a string value:

```
console.log("hello".toUpperCase()); // HELLO
```

The following methods are available on `String` values:

- Query: get the character or character code at a particular string index. Methods include `at()`, `charAt()`, `charCodeAt()`, and `codePointAt()`.
- Search: get information about a substring that conforms to a pattern, or test if a particular substring exists. Methods include `indexOf()`, `lastIndexOf()`, `startsWith()`, `endsWith()`, `includes()`, `match()`, `matchAll()`, and `search()`
- Composition: combine strings into a longer string. Methods include `padStart()`, `padEnd()`, `concat()`, and `repeat()`.
- Decomposition: break a string into smaller strings. Methods include `split()`, `slice()`, `substring()`, `substr()`, `trim()`, `trimStart()`, and `trimEnd()`.
- Transformation: return a new string based on the current string's content. Methods include `toLowerCase()`, `toUpperCase()`, `toLocaleLowerCase()`, `toLocaleUpperCase()`, `normalize()`, and `toWellFormed()`.

When working with strings, there are two other objects that provide important functionality for string manipulation: `RegExp` and `Intl`. They are introduced in regular expressions and internationalization respectively.

Template literals

Template literals are string literals allowing embedded expressions. You can use multi-line strings and string interpolation features with them.

Template literals are enclosed by backtick (grave accent) characters (`` ` ``) instead of double or single quotes. Template literals can contain placeholders. These are indicated by the dollar sign and curly braces (`${expression}`).

Multi-lines

Any new line characters inserted in the source are part of the template literal. Using normal strings, you would have to use the following syntax in order to get multi-line strings:

```
console.log(
  "string text line 1\n\
string text line 2",
);
// "string text line 1
// string text line 2"
```

To get the same effect with multi-line strings, you can now write:

```
console.log(`string text line 1
string text line 2`);
// "string text line 1
// string text line 2"
```

Embedded expressions

In order to embed expressions within normal strings, you would use the following syntax:

```
const five = 5;
const ten = 10;
```

```
console.log(
  "Fifteen is " + (five + ten) + " and not " + (2 * five + ten) + ".",
);
// "Fifteen is 15 and not 20."
```

Now, with template literals, you are able to make use of the syntactic sugar making substitutions like this more readable:

```
const five = 5;
const ten = 10;
console.log(`Fifteen is ${five + ten} and not ${2 * five + ten}.`);
// "Fifteen is 15 and not 20."
```

For more information, read about Template literals in the JavaScript reference.

Regular expressions

- Previous
- Next

Regular expressions are patterns used to match character combinations in strings. In JavaScript, regular expressions are also objects. These patterns are used with the `exec()` and `test()` methods of `RegExp`, and with the `match()`, `matchAll()`, `replace()`, `replaceAll()`, `search()`, and `split()` methods of `String`. This chapter describes JavaScript regular expressions. It provides a brief overview of each syntax element. For a detailed explanation of each one's semantics, read the regular expressions reference.

Creating a regular expression

You construct a regular expression in one of two ways:

- Using a regular expression literal, which consists of a pattern enclosed between slashes, as follows:

  ```
  const re = /ab+c/;
  ```

  Regular expression literals provide compilation of the regular expression when the script is loaded. If the regular expression remains constant, using this can improve performance.

- Or calling the constructor function of the `RegExp` object, as follows:

  ```
  const re = new RegExp("ab+c");
  ```

  Using the constructor function provides runtime compilation of the regular expression. Use the constructor function when you know the regular expression pattern will be changing, or you don't know the pattern and are getting it from another source, such as user input.

Writing a regular expression pattern

A regular expression pattern is composed of simple characters, such as `/abc/`, or a combination of simple and special characters, such as `/ab*c/` or `/Chapter (\d+)\.\d*/`. The last example includes parentheses, which are used as a memory device. The match made with this part of the pattern is remembered for later use, as described in Using groups.

Using simple patterns

Simple patterns are constructed of characters for which you want to find a direct match. For example, the pattern `/abc/` matches character combinations in strings only when the exact sequence `"abc"` occurs (all characters together and in that order). Such a match would succeed in the strings `"Hi, do you know your abc's?"` and `"The latest airplane designs evolved from slabcraft."`. In both cases the match is with the substring `"abc"`. There is no match in the string `"Grab crab"` because while it contains the substring `"ab c"`, it does not contain the exact substring `"abc"`.

Using special characters

When the search for a match requires something more than a direct match, such as finding one or more b's, or finding white space, you can include special characters in the pattern. For example, to match *a single `"a"` followed by zero or more `"b"`s followed by `"c"`*, you'd use the pattern `/ab*c/`: the `*` after `"b"` means "0 or more occurrences of the preceding item." In the string `"cbbabbbbcdebc"`, this pattern will match the substring `"abbbbc"`.

The following pages provide lists of the different special characters that fit into each category, along with descriptions and examples.

Assertions guide

> Assertions include boundaries, which indicate the beginnings and endings of lines and words, and other patterns indicating in some way that a match is possible (including look-ahead, look-behind, and conditional expressions).

Character classes guide

> Distinguish different types of characters. For example, distinguishing between letters and digits.

Groups and backreferences guide

> Groups group multiple patterns as a whole, and capturing groups provide extra submatch information when using a regular expression pattern to match against a string. Backreferences refer to a previously captured group in the same regular expression.

Quantifiers guide

Indicate numbers of characters or expressions to match.

If you want to look at all the special characters that can be used in regular expressions in a single table, see the following:

Special characters in regular expressions.

Characters / constructs	Corresponding article
`[xyz]`, `[^xyz]`, `.`, `\d`, `\D`, `\w`, `\W`, `\s`, `\S`, `\t`, `\r`, `\n`, `\v`, `\f`, `[\b]`, `\0`, `\cX`, `\xHH`, `\uHHHH`, `\u{H…H}`, `x|y`	Character classes
`^`, `$`, `\b`, `\B`, `x(?=y)`, `x(?!y)`, `(?<=y)x`, `(?<!y)x`	Assertions
`(x)`, `(?<Name>x)`, `(?:x)`, `\n`, `\k<Name>`	Groups and backreferences
`x*`, `x+`, `x?`, `x{n}`, `x{n,}`, `x{n,m}`	Quantifiers

> **Note:** A larger cheat sheet is also available (only aggregating parts of those individual articles).

Escaping

If you need to use any of the special characters literally (actually searching for a `"*"`, for instance), you should escape it by putting a backslash in front of it. For instance, to search for `"a"` followed by `"*"` followed by `"b"`, you'd use `/a\*b/` — the backslash "escapes" the `"*"`, making it literal instead of special.

> **Note:** In many cases, when trying match a special character, you can wrap it in a character class as an alternative to escaping, for example `/a[*]b/`.

Similarly, if you're writing a regular expression literal and need to match a slash ("/"), you need to escape that (otherwise, it terminates the pattern). For instance, to search for the string "/example/" followed by one or more alphabetic characters, you'd use `/\/example\/[a-z]+/i`—the backslashes before each slash make them literal.

To match a literal backslash, you need to escape the backslash. For instance, to match the string "C:\" where "C" can be any letter, you'd use `/[A-Z]:\\/` — the first backslash escapes the one after it, so the expression searches for a single literal backslash.

If using the `RegExp` constructor with a string literal, remember that the backslash is an escape in string literals, so to use it in the regular expression, you need to escape it at the string literal level. `/a\*b/` and `new RegExp("a\\*b")` create the same expression, which searches for "a" followed by a literal "*" followed by "b".

The `RegExp.escape()` function returns a new string where all special characters in regex syntax are escaped. This allows you to do `new RegExp(RegExp.escape("a*b"))` to create a regular expression that matches only the string `"a*b"`.

Using parentheses

Parentheses around any part of the regular expression pattern causes that part of the matched substring to be remembered. Once remembered, the substring can be recalled for other use. See Groups and backreferences for more details.

Using regular expressions in JavaScript

Regular expressions are used with the `RegExp` methods `test()` and `exec()` and with the `String` methods `match()`, `matchAll()`, `replace()`, `replaceAll()`, `search()`, and `split()`.

Method	Description
`exec()`	Executes a search for a match in a string. It returns an array of information or `null` on a mismatch.
`test()`	Tests for a match in a string. It returns `true` or `false`.
`match()`	Returns an array containing all of the matches, including capturing groups, or `null` if no match is found.
`matchAll()`	Returns an iterator containing all of the matches, including capturing groups.
`search()`	Tests for a match in a string. It returns the index of the match, or `-1` if the search fails.
`replace()`	Executes a search for a match in a string, and replaces the matched substring with a replacement substring.
`replaceAll()`	Executes a search for all matches in a string, and replaces the matched substrings with a replacement substring.
`split()`	Uses a regular expression or a fixed string to break a string into an array of substrings.

When you want to know whether a pattern is found in a string, use the `test()` or `search()` methods; for more information (but slower execution) use the `exec()` or `match()` methods. If you use `exec()` or `match()` and if the match succeeds, these methods return an array and update properties of the associated regular expression object and also of the predefined regular expression object, `RegExp`. If the match fails, the `exec()` method returns `null` (which coerces to `false`).

In the following example, the script uses the `exec()` method to find a match in a string.

```
const myRe = /d(b+)d/g;
const myArray = myRe.exec("cdbbdbsbz");
```

If you do not need to access the properties of the regular expression, an alternative way of creating `myArray` is with this script:

```
const myArray = /d(b+)d/g.exec("cdbbdbsbz");
// similar to 'cdbbdbsbz'.match(/d(b+)d/g); however,
// 'cdbbdbsbz'.match(/d(b+)d/g) outputs [ "dbbd" ]
// while /d(b+)d/g.exec('cdbbdbsbz') outputs [ 'dbbd', 'bb', index: 1, input: 'cdbbdbsbz' ]
```

(See Using the global search flag with `exec()` for further info about the different behaviors.)

If you want to construct the regular expression from a string, yet another alternative is this script:

```
const myRe = new RegExp("d(b+)d", "g");
const myArray = myRe.exec("cdbbdbsbz");
```

With these scripts, the match succeeds and returns the array and updates the properties shown in the following table.

Results of regular expression execution.

Object	Property or index	Description	In this example
`myArray`		The matched string and all remembered substrings.	`['dbbd', 'bb', index: 1, input: 'cdbbdbsbz']`
	`index`	The 0-based index of the match in the input string.	`1`
	`input`	The original string.	`'cdbbdbsbz'`
	`[0]`	The last matched characters.	`'dbbd'`
`myRe`	`lastIndex`	The index at which to start the next match. (This property is set only if the regular expression uses the g option, described in Advanced Searching With Flags.)	`5`
	`source`	The text of the pattern. Updated at the time that the regular expression is created, not executed.	`'d(b+)d'`

As shown in the second form of this example, you can use a regular expression created with an object initializer without assigning it to a variable. If you do, however, every occurrence is a new regular expression. For this reason, if you use this form without assigning it to a variable, you cannot subsequently access the properties of that regular expression. For example, assume you have this script:

```
const myRe = /d(b+)d/g;
const myArray = myRe.exec("cdbbdbsbz");
console.log(`The value of lastIndex is ${myRe.lastIndex}`);

// "The value of lastIndex is 5"
```

However, if you have this script:

```
const myArray = /d(b+)d/g.exec("cdbbdbsbz");
console.log(`The value of lastIndex is ${/d(b+)d/g.lastIndex}`);

// "The value of lastIndex is 0"
```

The occurrences of `/d(b+)d/g` in the two statements are different regular expression objects and hence have different values for their `lastIndex` property. If you need to access the properties of a regular expression created with an object initializer, you should first assign it to a variable.

Advanced searching with flags

Regular expressions have optional flags that allow for functionality like global searching and case-insensitive searching. These flags can be used separately or together in any order, and are included as part of the regular expression.

Flag	Description	Corresponding property
`d`	Generate indices for substring matches.	`hasIndices`
`g`	Global search.	`global`
`i`	Case-insensitive search.	`ignoreCase`
`m`	Makes `^` and `$` match the start and end of each line instead of those of the entire string.	`multiline`
`s`	Allows `.` to match newline characters.	`dotAll`
`u`	"Unicode"; treat a pattern as a sequence of Unicode code points.	`unicode`
`v`	An upgrade to the `u` mode with more Unicode features.	`unicodeSets`
`y`	Perform a "sticky" search that matches starting at the current position in the target string.	`sticky`

To include a flag with the regular expression, use this syntax:

```
const re = /pattern/flags;
```

or

```
const re = new RegExp("pattern", "flags");
```

Note that the flags are an integral part of a regular expression. They cannot be added or removed later.

For example, `re = /\w+\s/g` creates a regular expression that looks for one or more characters followed by a space, and it looks for this combination throughout the string.

```
const re = /\w+\s/g;
const str = "fee fi fo fum";
const myArray = str.match(re);
console.log(myArray);

// ["fee ", "fi ", "fo "]
```

You could replace the line:

```
const re = /\w+\s/g;
```

with:

```
const re = new RegExp("\\w+\\s", "g");
```

and get the same result.

The `m` flag is used to specify that a multiline input string should be treated as multiple lines. If the `m` flag is used, `^` and `$` match at the start or end of any line within the input string instead of the start or end of the entire string.

The `i`, `m`, and `s` flags can be enabled or disabled for specific parts of a regex using the modifier syntax.

Using the global search flag with exec()

`RegExp.prototype.exec()` method with the `g` flag returns each match and its position iteratively.

```
const str = "fee fi fo fum";
const re = /\w+\s/g;

console.log(re.exec(str)); // ["fee ", index: 0, input: "fee fi fo fum"]
console.log(re.exec(str)); // ["fi ", index: 4, input: "fee fi fo fum"]
console.log(re.exec(str)); // ["fo ", index: 7, input: "fee fi fo fum"]
console.log(re.exec(str)); // null
```

In contrast, `String.prototype.match()` method returns all matches at once, but without their position.

```
console.log(str.match(re)); // ["fee ", "fi ", "fo "]
```

Using unicode regular expressions

The `u` flag is used to create "unicode" regular expressions; that is, regular expressions which support matching against unicode text. An important feature that's enabled in unicode mode is Unicode property escapes. For example, the following regular expression might be used to match against an arbitrary unicode "word":

```
/\p{L}*/u;
```

Unicode regular expressions have different execution behavior as well. `RegExp.prototype.unicode` contains more explanation about this.

Examples

> **Note:** Several examples are also available in:
>
> - The reference pages for `exec()`, `test()`, `match()`, `matchAll()`, `search()`, `replace()`, `split()`
> - The guide articles: character classes, assertions, groups and backreferences, quantifiers

Using special characters to verify input

In the following example, the user is expected to enter a phone number. When the user presses the "Check" button, the script checks the validity of the number. If the number is valid (matches the character sequence specified by the regular expression), the script shows a message thanking the user and confirming the number. If the number is invalid, the script informs the user that the phone number is not valid.

The regular expression looks for:

1. the beginning of the line of data: `^`
2. followed by three numeric characters `\d{3}` OR | a left parenthesis `\(`, followed by three digits `\d{3}`, followed by a close parenthesis `\)`, in a non-capturing group `(?:)`
3. followed by one dash, forward slash, or decimal point in a capturing group `()`
4. followed by three digits `\d{3}`
5. followed by the match remembered in the (first) captured group `\1`
6. followed by four digits `\d{4}`
7. followed by the end of the line of data: `$`

HTML

```
<p>
  Enter your phone number (with area code) and then click "Check".
  <br />
```

```
  The expected format is like ###-###-####.
</p>
<form id="form">
  <input id="phone" />
  <button type="submit">Check</button>
</form>
<p id="output"></p>
```

JavaScript

```
const form = document.querySelector("#form");
const input = document.querySelector("#phone");
const output = document.querySelector("#output");

const re = /^(?:\d{3}|\(\d{3}\))([-/.])\d{3}\1\d{4}$/;

function testInfo(phoneInput) {
  const ok = re.exec(phoneInput.value);

  output.textContent = ok
    ? `Thanks, your phone number is ${ok[0]}`
    : `${phoneInput.value} isn't a phone number with area code!`;
}

form.addEventListener("submit", (event) => {
  event.preventDefault();
  testInfo(input);
});
```

Assertions

Assertions include boundaries, which indicate the beginnings and endings of lines and words, and other patterns indicating in some way that a match is possible (including look-ahead, look-behind, and conditional expressions).

Try it

```
const text = "A quick fox";

const regexpLastWord = /\w+$/;
console.log(text.match(regexpLastWord));
// Expected output: Array ["fox"]

const regexpWords = /\b\w+\b/g;
console.log(text.match(regexpWords));
// Expected output: Array ["A", "quick", "fox"]

const regexpFoxQuality = /\w+(?= fox)/;
console.log(text.match(regexpFoxQuality));
// Expected output: Array ["quick"]
```

Types

Boundary-type assertions

Characters	Meaning
^	**Input boundary beginning assertion:** Matches the beginning of input. If the `multiline` (m) flag is enabled, also matches immediately after a line break character. For example, `/^A/` does not match the "A" in "an A", but does match the first "A" in "An A".

Characters	Meaning
	Note: This character has a different meaning when it appears at the start of a character class.
`$`	**Input boundary end assertion:** Matches the end of input. If the `multiline` (m) flag is enabled, also matches immediately before a line break character. For example, `/t$/` does not match the "t" in "eater", but does match it in "eat".
`\A`	**Buffer boundary start assertion:** Matches the start of the entire string regardless of the presence of the `m` flag. Only valid in Unicode-aware mode.
`\z`	**Buffer boundary end assertion:** Matches the end of the entire string regardless of the presence of the `m` flag. Only valid in Unicode-aware mode.
`\Z`	**Buffer boundary end assertion with optional newline:** Matches the end of the entire string, but allows an optional trailing newline character sequence (either a line terminator or a `\r\n` sequence). Only valid in Unicode-aware mode.
`\b`	**Word boundary assertion:** Matches a word boundary. This is the position where a word character is not followed or preceded by another word-character, such as between a letter and a space. Note that a matched word boundary is not included in the match. In other words, the length of a matched word boundary is zero. Examples: • `/\bm/` matches the "m" in "moon". • `/oo\b/` does not match the "oo" in "moon", because "oo" is followed by "n" which is a word character. • `/oon\b/` matches the "oon" in "moon", because "oon" is the end of the string, thus not followed by a word character. • `/\w\b\w/` will never match anything, because a word character can never be followed by both a non-word and a word character. To match a backspace character (`[\b]`), see Character Classes.
`\B`	**Non-word-boundary assertion:** Matches a non-word boundary. This is a position where the previous and next character are of the same type: Either both must be words, or both must be non-words, for example between two letters or between two spaces. The beginning and end of a string are considered non-words. Same as the matched word boundary, the matched non-word boundary is also not included in the match. For example, `/\Bon/` matches "on" in "at noon", and `/ye\B/` matches "ye" in "possibly yesterday".

Other assertions

> **Note:** The `?` character may also be used as a quantifier.

Characters	Meaning
`x(?=y)`	**Lookahead assertion:** Matches "x" only if "x" is followed by "y". For example, `/Jack(?=Sprat)/` matches "Jack" only if it is followed by "Sprat". `/Jack(?=Sprat|Frost)/` matches "Jack" only if it is followed by "Sprat" or "Frost". However, neither "Sprat" nor "Frost" is part of the match results.
`x(?!y)`	**Negative lookahead assertion:** Matches "x" only if "x" is not followed by "y". For example, `/\d+(?!\.)/` matches a number only if it is not followed by a decimal point. `/\d+(?!\.)/.exec('3.141')` matches "141" but not "3".
`(?<=y)x`	**Lookbehind assertion:** Matches "x" only if "x" is preceded by "y". For example, `/(?<=Jack)Sprat/` matches "Sprat" only if it is preceded by "Jack". `/(?<=Jack|Tom)Sprat/` matches "Sprat" only if it is preceded by "Jack" or "Tom". However, neither "Jack" nor "Tom" is part of the match results.
`(?<!y)x`	**Negative lookbehind assertion:** Matches "x" only if "x" is not preceded by "y". For example, `/(?<!-)\d+/` matches a number only if it is not preceded by a minus sign. `/(?<!-)\d+/.exec('3')` matches "3". `/(?<!-)\d+/.exec('-3')` match is not found because the number is preceded by the minus sign.

Examples

General boundary-type overview example

```
// Using Regex boundaries to fix buggy string.
buggyMultiline = `tey, ihe light-greon apple
tangs on ihe greon traa`;

// 1) Use ^ to fix the matching at the beginning of the string, and right after newline.
buggyMultiline = buggyMultiline.replace(/^t/gim, "h");
```

```
console.log(1, buggyMultiline); // fix 'tey' => 'hey' and 'tangs' => 'hangs' but do not touch 'traa'.

// 2) Use $ to fix matching at the end of the text.
buggyMultiline = buggyMultiline.replace(/aa$/gim, "ee.");
console.log(2, buggyMultiline); // fix 'traa' => 'tree.'.

// 3) Use \b to match characters right on border between a word and a space.
buggyMultiline = buggyMultiline.replace(/\bi/gim, "t");
console.log(3, buggyMultiline); // fix 'ihe' => 'the' but do not touch 'light'.

// 4) Use \B to match characters inside borders of an entity.
fixedMultiline = buggyMultiline.replace(/\Bo/gim, "e");
console.log(4, fixedMultiline); // fix 'greon' => 'green' but do not touch 'on'.
```

Matching the beginning of input using a ^ control character

Use `^` for matching at the beginning of input. In this example, we can get the fruits that start with 'A' by a `/^A/` regex. For selecting appropriate fruits we can use the `filter` method with an arrow function.

```
const fruits = ["Apple", "Watermelon", "Orange", "Avocado", "Strawberry"];

// Select fruits started with 'A' by /^A/ Regex.
// Here '^' control symbol used only in one role: Matching beginning of an input.

const fruitsStartsWithA = fruits.filter((fruit) => /^A/.test(fruit));
console.log(fruitsStartsWithA); // [ 'Apple', 'Avocado' ]
```

In the second example `^` is used both for matching at the beginning of input and for creating negated or complemented character class when used within character classes.

```
const fruits = ["Apple", "Watermelon", "Orange", "Avocado", "Strawberry"];

// Selecting fruits that do not start by 'A' with a /^[^A]/ regex.
// In this example, two meanings of '^' control symbol are represented:
// 1) Matching beginning of the input
// 2) A negated or complemented character class: [^A]
// That is, it matches anything that is not enclosed in the square brackets.

const fruitsStartsWithNotA = fruits.filter((fruit) => /^[^A]/.test(fruit));

console.log(fruitsStartsWithNotA); // [ 'Watermelon', 'Orange', 'Strawberry' ]
```

See more examples in the input boundary assertion reference.

Matching a word boundary

In this example, we match fruit names containing a word that ends in "en" or "ed".

```
const fruitsWithDescription = ["Red apple", "Orange orange", "Green Avocado"];

// Select descriptions that contains 'en' or 'ed' words endings:
const enEdSelection = fruitsWithDescription.filter((description) =>
  /(?:en|ed)\b/.test(description),
);

console.log(enEdSelection); // [ 'Red apple', 'Green Avocado' ]
```

See more examples in the word boundary assertion reference.

Lookahead assertion

In this example, we match the word "First" only if it is followed by the word "test", but we do not include "test" in the match results.

```
const regex = /First(?= test)/g;

console.log("First test".match(regex)); // [ 'First' ]
console.log("First peach".match(regex)); // null
console.log("This is a First test in a year.".match(regex)); // [ 'First' ]
console.log("This is a First peach in a month.".match(regex)); // null
```

See more examples in the lookahead assertion reference.

Basic negative lookahead assertion

For example, `/\d+(?!\.)/` matches a number only if it is not followed by a decimal point. `/\d+(?!\.)/.exec('3.141')` matches "141" but not "3".

```
console.log(/\d+(?!\.)/g.exec("3.141")); // [ '141', index: 2, input: '3.141' ]
```

See more examples in the lookahead assertion reference.

Different meaning of '?!' combination usage in assertions and character classes

The `?!` combination has different meanings in assertions like `/x(?!y)/` and character classes like `[^?!]`.

```
const orangeNotLemon =
  "Do you want to have an orange? Yes, I do not want to have a lemon!";

// Different meaning of '?!' combination usage in Assertions /x(?!y)/ and Ranges /[^?!]/
const selectNotLemonRegex = /[^?!]+have(?! a lemon)[^?!]+[?!]/gi;
console.log(orangeNotLemon.match(selectNotLemonRegex)); // [ 'Do you want to have an orange?' ]

const selectNotOrangeRegex = /[^?!]+have(?! an orange)[^?!]+[?!]/gi;
console.log(orangeNotLemon.match(selectNotOrangeRegex)); // [ ' Yes, I do not want to have a lemon!' ]
```

Lookbehind assertion

In this example, we replace the word "orange" with "apple" only if it is preceded by the word "ripe".

```
const oranges = ["ripe orange A", "green orange B", "ripe orange C"];

const newFruits = oranges.map((fruit) =>
  fruit.replace(/(?<=ripe )orange/, "apple"),
);
console.log(newFruits); // ['ripe apple A', 'green orange B', 'ripe apple C']
```

See more examples in the lookbehind assertion reference.

Character classes

Character classes distinguish kinds of characters such as, for example, distinguishing between letters and digits.

Try it

```
const chessStory = "He played the King in a8 and she moved her Queen in c2.";
const regexpCoordinates = /\w\d/g;
console.log(chessStory.match(regexpCoordinates));
// Expected output: Array [ 'a8', 'c2']

const moods = "happy 😊, confused 😳, sad 😳";
const regexpEmoticons = /[\u{1F600}-\u{1F64F}]/gu;
console.log(moods.match(regexpEmoticons));
// Expected output: Array ['😊', '😳', '😳']
```

Types

Characters	Meaning
`[xyz]` `[a-c]`	**Character class:** Matches any one of the enclosed characters. You can specify a range of characters by using a hyphen, but if the hyphen appears as the first or last character enclosed in the square brackets, it is taken as a literal hyphen to be included in the character class as a normal character. For example, `[abcd]` is the same as `[a-d]`. They match the "b" in "brisket", and the "c" in "chop". For example, `[abcd-]` and `[-abcd]` match the "b" in "brisket", the "c" in "chop", and the "-" (hyphen) in "non-profit". For example, `[\w-]` is the same as `[A-Za-z0-9_-]`. They both match the "b" in "brisket", the "c" in "chop", and the "n" in "non-profit". When the `unicodeSets` (`v`) flag is enabled, the character class has some additional features. See the character class reference for more information.
`[^xyz]` `[^a-c]`	**Negated character class:** Matches anything that is not enclosed in the square brackets. You can specify a range of characters by using a hyphen, but if the hyphen appears as the first character after the `^` or the last character enclosed in the square brackets, it is taken as a literal hyphen to be included in the character class as a normal character. For example, `[^abc]` is the same as `[^a-c]`. They initially match "o" in "bacon" and "h" in "chop". > **Note:** The ^ character may also indicate the beginning of input.

Characters	Meaning
`.`	**Wildcard:** Matches any single character *except* line terminators: `\n`, `\r`, `\u2028` or `\u2029`. For example, `/.y/` matches "my" and "ay", but not "yes", in "yes make my day", as there is no character before "y" in "yes". If the `dotAll` (s) flag is enabled, also matches line terminators. Inside a character class, the dot loses its special meaning and matches a literal dot.
`\d`	**Digit character class escape:** Matches any digit (Arabic numeral). Equivalent to `[0-9]`. For example, `/\d/` or `/[0-9]/` matches "2" in "B2 is the suite number".
`\D`	**Non-digit character class escape:** Matches any character that is not a digit (Arabic numeral). Equivalent to `[^0-9]`. For example, `/\D/` or `/[^0-9]/` matches "B" in "B2 is the suite number".
`\w`	**Word character class escape:** Matches any alphanumeric character from the basic Latin alphabet, including the underscore. Equivalent to `[A-Za-z0-9_]`. For example, `/\w/` matches "a" in "apple", "5" in "$5.28", "3" in "3D" and "m" in "Émanuel".
`\W`	**Non-word character class escape:** Matches any character that is not a word character from the basic Latin alphabet. Equivalent to `[^A-Za-z0-9_]`. For example, `/\W/` or `/[^A-Za-z0-9_]/` matches "%" in "50%" and "É" in "Émanuel".
`\s`	**White space character class escape:** Matches a single white space character, including space, tab, form feed, line feed, and other Unicode spaces. Equivalent to `[\f\n\r\t\v\u0020\u00a0\u1680\u2000-\u200a\u2028\u2029\u202f\u205f\u3000\ufeff]`. For example, `/\s\w*/` matches " bar" in "foo bar".
`\S`	**Non-white space character class escape:** Matches a single character other than white space. Equivalent to `[^\f\n\r\t\v\u0020\u00a0\u1680\u2000-\u200a\u2028\u2029\u202f\u205f\u3000\ufeff]`. For example, `/\S\w*/` matches "foo" in "foo bar".
`\t`	Matches a horizontal tab.
`\r`	Matches a carriage return.
`\n`	Matches a linefeed.
`\v`	Matches a vertical tab.
`\f`	Matches a form-feed.
`[\b]`	Matches a backspace. If you're looking for the word-boundary assertion (`\b`), see Assertions.
`\0`	Matches a NUL character. Do not follow this with another digit.
`\c`*`X`*	Matches a control character using caret notation, where "X" is a letter from A–Z or a–z (corresponding to code points `U+0001`–`U+001A`). For example, `/\cM\cJ/` matches "\r\n".
`\x`*`hh`*	**Hex escape:** Matches the character with the code *`hh`* (two hexadecimal digits).
`\u`*`HHHH`*	**Unicode escape:** Matches a UTF-16 code-unit with the value *`HHHH`* (four hexadecimal digits).
`\u{`*`H…H`*`}`	**Unicode code point escape:** Matches the character with the Unicode value `U+`*`H…H`* (1 to 6 hexadecimal digits). Only valid in Unicode-aware mode.
`\p{`*`UnicodeProperty`*`}`, `\P{`*`UnicodeProperty`*`}`	**Unicode character class escape:** Matches a character based on its Unicode character properties: for example, emoji characters, or Japanese *katakana* characters, or Chinese/Japanese Han/Kanji characters, etc.). Only valid in Unicode-aware mode.
`\`	Indicates that the following character should be treated specially, or "escaped". It behaves one of two ways. • For characters that are usually treated literally, indicates that the next character is special and not to be interpreted literally. For example, `/b/` matches the character "b". By placing a backslash in front of "b", that is by using `/\b/`, the character becomes special to mean match a word boundary. • For characters that are usually treated specially, indicates that the next character is not special and should be interpreted literally. For example, "*" is a special character that means 0 or more occurrences of the preceding character should be matched; for example, `/a*/` means match 0 or more "a"s. To match `*` literally, precede it with a backslash; for example, `/a\*/` matches "a*". **Note:** To match this character literally, escape it with itself. In other words to search for `\` use `/\\/`.

Characters	Meaning
x|*y*	**Disjunction:** Matches either "x" or "y". Each component, separated by a pipe (`|`), is called an *alternative*. For example, `/green|red/` matches "green" in "green apple" and "red" in "red apple". > **Note:** A disjunction is another way to specify "a set of choices", but it's not a character class. Disjunctions are not atoms — you need to use a group to make it part of a bigger pattern. `[abc]` is functionally equivalent to `(?:a|b|c)`.

Examples

Looking for a series of digits

In this example, we match a sequence of 4 digits with `\d{4}`. `\b` indicates a word boundary (i.e., do not start or end matching in the middle of a number sequence).

```
const randomData = "015 354 8787 687351 3512 8735";
const regexpFourDigits = /\b\d{4}\b/g;

console.table(randomData.match(regexpFourDigits));
// ['8787', '3512', '8735']
```

See more examples in the character class escape reference.

Looking for a word (from the latin alphabet) starting with A

In this example, we match a word starting with the letter A. `\b` indicates a word boundary (i.e., do not start matching in the middle of a word). `[aA]` indicates the letter "a" or "A". `\w+` indicates any character *from the Latin alphabet*, multiple times (`+` is a quantifier). Note that because we already match until there are no more word characters, an end `\b` boundary is not necessary.

```
const aliceExcerpt =
  "I'm sure I'm not Ada,' she said, 'for her hair goes in such long ringlets, and mine doesn't go in ringlets at all.";
const regexpWordStartingWithA = /\b[aA]\w+/g;

console.table(aliceExcerpt.match(regexpWordStartingWithA));
// ['Ada', 'and', 'at', 'all']
```

See more examples in the character class escape reference.

Looking for a word (from Unicode characters)

Instead of the Latin alphabet, we can use a range of Unicode characters to identify a word (thus being able to deal with text in other languages like Russian or Arabic). The "Basic Multilingual Plane" of Unicode contains most of the characters used around the world and we can use character classes and ranges to match words written with those characters.

```
const nonEnglishText = "Приключения Алисы в Стране чудес";
const regexpBMPWord = /([\u0000-\u0019\u0021-\uFFFF])+/gu;
// BMP goes through U+0000 to U+FFFF but space is U+0020

console.table(nonEnglishText.match(regexpBMPWord));
["Приключения", "Алисы", "в", "Стране", "чудес"];
```

See more examples in the Unicode character class escape reference.

Counting vowels

In this example, we count the number of vowels (A, E, I, O, U, Y) in a text. The `g` flag is used to match all occurrences of the pattern in the text. The `i` flag is used to make the pattern case-insensitive, so it matches both uppercase and lowercase vowels.

```
const aliceExcerpt =
  "There was a long silence after this, and Alice could only hear whispers now and then.";
const regexpVowels = /[aeiouy]/gi;

console.log("Number of vowels:", aliceExcerpt.match(regexpVowels).length);
// Number of vowels: 26
```

Regular expression syntax cheat sheet

This page provides an overall cheat sheet of all the capabilities of `RegExp` syntax by aggregating the content of the articles in the `RegExp` guide. If you need more information on a specific topic, please follow the link on the corresponding heading to access the full article or head to the guide.

Character classes

Character classes distinguish kinds of characters such as, for example, distinguishing between letters and digits.

Characters	Meaning
`[xyz]` `[a-c]`	**Character class:** Matches any one of the enclosed characters. You can specify a range of characters by using a hyphen, but if the hyphen appears as the first or last character enclosed in the square brackets, it is taken as a literal hyphen to be included in the character class as a normal character. For example, `[abcd]` is the same as `[a-d]`. They match the "b" in "brisket", and the "c" in "chop". For example, `[abcd-]` and `[-abcd]` match the "b" in "brisket", the "c" in "chop", and the "-" (hyphen) in "non-profit". For example, `[\w-]` is the same as `[A-Za-z0-9_-]`. They both match the "b" in "brisket", the "c" in "chop", and the "n" in "non-profit".
`[^xyz]` `[^a-c]`	**Negated character class:** Matches anything that is not enclosed in the square brackets. You can specify a range of characters by using a hyphen, but if the hyphen appears as the first character after the `^` or the last character enclosed in the square brackets, it is taken as a literal hyphen to be included in the character class as a normal character. For example, `[^abc]` is the same as `[^a-c]`. They initially match "o" in "bacon" and "h" in "chop". **Note:** The ^ character may also indicate the beginning of input.
`.`	**Wildcard:** Matches any single character *except* line terminators: `\n`, `\r`, `\u2028` or `\u2029`. For example, `/.y/` matches "my" and "ay", but not "yes", in "yes make my day", as there is no character before "y" in "yes". If the `dotAll` (s) flag is enabled, also matches line terminators. Inside a character class, the dot loses its special meaning and matches a literal dot.
`\d`	**Digit character class escape:** Matches any digit (Arabic numeral). Equivalent to `[0-9]`. For example, `/\d/` or `/[0-9]/` matches "2" in "B2 is the suite number".
`\D`	**Non-digit character class escape:** Matches any character that is not a digit (Arabic numeral). Equivalent to `[^0-9]`. For example, `/\D/` or `/[^0-9]/` matches "B" in "B2 is the suite number".
`\w`	**Word character class escape:** Matches any alphanumeric character from the basic Latin alphabet, including the underscore. Equivalent to `[A-Za-z0-9_]`. For example, `/\w/` matches "a" in "apple", "5" in "$5.28", "3" in "3D" and "m" in "Émanuel".
`\W`	**Non-word character class escape:** Matches any character that is not a word character from the basic Latin alphabet. Equivalent to `[^A-Za-z0-9_]`. For example, `/\W/` or `/[^A-Za-z0-9_]/` matches "%" in "50%" and "É" in "Émanuel".
`\s`	**White space character class escape:** Matches a single white space character, including space, tab, form feed, line feed, and other Unicode spaces. Equivalent to `[\f\n\r\t\v\u0020\u00a0\u1680\u2000-\u200a\u2028\u2029\u202f\u205f\u3000\ufeff]`. For example, `/\s\w*/` matches " bar" in "foo bar".
`\S`	**Non-white space character class escape:** Matches a single character other than white space. Equivalent to `[^\f\n\r\t\v\u0020\u00a0\u1680\u2000-\u200a\u2028\u2029\u202f\u205f\u3000\ufeff]`. For example, `/\S\w*/` matches "foo" in "foo bar".
`\t`	Matches a horizontal tab.
`\r`	Matches a carriage return.
`\n`	Matches a linefeed.
`\v`	Matches a vertical tab.
`\f`	Matches a form-feed.
`[\b]`	Matches a backspace. If you're looking for the word-boundary assertion (`\b`), see Assertions.
`\0`	Matches a NUL character. Do not follow this with another digit.
`\c`*X*	Matches a control character using caret notation, where "X" is a letter from A–Z or a–z (corresponding to code points `U+0001`–`U+001A`). For example, `/\cM\cJ/` matches "\r\n".
`\x`*hh*	**Hex escape:** Matches the character with the code *hh* (two hexadecimal digits).

Characters	Meaning
`\uHHHH`	**Unicode escape:** Matches a UTF-16 code-unit with the value *HHHH* (four hexadecimal digits).
`\u{H…H}`	**Unicode code point escape:** Matches the character with the Unicode value *U+H…H* (1 to 6 hexadecimal digits). Only valid in Unicode-aware mode.
`\p{UnicodeProperty}`, `\P{UnicodeProperty}`	**Unicode character class escape:** Matches a character based on its Unicode character properties: for example, emoji characters, or Japanese *katakana* characters, or Chinese/Japanese Han/Kanji characters, etc.). Only valid in Unicode-aware mode.
`\`	Indicates that the following character should be treated specially, or "escaped". It behaves one of two ways. • For characters that are usually treated literally, indicates that the next character is special and not to be interpreted literally. For example, `/b/` matches the character "b". By placing a backslash in front of "b", that is by using `/\b/`, the character becomes special to mean match a word boundary. • For characters that are usually treated specially, indicates that the next character is not special and should be interpreted literally. For example, "*" is a special character that means 0 or more occurrences of the preceding character should be matched; for example, `/a*/` means match 0 or more "a"s. To match `*` literally, precede it with a backslash; for example, `/a\*/` matches "a*". **Note:** To match this character literally, escape it with itself. In other words to search for `\` use `/\\/`.
x|*y*	**Disjunction:** Matches either "x" or "y". Each component, separated by a pipe (`|`), is called an *alternative*. For example, `/green|red/` matches "green" in "green apple" and "red" in "red apple". **Note:** A disjunction is another way to specify "a set of choices", but it's not a character class. Disjunctions are not atoms — you need to use a group to make it part of a bigger pattern. `[abc]` is functionally equivalent to `(?:a|b|c)`.

Assertions

Assertions include boundaries, which indicate the beginnings and endings of lines and words, and other patterns indicating in some way that a match is possible (including look-ahead, look-behind, and conditional expressions).

Boundary-type assertions

Characters	Meaning
`^`	**Input boundary beginning assertion:** Matches the beginning of input. If the `multiline` (m) flag is enabled, also matches immediately after a line break character. For example, `/^A/` does not match the "A" in "an A", but does match the first "A" in "An A". **Note:** This character has a different meaning when it appears at the start of a character class.
`$`	**Input boundary end assertion:** Matches the end of input. If the `multiline` (m) flag is enabled, also matches immediately before a line break character. For example, `/t$/` does not match the "t" in "eater", but does match it in "eat".
`\A`	**Buffer boundary start assertion:** Matches the start of the entire string regardless of the presence of the `m` flag. Only valid in Unicode-aware mode.
`\z`	**Buffer boundary end assertion:** Matches the end of the entire string regardless of the presence of the `m` flag. Only valid in Unicode-aware mode.
`\Z`	**Buffer boundary end assertion with optional newline:** Matches the end of the entire string, but allows an optional trailing newline character sequence (either a line terminator or a `\r\n` sequence). Only valid in Unicode-aware mode.
`\b`	**Word boundary assertion:** Matches a word boundary. This is the position where a word character is not followed or preceded by another word-character, such as between a letter and a space. Note that a matched word boundary is not included in the match. In other words, the length of a matched word boundary is zero. Examples: • `/\bm/` matches the "m" in "moon". • `/oo\b/` does not match the "oo" in "moon", because "oo" is followed by "n" which is a word character. • `/oon\b/` matches the "oon" in "moon", because "oon" is the end of the string, thus not followed by a word character. • `/\w\b\w/` will never match anything, because a word character can never be followed by both a non-word and a word character. To match a backspace character (`[\b]`), see Character Classes.

Characters	Meaning
`\B`	**Non-word-boundary assertion:** Matches a non-word boundary. This is a position where the previous and next character are of the same type: Either both must be words, or both must be non-words, for example between two letters or between two spaces. The beginning and end of a string are considered non-words. Same as the matched word boundary, the matched non-word boundary is also not included in the match. For example, `/\Bon/` matches "on" in "at noon", and `/ye\B/` matches "ye" in "possibly yesterday".

Other assertions

> **Note:** The `?` character may also be used as a quantifier.

Characters	Meaning
`x(?=y)`	**Lookahead assertion:** Matches "x" only if "x" is followed by "y". For example, `/Jack(?=Sprat)/` matches "Jack" only if it is followed by "Sprat". `/Jack(?=Sprat|Frost)/` matches "Jack" only if it is followed by "Sprat" or "Frost". However, neither "Sprat" nor "Frost" is part of the match results.
`x(?!y)`	**Negative lookahead assertion:** Matches "x" only if "x" is not followed by "y". For example, `/\d+(?!\.)/` matches a number only if it is not followed by a decimal point. `/\d+(?!\.)/.exec('3.141')` matches "141" but not "3".
`(?<=y)x`	**Lookbehind assertion:** Matches "x" only if "x" is preceded by "y". For example, `/(?<=Jack)Sprat/` matches "Sprat" only if it is preceded by "Jack". `/(?<=Jack|Tom)Sprat/` matches "Sprat" only if it is preceded by "Jack" or "Tom". However, neither "Jack" nor "Tom" is part of the match results.
`(?<!y)x`	**Negative lookbehind assertion:** Matches "x" only if "x" is not preceded by "y". For example, `/(?<!-)\d+/` matches a number only if it is not preceded by a minus sign. `/(?<!-)\d+/.exec('3')` matches "3". `/(?<!-)\d+/.exec('-3')` match is not found because the number is preceded by the minus sign.

Groups and backreferences

Groups and backreferences indicate groups of expression characters.

Characters	Meaning
`(x)`	**Capturing group:** Matches *x* and remembers the match. For example, `/(foo)/` matches and remembers "foo" in "foo bar". A regular expression may have multiple capturing groups. In results, matches to capturing groups typically in an array whose members are in the same order as the left parentheses in the capturing group. This is usually just the order of the capturing groups themselves. This becomes important when capturing groups are nested. Matches are accessed using the index of the result's elements (`[1], …, [n]`) or from the predefined `RegExp` object's properties (`$1, …, $9`). Capturing groups have a performance penalty. If you don't need the matched substring to be recalled, prefer non-capturing parentheses (see below). `String.prototype.match()` won't return groups if the `/.../g` flag is set. However, you can still use `String.prototype.matchAll()` to get all matches.
`(?<Name>x)`	**Named capturing group:** Matches "x" and stores it on the groups property of the returned matches under the name specified by `<Name>`. The angle brackets (`<` and `>`) are required for group name. For example, to extract the United States area code from a phone number, we could use `/\((?<area>\d\d\d)\)/`. The resulting number would appear under `matches.groups.area`.
`(?:x)`	**Non-capturing group:** Matches "x" but does not remember the match. The matched substring cannot be recalled from the resulting array's elements (`[1], …, [n]`) or from the predefined `RegExp` object's properties (`$1, …, $9`).
`(?flags:x)`, `(?flags-flags:x)`	**Modifier:** Enables or disables the specified flags only to the enclosed pattern. Only the `i`, `m`, and `s` flags can be used in a modifier.
`\n`	**Backreference:** Where "n" is a positive integer. Matches the same substring matched by the nth capturing group in the regular expression (counting left parentheses). For example, `/apple(,)\sorange\1/` matches "apple, orange," in "apple, orange, cherry, peach".
`\k<Name>`	**Named backreference:** A back reference to the last substring matching the **Named capture group** specified by `<Name>`. For example, `/(?<title>\w+), yes \k<title>/` matches "Sir, yes Sir" in "Do you copy? Sir, yes Sir!".

Characters	Meaning
	Note: `\k` is used literally here to indicate the beginning of a back reference to a Named capture group.

Quantifiers

Quantifiers indicate numbers of characters or expressions to match.

Note: In the following, *item* refers not only to singular characters, but also includes character classes and groups and backreferences.

Characters	Meaning
*x**	Matches the preceding item "x" 0 or more times. For example, `/bo*/` matches "boooo" in "A ghost booooed" and "b" in "A bird warbled", but nothing in "A goat grunted".
x+	Matches the preceding item "x" 1 or more times. Equivalent to `{1,}`. For example, `/a+/` matches the "a" in "candy" and all the "a"'s in "caaaaaaandy".
x?	Matches the preceding item "x" 0 or 1 times. For example, `/e?le?/` matches the "el" in "angel" and the "le" in "angle." If used immediately after any of the quantifiers `*`, `+`, `?`, or `{}`, makes the quantifier non-greedy (matching the minimum number of times), as opposed to the default, which is greedy (matching the maximum number of times).
x{*n*}	Where "n" is a non-negative integer, matches exactly "n" occurrences of the preceding item "x". For example, `/a{2}/` doesn't match the "a" in "candy", but it matches all of the "a"'s in "caandy", and the first two "a"'s in "caaandy".
x{*n*,}	Where "n" is a non-negative integer, matches at least "n" occurrences of the preceding item "x". For example, `/a{2,}/` doesn't match the "a" in "candy", but matches all of the a's in "caandy" and in "caaaaaaandy".
x{*n*,*m*}	Where "n" and "m" are non-negative integers and `m >= n`, matches at least "n" and at most "m" occurrences of the preceding item "x". For example, `/a{1,3}/` matches nothing in "cndy", the "a" in "candy", the two "a"'s in "caandy", and the first three "a"'s in "caaaaaaandy". Notice that when matching "caaaaaaandy", the match is "aaa", even though the original string had more "a"s in it.
*x**? *x*+? *x*?? *x*{n}? *x*{n,}? *x*{n,m}?	By default quantifiers like `*` and `+` are "greedy", meaning that they try to match as many times as possible. The `?` character after the quantifier makes the quantifier "non-greedy": meaning that it will stop as soon as it finds the minimum number of matches. For example, given a string like "some <foo> <bar> new </bar> </foo> thing": • `/<.*>/` will match "<foo> <bar> new </bar> </foo>" • `/<.*?>/` will match "<foo>" **Note:** Adding `?` after `{n}` is syntactically valid but practically useless. Since `{n}` always matches exactly n times, `x{n}?` behaves the same as `x{n}`.

Groups and backreferences

Groups group multiple patterns as a whole, and capturing groups provide extra submatch information when using a regular expression pattern to match against a string. Backreferences refer to a previously captured group in the same regular expression.

Try it

```
// Groups
const imageDescription = "This image has a resolution of 1440×900 pixels.";
const regexpSize = /(\d+)×(\d+)/;
const match = imageDescription.match(regexpSize);
console.log(`Width: ${match[1]} / Height: ${match[2]}.`);
// Expected output: "Width: 1440 / Height: 900."

// Backreferences
const findDuplicates = "foo foo bar";
const regex = /\b(\w+)\s+\1\b/g;
console.log(findDuplicates.match(regex));
// Expected output: Array ["foo foo"]
```

Types

Characters	Meaning
(*x*)	**Capturing group:** Matches *x* and remembers the match. For example, `/(foo)/` matches and remembers "foo" in "foo bar".

Characters	Meaning
	A regular expression may have multiple capturing groups. In results, matches to capturing groups typically in an array whose members are in the same order as the left parentheses in the capturing group. This is usually just the order of the capturing groups themselves. This becomes important when capturing groups are nested. Matches are accessed using the index of the result's elements (`[1], …, [n]`) or from the predefined `RegExp` object's properties (`$1, …, $9`). Capturing groups have a performance penalty. If you don't need the matched substring to be recalled, prefer non-capturing parentheses (see below). `String.prototype.match()` won't return groups if the `/.../g` flag is set. However, you can still use `String.prototype.matchAll()` to get all matches.
`(?<Name>x)`	**Named capturing group:** Matches "x" and stores it on the groups property of the returned matches under the name specified by `<Name>`. The angle brackets (`<` and `>`) are required for group name. For example, to extract the United States area code from a phone number, we could use `/\((?<area>\d\d\d)\)/`. The resulting number would appear under `matches.groups.area`.
`(?:x)`	**Non-capturing group:** Matches "x" but does not remember the match. The matched substring cannot be recalled from the resulting array's elements (`[1], …, [n]`) or from the predefined `RegExp` object's properties (`$1, …, $9`).
`(?flags:x)`, `(?flags-flags:x)`	**Modifier:** Enables or disables the specified flags only to the enclosed pattern. Only the `i`, `m`, and `s` flags can be used in a modifier.
`\n`	**Backreference:** Where "n" is a positive integer. Matches the same substring matched by the nth capturing group in the regular expression (counting left parentheses). For example, `/apple(,)\sorange\1/` matches "apple, orange," in "apple, orange, cherry, peach".
`\k<Name>`	**Named backreference:** A back reference to the last substring matching the **Named capture group** specified by `<Name>`. For example, `/(?<title>\w+), yes \k<title>/` matches "Sir, yes Sir" in "Do you copy? Sir, yes Sir!". > **Note:** `\k` is used literally here to indicate the beginning of a back reference to a Named capture group.

Examples

Using groups

In this example, we match two words in a structured format by using capturing groups to remember them. `\w+` matches one or more word characters, and the parentheses `()` create a capturing group. The `g` flag is used to match all occurrences.

```
const personList = `First_Name: John, Last_Name: Doe
First_Name: Jane, Last_Name: Smith`;

const regexpNames = /First_Name: (\w+), Last_Name: (\w+)/g;
for (const match of personList.matchAll(regexpNames)) {
  console.log(`Hello ${match[1]} ${match[2]}`);
}
```

See more examples in the capturing group reference.

Using named groups

This example is the same as above, but we use named capturing groups to remember the matched words instead. This way, we can access the matched words by their meanings.

```
const personList = `First_Name: John, Last_Name: Doe
First_Name: Jane, Last_Name: Smith`;

const regexpNames =
  /First_Name: (?<firstName>\w+), Last_Name: (?<lastName>\w+)/g;
for (const match of personList.matchAll(regexpNames)) {
  console.log(`Hello ${match.groups.firstName} ${match.groups.lastName}`);
}
```

See more examples in the named capturing group reference.

Using groups and back references

In this example, we first match a single or double quote character with `['"]`, remember it, match an arbitrary number of characters with `.*?` (`*?` is a non-greedy quantifier), until we match the remembered quote character again with `\1`. The `\1` is a backreference to the first capturing group, which matches the same type of quote. The result will therefore be two strings: `"'"` and `'"'`.

```
const quote = `Single quote "'" and double quote '"'`;
const regexpQuotes = /(['"]).*?\1/g;
```

```
for (const match of quote.matchAll(regexpQuotes)) {
  console.log(match[0]);
}
```

See more examples in the backreference reference.

Using groups and match indices

By providing the `d` flag, the indices of each capturing group is returned. This is especially useful if you are correlating each matched group with the original text — for example, to provide compiler diagnostics.

```
const code = `function add(x, y) {
  return x + y;
}`;
const functionRegexp =
  /(function\s+)(?<name>[$_\p{ID_Start}][$\p{ID_Continue}]*)/du;
const match = functionRegexp.exec(code);
const lines = code.split("\n");
lines.splice(
  1,
  0,
  " ".repeat(match.indices[1][1] - match.indices[1][0]) +
    "^".repeat(match.indices.groups.name[1] - match.indices.groups.name[0]),
);
console.log(lines.join("\n"));
// function add(x, y) {
//          ^^^
//   return x + y;
// }
```

Quantifiers

Quantifiers indicate numbers of characters or expressions to match.

Try it

```
const ghostSpeak = "booh booooooooh";
const regexpSpooky = /bo{3,}h/;
console.log(ghostSpeak.match(regexpSpooky));
// Expected output: Array ["booooooooh"]

const modifiedQuote = "[He] ha[s] to go read this novel [Alice in Wonderland].";
const regexpModifications = /\[.*?\]/g;
console.log(modifiedQuote.match(regexpModifications));
// Expected output: Array ["[He]", "[s]", "[Alice in Wonderland]"]

const regexpTooGreedy = /\[.*\]/g;
console.log(modifiedQuote.match(regexpTooGreedy));
// Expected output: Array ["[He] ha[s] to go read this novel [Alice in Wonderland]"]
```

Types

> **Note:** In the following, *item* refers not only to singular characters, but also includes character classes and groups and backreferences.

Characters	Meaning
*x**	Matches the preceding item "x" 0 or more times. For example, `/bo*/` matches "boooo" in "A ghost booooed" and "b" in "A bird warbled", but nothing in "A goat grunted".
x+	Matches the preceding item "x" 1 or more times. Equivalent to `{1,}`. For example, `/a+/` matches the "a" in "candy" and all the "a"'s in "caaaaaaandy".
x?	Matches the preceding item "x" 0 or 1 times. For example, `/e?le?/` matches the "el" in "angel" and the "le" in "angle."

Characters	Meaning
	If used immediately after any of the quantifiers `*`, `+`, `?`, or `{}`, makes the quantifier non-greedy (matching the minimum number of times), as opposed to the default, which is greedy (matching the maximum number of times).
x{*n*}	Where "n" is a non-negative integer, matches exactly "n" occurrences of the preceding item "x". For example, `/a{2}/` doesn't match the "a" in "candy", but it matches all of the "a"'s in "caandy", and the first two "a"'s in "caaandy".
x{*n*,}	Where "n" is a non-negative integer, matches at least "n" occurrences of the preceding item "x". For example, `/a{2,}/` doesn't match the "a" in "candy", but matches all of the a's in "caandy" and in "caaaaaaandy".
x{*n*,*m*}	Where "n" and "m" are non-negative integers and `m >= n`, matches at least "n" and at most "m" occurrences of the preceding item "x". For example, `/a{1,3}/` matches nothing in "cndy", the "a" in "candy", the two "a"'s in "caandy", and the first three "a"'s in "caaaaaaandy". Notice that when matching "caaaaaaandy", the match is "aaa", even though the original string had more "a"s in it.
*x**? *x*+? *x*?? *x*{n}? *x*{n,}? *x*{n,m}?	By default quantifiers like `*` and `+` are "greedy", meaning that they try to match as many times as possible. The `?` character after the quantifier makes the quantifier "non-greedy": meaning that it will stop as soon as it finds the minimum number of matches. For example, given a string like "some <foo> <bar> new </bar> </foo> thing": • `/<.*>/` will match "<foo> <bar> new </bar> </foo>" • `/<.*?>/` will match "<foo>" **Note:** Adding `?` after `{n}` is syntactically valid but practically useless. Since `{n}` always matches exactly n times, `x{n}?` behaves the same as `x{n}`.

Examples

Repeated pattern

In this example, we match one or more word characters with `\w+`, then one or more characters "a" with `a+`, and finally end at a word boundary with `\b`.

```
const wordEndingWithAs = /\w+a+\b/;
const delicateMessage = "This is Spartaaaaaaa";

console.table(delicateMessage.match(wordEndingWithAs)); // [ "Spartaaaaaaa" ]
```

Counting characters

In this example, we match words that have a single letter, words that have between 2 and 6 letters, and words that have 13 or more letters.

```
const singleLetterWord = /\b\w\b/g;
const notSoLongWord = /\b\w{2,6}\b/g;
const longWord = /\b\w{13,}\b/g;

const sentence = "Why do I have to learn multiplication table?";

console.table(sentence.match(singleLetterWord)); // ["I"]
console.table(sentence.match(notSoLongWord)); // [ "Why", "do", "have", "to", "learn", "table" ]
console.table(sentence.match(longWord)); // ["multiplication"]
```

Optional character

In this example, we match words that either end with "our" or "or".

```
const britishText = "He asked his neighbour a favour.";
const americanText = "He asked his neighbor a favor.";

const regexpEnding = /\w+ou?r/g;
// \w+ One or several letters
// o   followed by an "o",
// u?  optionally followed by a "u"
// r   followed by an "r"

console.table(britishText.match(regexpEnding));
// ["neighbour", "favour"]

console.table(americanText.match(regexpEnding));
// ["neighbor", "favor"]
```

Greedy versus non-greedy

In this example, we match one or more word characters or spaces with `[\w ]+` and `[\w ]+?`. The first one is greedy and the second one is non-greedy. Note how the second one stops as soon as it meets the minimal requirement.

```
const text = "I must be getting somewhere near the center of the earth.";
const greedyRegexp = /[\w ]+/;

console.log(text.match(greedyRegexp)[0]);
// "I must be getting somewhere near the center of the earth"
// almost all of the text matches (leaves out the dot character)

const nonGreedyRegexp = /[\w ]+?/; // Notice the question mark
console.log(text.match(nonGreedyRegexp));
// "I"
// The match is the smallest one possible
```

Representing dates & times

- Previous
- Next

> **Note:** The `Date` object is now considered legacy and should be avoided in new code. We will update this page with modern alternatives soon.

Date object

JavaScript does not have a date data type. However, you can use the `Date` object and its methods to work with dates and times in your applications. The `Date` object has a large number of methods for setting, getting, and manipulating dates. It does not have any properties.

JavaScript handles dates similarly to Java. The two languages have many of the same date methods, and both languages store dates as the number of milliseconds since midnight at the beginning of January 1, 1970, UTC, with a Unix Timestamp being the number of seconds since the same instant. The instant at the midnight at the beginning of January 1, 1970, UTC is called the epoch.

The `Date` object range is -100,000,000 days to 100,000,000 days relative to the epoch.

To create a `Date` object:

```
const dateObjectName = new Date([parameters]);
```

where `dateObjectName` is the name of the `Date` object being created; it can be a new object or a property of an existing object.

Calling `Date` without the `new` keyword returns a string representing the current date and time.

The `parameters` in the preceding syntax can be any of the following:

- Nothing: creates today's date and time. For example, `today = new Date();`.
- A string representing a date, in many different forms. The exact forms supported differ among engines, but the following form is always supported: `YYYY-MM-DDTHH:mm:ss.sssZ`. For example, `xmas95 = new Date("1995-12-25")`. If you omit hours, minutes, or seconds, the value will be set to zero.
- A set of integer values for year, month, and day. For example, `xmas95 = new Date(1995, 11, 25)`.
- A set of integer values for year, month, day, hour, minute, and seconds. For example, `xmas95 = new Date(1995, 11, 25, 9, 30, 0);`.

Methods of the Date object

The `Date` object methods for handling dates and times fall into these broad categories:

- "set" methods, for setting date and time values in `Date` objects.
- "get" methods, for getting date and time values from `Date` objects.
- "to" methods, for returning string values from `Date` objects.
- parse and UTC methods, for parsing `Date` strings.

With the "get" and "set" methods you can get and set seconds, minutes, hours, day of the month, day of the week, months, and years separately. There is a `getDay` method that returns the day of the week, but no corresponding `setDay` method, because the day of the week is set automatically. These methods use integers to represent these values as follows:

- Seconds and minutes: 0 to 59
- Hours: 0 to 23
- Day: 0 (Sunday) to 6 (Saturday)
- Date: 1 to 31 (day of the month)
- Months: 0 (January) to 11 (December)
- Year: years since 1900

For example, suppose you define the following date:

```
const xmas95 = new Date("1995-12-25");
```

Then `xmas95.getMonth()` returns 11, and `xmas95.getFullYear()` returns 1995.

The `getTime` and `setTime` methods are useful for comparing dates. The `getTime` method returns the number of milliseconds since the epoch for a `Date` object.

For example, the following code displays the number of days left in the current year:

```
const today = new Date();
const endYear = new Date(1995, 11, 31, 23, 59, 59, 999); // Set day and month
endYear.setFullYear(today.getFullYear()); // Set year to this year
const msPerDay = 24 * 60 * 60 * 1000; // Number of milliseconds per day
let daysLeft = (endYear.getTime() - today.getTime()) / msPerDay;
daysLeft = Math.round(daysLeft); // Returns days left in the year
```

This example creates a `Date` object named `today` that contains today's date. It then creates a `Date` object named `endYear` and sets the year to the current year. Then, using the number of milliseconds per day, it computes the number of days between `today` and `endYear`, using `getTime` and rounding to a whole number of days.

The `parse` method is useful for assigning values from date strings to existing `Date` objects. For example, the following code uses `parse` and `setTime` to assign a date value to the `ipoDate` object:

```
const ipoDate = new Date();
ipoDate.setTime(Date.parse("Aug 9, 1995"));
```

Example

In the following example, the function `JSClock()` returns the time in the format of a digital clock.

```
function JSClock() {
  const time = new Date();
  const hour = time.getHours();
  const minute = time.getMinutes();
  const second = time.getSeconds();
  let temp = String(hour % 12);
  if (temp === "0") {
    temp = "12";
  }
  temp += (minute < 10 ? ":0" : ":") + minute;
  temp += (second < 10 ? ":0" : ":") + second;
  temp += hour >= 12 ? " P.M." : " A.M.";
  return temp;
}
```

The `JSClock` function first creates a new `Date` object called `time`; since no arguments are given, time is created with the current date and time. Then calls to the `getHours`, `getMinutes`, and `getSeconds` methods assign the value of the current hour, minute, and second to `hour`, `minute`, and `second`.

The following statements build a string value based on the time. The first statement creates a variable `temp`. Its value is `hour % 12`, which is `hour` in the 12-hour system. Then, if the hour is `0`, it gets re-assigned to `12`, so that midnights and noons are displayed as `12:00` instead of `0:00`.

The next statement appends a `minute` value to `temp`. If the value of `minute` is less than 10, the conditional expression adds a string with a preceding zero; otherwise it adds a string with a demarcating colon. Then a statement appends a seconds value to `temp` in the same way.

Finally, a conditional expression appends "P.M." to `temp` if `hour` is 12 or greater; otherwise, it appends "A.M." to `temp`.

JavaScript resource management

- Previous
- Next

This guide talks about how to do *resource management* in JavaScript. Resource management is not exactly the same as memory management, which is a more advanced topic and usually handled automatically by JavaScript. Resource management is about managing resources that are *not* automatically cleaned up by JavaScript. Sometimes, it's okay to have some unused objects in memory, because they don't interfere with application logic, but resource leaks often lead to things not working, or a lot of excess memory usage. Therefore, this is not an optional feature about optimization, but a core feature to write correct programs!

> **Note:** While memory management and resource management are two separate topics, sometimes you can hook into the memory management system to do resource management, as a last resort. For example, if you have a JavaScript object representing a handle of an external resource, you can create a `FinalizationRegistry` to clean up the resource when the handle is garbage collected, because there is definitely no way to access the resource afterwards. However, there is no guarantee that the finalizer will run, so it's not a good idea to rely on it for critical resources.

Problem

Let's first look at a few examples of resources that need to be managed:

- **File handles**: A file handle is used to read and write bytes in a file. When you are done with it, you must call `fileHandle.close()`, otherwise the file will remain open, even when the JS object is no longer accessible. As the linked Node.js docs say:

> If a `<FileHandle>` is not closed using the `fileHandle.close()` method, it will try to automatically close the file descriptor and emit a process warning, helping to prevent memory leaks. Please do not rely on this behavior because it can be unreliable and the file may not be closed. Instead, always explicitly close `<FileHandle>`s. Node.js may change this behavior in the future.

- **Network connections**: Some connections, such as `WebSocket` and `RTCPeerConnection`, need to be closed if no messages are transmitted. Otherwise, the connection remains open, and connection pools are often very limited in size.
- **Stream readers**: If you don't call `ReadableStreamDefaultReader.releaseLock()`, the stream will be locked and does not permit another reader to consume it.

Here is one concrete example, using a readable stream:

```
const stream = new ReadableStream({
  start(controller) {
    controller.enqueue("a");
    controller.enqueue("b");
    controller.enqueue("c");
    controller.close();
  },
});

async function readUntil(stream, text) {
  const reader = stream.getReader();
  let chunk = await reader.read();

  while (!chunk.done && chunk.value !== text) {
    console.log(chunk);
    chunk = await reader.read();
  }
  // We forgot to release the lock here
}

readUntil(stream, "b").then(() => {
  const anotherReader = stream.getReader();
  // TypeError: ReadableStreamDefaultReader constructor can only
  // accept readable streams that are not yet locked to a reader
});
```

Here, we have a stream that emits three chunks of data. We read from the stream until we find the letter "b". When `readUntil` returns, the stream is only partially consumed, so we should be able to continue to read from it using another reader. However, we forgot to release the lock, so although `reader` is no longer available, the stream is still locked and we cannot create another reader.

The solution in this case is straightforward: call `reader.releaseLock()` at the end of `readUntil`. But, a few issues still remain:

- Inconsistency: different resources have different ways to release them. For example, we have `close()`, `releaseLock()`, `disconnect()`, etc. The pattern does not generalize.
- Error handling: what happens if the `reader.read()` call fails? Then `readUntil` would terminate and never get to the `reader.releaseLock()` call. We can fix this using `try...finally`:

  ```
  async function readUntil(stream, text) {
    const reader = stream.getReader();
    try {
      let chunk = await reader.read();

      while (!chunk.done && chunk.value !== text) {
        console.log(chunk);
        chunk = await reader.read();
      }
    } finally {
      reader.releaseLock();
    }
  }
  ```

  But you have to remember to do this every time you have some important resource to release.
- Scoping: in the above example, `reader` is already closed when we exit the `try...finally` statement, but it continues to be available in its scope. This means you may accidentally use it after it's closed.
- Multiple resources: if we have two readers on different streams, we have to remember to release both of them. This is a respectable attempt to do so:

  ```
  const reader1 = stream1.getReader();
  const reader2 = stream2.getReader();
  try {
    // do something with reader1 and reader2
  } finally {
    reader1.releaseLock();
    reader2.releaseLock();
  }
  ```

  However, this introduces more error handling troubles. If `stream2.getReader()` throws, then `reader1` does not get released; if `reader1.releaseLock()` throws an error, then `reader2` does not get released. This means we actually have to wrap each resource acquisition-release pair in its own `try...finally`:

```
const reader1 = stream1.getReader();
try {
  const reader2 = stream2.getReader();
  try {
    // do something with reader1 and reader2
  } finally {
    reader2.releaseLock();
  }
} finally {
  reader1.releaseLock();
}
```

You see how a seemingly benign task of calling `releaseLock` can quickly lead to nested boilerplate code. This is why JavaScript provides integrated language support for resource management.

The <code>using</code> and <code>await using</code> declarations

The solution we have is two special kinds of variable declaration: `using` and `await using`. They are similar to `const`, but they automatically release the resource when the variable goes out of scope as long as the resource is *disposable*. Using the same example as above, we can rewrite it as:

```
{
  using reader1 = stream1.getReader();
  using reader2 = stream2.getReader();

  // do something with reader1 and reader2

  // Before we exit the block, reader1 and reader2 are automatically released
}
```

> **Note:** At the time of writing, `ReadableStreamDefaultReader` does not implement the disposable protocol. This is a hypothetical example.

First, notice the extra braces around the code. This creates a new block scope for the `using` declarations. Resources declared with `using` are automatically freed when they go out of the scope of `using`, which, in this case, is whenever we are exiting the block, either because all statements have executed, or because an error or `return`/`break`/`continue` was encountered somewhere.

This means `using` can only be used in a scope that has a clear lifetime—namely, it cannot be used at the top level of a script, because variables at the top level of a script are in scope for all future scripts on the page, which practically means the resource can never be freed if the page never unloads. However, you can use it at the top level of a module, because the module scope ends when the module finishes executing.

Now we know *when* `using` does cleanup. But *how* is it done? `using` requires the resource to implement the *disposable* protocol. An object is disposable if it has the `[Symbol.dispose]()` method. This method is called with no arguments to perform cleanup. For example, in the reader case, the `[Symbol.dispose]` property can be a simple alias or wrapper of `releaseLock`:

```
// For demonstration
class MyReader {
  // A wrapper
  [Symbol.dispose]() {
    this.releaseLock();
  }
  releaseLock() {
    // Logic to release resources
  }
}

// OR, an alias
MyReader.prototype[Symbol.dispose] = MyReader.prototype.releaseLock;
```

Through the disposable protocol, `using` can dispose all resources in a consistent fashion without understanding what type of resource it is.

Every scope has a list of resources associated with it, in the order they were declared. When the scope exits, the resources are disposed in reverse order, by calling their `[Symbol.dispose]()` method. For example, in the example above, `reader1` is declared before `reader2`, so `reader2` is disposed first, then `reader1`. Errors thrown when attempting to dispose one resource will not prevent disposal of other resources. This is consistent with the `try...finally` pattern, and respects possible dependencies between resources.

`await using` is very similar to `using`. The syntax tells you that an `await` happens somewhere—not when the resource is declared, but actually when it's disposed. `await using` requires the resource to be *async disposable*, which means it has a `[Symbol.asyncDispose]()` method. This method is called with no arguments and returns a promise that resolves when the cleanup is done. This is useful when the cleanup is asynchronous, such as `fileHandle.close()`, in which case the result of the disposal can only be known asynchronously.

```
{
  await using fileHandle = open("file.txt", "w");
  await fileHandle.write("Hello");

  // fileHandle.close() is called and awaited
}
```

Because `await using` requires doing an `await`, it is only permitted in contexts where `await` is, which includes inside `async` functions and top-level `await` in modules.

Resources are cleaned up sequentially, not concurrently: the return value of one resource's `[Symbol.asyncDispose]()` method will be `await`ed before the next resource's `[Symbol.asyncDispose]()` method is called.

Some things to note:

- `using` and `await using` are *opt in*. If you declare your resource using `let`, `const`, or `var`, no automatic disposal happens, just like any other non-disposable values.
- `using` and `await using` require the resource to be disposable (or async disposable). If the resource does not have the `[Symbol.dispose]()` or `[Symbol.asyncDispose]()` method respectively, you will get a `TypeError` at the line of declaration. The resource can be `null` or `undefined`, however, allowing you to conditionally acquire resources.
- Like `const`, `using` and `await using` variables cannot be re-assigned, although the properties of the objects they hold can be changed. However, the `[Symbol.dispose]()`/`[Symbol.asyncDispose]()` method is already saved at the time of declaration, so changing the method after the declaration does not affect the cleanup.
- There are some gotchas when conflating scopes with resource lifetime. See `using` for a few examples.

The <code>DisposableStack</code> and <code>AsyncDisposableStack</code> objects

`using` and `await using` are special syntaxes. Syntaxes are convenient and hide a lot of the complexity, but sometimes you need to do things manually.

For one common example: what if you don't want to dispose the resource at the end of *this* scope, but at some *later* scope? Consider this:

```
let reader;
if (someCondition) {
  reader = stream.getReader();
} else {
  reader = stream.getReader({ mode: "byob" });
}
```

As we said, `using` is like `const`: it must be initialized and can't be reassigned, so you may attempt this:

```
if (someCondition) {
  using reader = stream.getReader();
} else {
  using reader = stream.getReader({ mode: "byob" });
}
```

However, this means all logic has to be written inside the `if` or `else`, causing a lot of duplication. What we want to do is to acquire and register the resource in one scope but dispose it in another. We can use a `DisposableStack` for this purpose, which is an object which holds a collection of disposable resources and which itself is disposable:

```
{
  using disposer = new DisposableStack();
  let reader;
  if (someCondition) {
    reader = disposer.use(stream.getReader());
  } else {
    reader = disposer.use(stream.getReader({ mode: "byob" }));
  }
  // Do something with reader
  // Before scope exit, disposer is disposed, which disposes reader
}
```

You may have a resource that does not yet implement the disposable protocol, so it will be rejected by `using`. In this case, you can use `adopt()`.

```
{
  using disposer = new DisposableStack();
  // Suppose reader does not have the [Symbol.dispose]() method,
  // then it cannot be used with using.
  // However, we can manually pass a disposer function to disposer.adopt
  const reader = disposer.adopt(stream.getReader(), (reader) =>
    reader.releaseLock(),
  );
  // Do something with reader
  // Before scope exit, disposer is disposed, which disposes reader
}
```

You may have a disposal action to perform but it's not "tethered" to any resource in particular. Maybe you just want to log a message saying "All database connections closed" when there are multiple connections open simultaneously. In this case, you can use `defer()`.

```
{
  using disposer = new DisposableStack();
  disposer.defer(() => console.log("All database connections closed"));
  const connection1 = disposer.use(openConnection());
  const connection2 = disposer.use(openConnection());
  // Do something with connection1 and connection2
  // Before scope exit, disposer is disposed, which first disposes connection1
  // and connection2 and then logs the message
}
```

You may want to do *conditional* disposal—for example, only dispose claimed resources when an error occurred. In this case, you can use `move()` to preserve the resources which would otherwise be disposed.

```
class MyResource {
  #resource1;
  #resource2;
```

```
  #disposables;
  constructor() {
    using disposer = new DisposableStack();
    this.#resource1 = disposer.use(getResource1());
    this.#resource2 = disposer.use(getResource2());
    // If we made it here, then there were no errors during construction and
    // we can safely move the disposables out of `disposer` and into `#disposables`.
    this.#disposables = disposer.move();
    // If construction failed, then `disposer` would be disposed before reaching
    // the line above, disposing `#resource1` and `#resource2`.
  }
  [Symbol.dispose]() {
    this.#disposables.dispose(); // Dispose `#resource2` and `#resource1`.
  }
}
```

`AsyncDisposableStack` is like `DisposableStack`, but for use with async disposable resources. Its `use()` method expects an async disposable, its `adopt()` method expects an async cleanup function, and its `dispose()` method expects an async callback. It provides a `[Symbol.asyncDispose]()` method. You can still pass it sync resources if you have a mix of both sync and async.

The reference for `DisposableStack` contains more examples and details.

Error handling

A major use case of the resource management feature is to ensure that resources are always disposed, even when an error occurs. Let us investigate some complex error handling scenarios.

We start with the following code, which, by using `using`, is robust against errors:

```
async function readUntil(stream, text) {
  // Use `using` instead of `await using` because `releaseLock` is synchronous
  using reader = stream.getReader();
  let chunk = await reader.read();

  while (!chunk.done && chunk.value !== text) {
    console.log(chunk.toUpperCase());
    chunk = await reader.read();
  }
}
```

Suppose that `chunk` turns out to be `null`. Then `!chunk.done` will throw a `TypeError`, causing the function to terminate. Before the function exits, `stream[Symbol.dispose]()` is called, which releases the lock on the stream.

```
const stream = new ReadableStream({
  start(controller) {
    controller.enqueue("a");
    controller.enqueue(null);
    controller.enqueue("b");
    controller.enqueue("c");
    controller.close();
  },
});

readUntil(stream, "b")
  .catch((e) => console.error(e)) // TypeError: chunk.toUpperCase is not a function
  .then(() => {
    const anotherReader = stream.getReader();
    // Successfully creates another reader
  });
```

So, `using` does not swallow any errors: all errors that occur are still thrown, but the resources get closed right before that. Now, what happens if the resource cleanup itself also throws an error? Let's use a more contrived example:

```
class MyReader {
  [Symbol.dispose]() {
    throw new Error("Failed to release lock");
  }
}

function doSomething() {
  using reader = new MyReader();
  throw new Error("Failed to read");
}

try {
  doSomething();
} catch (e) {
  console.error(e); // SuppressedError: An error was suppressed during disposal
}
```

There are two errors generated in the `doSomething()` call: an error thrown during `doSomething`, and an error thrown during disposal of `reader` because of the first error. Both errors are thrown together, so what you caught is a `SuppressedError`. This is a special error that wraps two errors: the `error` property contains the later error, and the `suppressed` property contains the earlier error, which gets "suppressed" by the later error.

If we have more than one resource, and *both* of them throw an error during disposal (this should be exceedingly rare–it's already rare for disposal to fail!), then each earlier error is suppressed by the later error, forming a chain of suppressed errors.

```
class MyReader {
  [Symbol.dispose]() {
    throw new Error("Failed to release lock on reader");
  }
}

class MyWriter {
  [Symbol.dispose]() {
    throw new Error("Failed to release lock on writer");
  }
}

function doSomething() {
  using reader = new MyReader();
  using writer = new MyWriter();
  throw new Error("Failed to read");
}

try {
  doSomething();
} catch (e) {
  console.error(e); // SuppressedError: An error was suppressed during disposal
  console.error(e.suppressed); // SuppressedError: An error was suppressed during disposal
  console.error(e.error); // Error: Failed to release lock on reader
  console.error(e.suppressed.suppressed); // Error: Failed to read
  console.error(e.suppressed.error); // Error: Failed to release lock on writer
}
```

- The `reader` is released last, so its error is the latest and therefore suppresses everything else: it shows up as `e.error`.
- The `writer` is released first, so its error is later than the original exiting error, but earlier than the `reader` error: it shows up as `e.suppressed.error`.
- The original error about "Failed to read" is the earliest error, so it shows up as `e.suppressed.suppressed`.

Examples

Automatically releasing object URLs

In the following example, we create an object URL to a blob (in a real application, this blob would be fetched from somewhere, such as a file or a fetch response) so we can download the blob as a file. In order to prevent a resource leak, we must free the object URL with `URL.revokeObjectURL()` when it is no longer needed (that is, when the download has successfully started). Because the URL itself is just a string and therefore doesn't implement the disposable protocol, we cannot directly declare `url` with `using`; therefore, we create a `DisposableStack` to serve as the disposer for `url`. The object URL is revoked as soon as `disposer` goes out of scope, which is when either `link.click()` finishes or an error occurs somewhere.

```
const downloadButton = document.getElementById("download-button");
const exampleBlob = new Blob(["example data"]);

downloadButton.addEventListener("click", () => {
  using disposer = new DisposableStack();
  const link = document.createElement("a");
  const url = disposer.adopt(
    URL.createObjectURL(exampleBlob),
    URL.revokeObjectURL,
  );

  link.href = url;
  link.download = "example.txt";
  link.click();
});
```

Automatically canceling in-progress requests

In the following example, we fetch a list of resources concurrently using `Promise.all()`. `Promise.all()` fails and rejects the resulting promise as soon as one request failed; however, the other pending requests continue to run, despite their results being inaccessible to the program. To avoid these remaining requests needlessly consuming resources, we need to automatically cancel in-progress requests whenever `Promise.all()` settles. We implement cancellation with an `AbortController`, and pass its `signal` to every `fetch()` call. If `Promise.all()` fulfills, then the function returns normally and the controller aborts, which is harmless because there's no pending request to cancel; if `Promise.all()` rejects and the function throws, then the controller aborts and cancels all pending requests.

```
async function getAllData(urls) {
  using disposer = new DisposableStack();
  const { signal } = disposer.adopt(new AbortController(), (controller) =>
    controller.abort(),
  );

  // Fetch all URLs in parallel
  // Automatically cancel any incomplete requests if any request fails
  const pages = await Promise.all(
    urls.map((url) =>
      fetch(url, { signal }).then((response) => {
        if (!response.ok)
          throw new Error(
            `Response error: ${response.status} - ${response.statusText}`,
```

```
          );
        return response.text();
      }),
    ),
  );
  return pages;
}
```

Pitfalls

The resource disposal syntax offers a lot of strong error handling guarantees that ensure the resources are always cleaned up no matter what happens, but there are some pitfalls you may still encounter:

- Forgetting to use `using` or `await using`. The resource management syntax is only there to help you when you know you need it, but there's nothing to yell at you if you forget to use it! Unfortunately, there's no good way to prevent this before-the-fact, because there are no syntactic clues that something is a disposable resource, and even for disposable resources, you may want to declare them without automatic disposal. You probably need a type checker combined with a linter to catch these issues, such as typescript-eslint (which is still planning to work on this feature).
- Use-after-free. Generally, the `using` syntax ensures that a resource is freed when it goes out of scope, but there are many ways to persist a value beyond its binding variable. JavaScript does not have an ownership mechanism like Rust, so you can declare an alias that doesn't use `using`, or preserve the resource in a closure, etc. The `using` reference contains many examples of such pitfalls. Again, there's no good way to properly detect this in a complicated control flow, so you need to be careful.

The resource management feature is not a silver bullet. It is definitely an improvement over manually invoking the disposal methods, but it is not smart enough to prevent all resource management bugs. You still need to be careful and understand the semantics of the resources you are using.

Conclusion

Here are the key components of the resource management system:

- `using` and `await using` declarations for automatic resource disposal.
- The *disposable* and *async disposable* protocols, using the `Symbol.dispose` and `Symbol.asyncDispose` respectively, for resources to implement.
- The `DisposableStack` and `AsyncDisposableStack` objects for cases where `using` and `await using` are not suitable.

With proper usage of these APIs, you can create systems interacting with external resources that remain strong and robust against all error conditions without lots of boilerplate code.

JavaScript typed arrays

- Previous
- Next

JavaScript typed arrays are array-like objects that provide a mechanism for reading and writing raw binary data in memory buffers.

Typed arrays are not intended to replace arrays for any kind of functionality. Instead, they provide developers with a familiar interface for manipulating binary data. This is useful when interacting with platform features, such as audio and video manipulation, access to raw data using WebSockets, and so forth. Each entry in a JavaScript typed array is a raw binary value in one of a number of supported formats, from 8-bit integers to 64-bit floating-point numbers.

Typed array objects share many of the same methods as arrays with similar semantics. However, typed arrays are *not* to be confused with normal arrays, as calling `Array.isArray()` on a typed array returns `false`. Moreover, not all methods available for normal arrays are supported by typed arrays (e.g., push and pop).

To achieve maximum flexibility and efficiency, JavaScript typed arrays split the implementation into *buffers* and *views*. A buffer is an object representing a chunk of data; it has no format to speak of, and offers no mechanism for accessing its contents. In order to access the memory contained in a buffer, you need to use a view. A view provides a *context* — that is, a data type, starting offset, and number of elements.

A diagram showing how different typed arrays may be views of the same underlying buffer. Each one has a different element number and width.

Buffers

There are two types of buffers: `ArrayBuffer` and `SharedArrayBuffer`. Both are low-level representations of a memory span. They have "array" in their names, but they don't have much to do with arrays — you cannot read or write to them directly. Instead, buffers are generic objects that just contain raw data. In order to access the memory represented by a buffer, you need to use a view.

Buffers support the following actions:

- *Allocate*: As soon as a new buffer is created, a new memory span is allocated and initialized to `0`.
- *Copy*: Using the `slice()` method, you can efficiently copy a portion of the memory without creating views to manually copy each byte.
- *Transfer*: Using the `transfer()` and `transferToFixedLength()` methods, you can transfer ownership of the memory span to a new buffer object. This is useful when transferring data between different execution contexts without copying. After the transfer, the original buffer is no longer usable. A `SharedArrayBuffer` cannot be transferred (as the buffer is already shared by all execution contexts).
- *Resize*: Using the `resize()` method, you can resize the memory span (either claim more memory space, as long as it doesn't pass the pre-set `maxByteLength` limit, or release some memory space). `SharedArrayBuffer` can only be grown but not shrunk.

The difference between `ArrayBuffer` and `SharedArrayBuffer` is that the former is always owned by a single execution context at a time. If you pass an `ArrayBuffer` to a different execution context, it is *transferred* and the original `ArrayBuffer` becomes unusable. This ensures that only one execution context can access the memory at a time. A `SharedArrayBuffer` is not transferred when passed to a different execution context, so it can be accessed by multiple execution contexts at the same time. This may introduce race conditions when multiple threads access the same memory span, so operations such as `Atomics` methods become useful.

Views

There are currently two main kinds of views: typed array views and `DataView`. Typed arrays provide utility methods that allow you to conveniently transform binary data. `DataView` is more low-level and allows granular control of how data is accessed. The ways to read and write data using the two views are very different.

Both kinds of views cause `ArrayBuffer.isView()` to return `true`. They both have the following properties:

`buffer`

: The underlying buffer that the view references.

`byteOffset`

: The offset, in bytes, of the view from the start of its buffer.

`byteLength`

: The length, in bytes, of the view.

Both constructors accept the above three as separate arguments, although typed array constructors accept `length` as the number of elements rather than the number of bytes.

Typed array views

Typed array views have self-descriptive names and provide views for all the usual numeric types like `Int8`, `Uint32`, `Float64` and so forth. There is one special typed array view, `Uint8ClampedArray`, which clamps the values between `0` and `255`. This is useful for Canvas data processing, for example.

Type	Value Range	Size in bytes	Web IDL type
`Int8Array`	-128 to 127	1	`byte`
`Uint8Array`	0 to 255	1	`octet`
`Uint8ClampedArray`	0 to 255	1	`octet`
`Int16Array`	-32768 to 32767	2	`short`
`Uint16Array`	0 to 65535	2	`unsigned short`
`Int32Array`	-2147483648 to 2147483647	4	`long`
`Uint32Array`	0 to 4294967295	4	`unsigned long`
`Float16Array`	`-65504` to `65504`	2	N/A
`Float32Array`	`-3.4e38` to `3.4e38`	4	`unrestricted float`
`Float64Array`	`-1.8e308` to `1.8e308`	8	`unrestricted double`
`BigInt64Array`	-2^{63} to $2^{63} - 1$	8	`bigint`
`BigUint64Array`	0 to $2^{64} - 1$	8	`bigint`

All typed array views have the same methods and properties, as defined by the `TypedArray` class. They only differ in the underlying data type and the size in bytes. This is discussed in more detail in Value encoding and normalization.

Typed arrays are, in principle, fixed-length, so array methods that may change the length of an array are not available. This includes `pop`, `push`, `shift`, `splice`, and `unshift`. In addition, `flat` is unavailable because there are no nested typed arrays, and related methods including `concat` and `flatMap` do not have great use cases so are unavailable. As `splice` is unavailable, so too is `toSpliced`. All other array methods are shared between `Array` and `TypedArray`.

On the other hand, `TypedArray` has the extra `set` and `subarray` methods that optimize working with multiple typed arrays that view the same buffer. The `set()` method allows setting multiple typed array indices at once, using data from another array or typed array. If the two typed arrays share the same underlying buffer, the operation may be more efficient as it's a fast memory move. The `subarray()` method creates a new typed array view that references the same buffer as the original typed array, but with a narrower span.

There's no way to directly change the length of a typed array without changing the underlying buffer. However, when the typed array views a resizable buffer and does not have a fixed `byteLength`, it is *length-tracking*, and will automatically resize to fit the underlying buffer as the resizable buffer is resized. See Behavior when viewing a resizable buffer for details.

Similar to regular arrays, you can access typed array elements using bracket notation. The corresponding bytes in the underlying buffer are retrieved and interpreted as a number. Any property access using a number (or the string representation of a number, since numbers are always converted to strings when accessing properties) will be proxied by the typed array — they never interact with the object itself. This means, for example:

- Out-of-bounds index access always returns `undefined`, without actually accessing the property on the object.
- Any attempt to write to such an out-of-bounds property has no effect: it does not throw an error but doesn't change the buffer or typed array either.
- Typed array indices appear to be configurable and writable, but any attempt to change their attributes will fail.

```
const uint8 = new Uint8Array([1, 2, 3]);
console.log(uint8[0]); // 1

// For illustrative purposes only. Not for production code.
uint8[-1] = 0;
uint8[2.5] = 0;
uint8[NaN] = 0;
console.log(Object.keys(uint8)); // ["0", "1", "2"]
console.log(uint8[NaN]); // undefined

// Non-numeric access still works
uint8[true] = 0;
console.log(uint8[true]); // 0
```

```
Object.freeze(uint8); // TypeError: Cannot freeze array buffer views with elements
```

DataView

The `DataView` is a low-level interface that provides a getter/setter API to read and write arbitrary data to the buffer. This is useful when dealing with different types of data, for example. Typed array views are in the native byte-order (see Endianness) of your platform. With a `DataView`, the byte-order can be controlled. By default, it's big-endian—the bytes are ordered from most significant to least significant. This can be reversed, with the bytes ordered from least significant to most significant (little-endian), using getter/setter methods.

`DataView` does not require alignment; multi-byte read and write can be started at any specified offset. The setter methods work the same way.

The following example uses a `DataView` to get the binary representation of any number:

```
function toBinary(
  x,
  { type = "Float64", littleEndian = false, separator = " ", radix = 16 } = {},
) {
  const bytesNeeded = globalThis[`${type}Array`].BYTES_PER_ELEMENT;
  const dv = new DataView(new ArrayBuffer(bytesNeeded));
  dv[`set${type}`](0, x, littleEndian);
  const bytes = Array.from({ length: bytesNeeded }, (_, i) =>
    dv
      .getUint8(i)
      .toString(radix)
      .padStart(8 / Math.log2(radix), "0"),
  );
  return bytes.join(separator);
}

console.log(toBinary(1.1)); // 3f f1 99 99 99 99 99 9a
console.log(toBinary(1.1, { littleEndian: true })); // 9a 99 99 99 99 99 f1 3f
console.log(toBinary(20, { type: "Int8", radix: 2 })); // 00010100
```

Web APIs using typed arrays

These are some examples of APIs that make use of typed arrays; there are others, and more are being added all the time.

`FileReader.prototype.readAsArrayBuffer()`

> The `FileReader.prototype.readAsArrayBuffer()` method starts reading the contents of the specified `Blob` or `File`.

`fetch()`

> The `body` option to `fetch()` can be a typed array or `ArrayBuffer`, enabling you to send these objects as the payload of a `POST` request.

`ImageData.data`

> Is a `Uint8ClampedArray` representing a one-dimensional array containing the data in the RGBA order, with integer values between `0` and `255` inclusive.

Examples

Using views with buffers

First of all, we will need to create a buffer, here with a fixed length of 16-bytes:

```
const buffer = new ArrayBuffer(16);
```

At this point, we have a chunk of memory whose bytes are all pre-initialized to 0. There's not a lot we can do with it, though. For example, we can confirm that the buffer is the right size:

```
if (buffer.byteLength === 16) {
  console.log("Yes, it's 16 bytes.");
} else {
  console.log("Oh no, it's the wrong size!");
}
```

Before we can really work with this buffer, we need to create a view. Let's create a view that treats the data in the buffer as an array of 32-bit signed integers:

```
const int32View = new Int32Array(buffer);
```

Now we can access the fields in the array just like a normal array:

```
for (let i = 0; i < int32View.length; i++) {
  int32View[i] = i * 2;
}
```

This fills out the 4 entries in the array (4 entries at 4 bytes each makes 16 total bytes) with the values `0`, `2`, `4`, and `6`.

Multiple views on the same data

Things start to get really interesting when you consider that you can create multiple views onto the same data. For example, given the code above, we can continue like this:

```
const int16View = new Int16Array(buffer);

for (let i = 0; i < int16View.length; i++) {
  console.log(`Entry ${i}: ${int16View[i]}`);
}
```

Here we create a 16-bit integer view that shares the same buffer as the existing 32-bit view and we output all the values in the buffer as 16-bit integers. Now we get the output `0`, `0`, `2`, `0`, `4`, `0`, `6`, `0` (assuming little-endian encoding):

```
Int16Array  |   0  |  0   |   2  |  0   |   4  |  0   |   6  |  0   |
Int32Array  |      0      |      2      |      4      |      6      |
ArrayBuffer | 00 00 00 00 | 02 00 00 00 | 04 00 00 00 | 06 00 00 00 |
```

You can go a step farther, though. Consider this:

```
int16View[0] = 32;
console.log(`Entry 0 in the 32-bit array is now ${int32View[0]}`);
```

The output from this is `"Entry 0 in the 32-bit array is now 32"`.

In other words, the two arrays are indeed viewed on the same data buffer, treating it as different formats.

```
Int16Array  |  32  |  0   |   2  |  0   |   4  |  0   |   6  |  0   |
Int32Array  |     32      |      2      |      4      |      6      |
ArrayBuffer | 20 00 00 00 | 02 00 00 00 | 04 00 00 00 | 06 00 00 00 |
```

You can do this with any view type, although if you set an integer and then read it as a floating-point number, you will probably get a strange result because the bits are interpreted differently.

```
const float32View = new Float32Array(buffer);
console.log(float32View[0]); // 4.484155085839415e-44
```

Reading text from a buffer

Buffers don't always represent numbers. For example, reading a file can give you a text data buffer. You can read this data out of the buffer using a typed array.

The following reads UTF-8 text using the `TextDecoder` web API:

```
const buffer = new ArrayBuffer(8);
const uint8 = new Uint8Array(buffer);
// Data manually written here, but pretend it was already in the buffer
uint8.set([228, 189, 160, 229, 165, 189]);
const text = new TextDecoder().decode(uint8);
console.log(text); // "你好"
```

The following reads UTF-16 text using the `String.fromCharCode()` method:

```
const buffer = new ArrayBuffer(8);
const uint16 = new Uint16Array(buffer);
// Data manually written here, but pretend it was already in the buffer
uint16.set([0x4f60, 0x597d]);
const text = String.fromCharCode(...uint16);
console.log(text); // "你好"
```

Working with complex data structures

By combining a single buffer with multiple views of different types, starting at different offsets into the buffer, you can interact with data objects containing multiple data types. This lets you, for example, interact with complex data structures from WebGL or data files.

Consider this C structure:

```
struct someStruct {
    unsigned long id;
    char username[16];
    float amountDue;
};
```

You can access a buffer containing data in this format like this:

```
const buffer = new ArrayBuffer(24);

// … read the data into the buffer …

const idView = new Uint32Array(buffer, 0, 1);
const usernameView = new Uint8Array(buffer, 4, 16);
const amountDueView = new Float32Array(buffer, 20, 1);
```

Then you can access, for example, the amount due with `amountDueView[0]`.

> **Note:** The data structure alignment in a C structure is platform-dependent. Take precautions and considerations for these padding differences.

Conversion to normal arrays

After processing a typed array, it is sometimes useful to convert it back to a normal array in order to benefit from the `Array` prototype. This can be done using `Array.from()`:

```
const typedArray = new Uint8Array([1, 2, 3, 4]);
const normalArray = Array.from(typedArray);
```

as well as the spread syntax:

```
const typedArray = new Uint8Array([1, 2, 3, 4]);
const normalArray = [...typedArray];
```

Using classes

- Previous
- Next

JavaScript is a prototype-based language — an object's behaviors are specified by its own properties and its prototype's properties. However, with the addition of classes, the creation of hierarchies of objects and the inheritance of properties and their values are much more in line with other object-oriented languages such as Java. In this section, we will demonstrate how objects can be created from classes.

In many other languages, *classes*, or constructors, are clearly distinguished from *objects*, or instances. In JavaScript, classes are mainly an abstraction over the existing prototypical inheritance mechanism — all patterns are convertible to prototype-based inheritance. Classes themselves are normal JavaScript values as well, and have their own prototype chains. In fact, most plain JavaScript functions can be used as constructors — you use the `new` operator with a constructor function to create a new object.

We will be playing with the well-abstracted class model in this tutorial, and discuss what semantics classes offer. If you want to dive deep into the underlying prototype system, you can read the Inheritance and the prototype chain guide.

This chapter assumes that you are already somewhat familiar with JavaScript and that you have used ordinary objects.

Overview of classes

If you have some hands-on experience with JavaScript, or have followed along with the guide, you probably have already used classes, even if you haven't created one. For example, this may seem familiar to you:

```
const bigDay = new Date(2019, 6, 19);
console.log(bigDay.toLocaleDateString());
if (bigDay.getTime() < Date.now()) {
  console.log("Once upon a time...");
}
```

On the first line, we created an instance of the class `Date`, and called it `bigDay`. On the second line, we called a method `toLocaleDateString()` on the `bigDay` instance, which returns a string. Then, we compared two numbers: one returned from the `getTime()` method, the other directly called from the `Date` class *itself*, as `Date.now()`.

`Date` is a built-in class of JavaScript. From this example, we can get some basic ideas of what classes do:

- Classes create objects through the `new` operator.
- Each object has some properties (data or method) added by the class.
- The class stores some properties (data or method) itself, which are usually used to interact with instances.

These correspond to the three key features of classes:

- Constructor;
- Instance methods and instance fields;
- Static methods and static fields.

Declaring a class

Classes are usually created with *class declarations*.

```
class MyClass {
  // class body...
}
```

Within a class body, there are a range of features available.

```
class MyClass {
  // Constructor
  constructor() {
    // Constructor body
  }
  // Instance field
  myField = "foo";
  // Instance method
  myMethod() {
    // myMethod body
  }
  // Static field
  static myStaticField = "bar";
  // Static method
  static myStaticMethod() {
    // myStaticMethod body
  }
  // Static block
  static {
    // Static initialization code
  }
  // Fields, methods, static fields, and static methods all have
  // "private" forms
  #myPrivateField = "bar";
}
```

If you came from a pre-ES6 world, you may be more familiar with using functions as constructors. The pattern above would roughly translate to the following with function constructors:

```
function MyClass() {
  this.myField = "foo";
  // Constructor body
}
MyClass.myStaticField = "bar";
MyClass.myStaticMethod = function () {
  // myStaticMethod body
};
MyClass.prototype.myMethod = function () {
  // myMethod body
};

(function () {
  // Static initialization code
})();
```

> **Note:** Private fields and methods are new features in classes with no trivial equivalent in function constructors.

Constructing a class

After a class has been declared, you can create instances of it using the `new` operator.

```
const myInstance = new MyClass();
console.log(myInstance.myField); // 'foo'
myInstance.myMethod();
```

Typical function constructors can both be constructed with `new` and called without `new`. However, attempting to "call" a class without `new` will result in an error.

```
const myInstance = MyClass(); // TypeError: Class constructor MyClass cannot be invoked without 'new'
```

Class declaration hoisting

Unlike function declarations, class declarations are not hoisted (or, in some interpretations, hoisted but with the temporal dead zone restriction), which means you cannot use a class before it is declared.

```
new MyClass(); // ReferenceError: Cannot access 'MyClass' before initialization

class MyClass {}
```

This behavior is similar to variables declared with `let` and `const`.

Class expressions

Similar to functions, class declarations also have their expression counterparts.

```
const MyClass = class {
  // Class body...
};
```

Class expressions can have names as well. The expression's name is only visible to the class's body.

```
const MyClass = class MyClassLongerName {
  // Class body. Here MyClass and MyClassLongerName point to the same class.
};
new MyClassLongerName(); // ReferenceError: MyClassLongerName is not defined
```

Constructor

Perhaps the most important job of a class is to act as a "factory" for objects. For example, when we use the `Date` constructor, we expect it to give a new object which represents the date data we passed in — which we can then manipulate with other methods the instance exposes. In classes, the instance creation is done by the constructor.

As an example, we would create a class called `Color`, which represents a specific color. Users create colors through passing in an RGB triplet.

```
class Color {
  constructor(r, g, b) {
    // Assign the RGB values as a property of `this`.
    this.values = [r, g, b];
  }
}
```

Open your browser's devtools, paste the above code into the console, and then create an instance:

```
const red = new Color(255, 0, 0);
console.log(red);
```

You should see some output like this:

```
Object { values: (3) […] }
  values: Array(3) [ 255, 0, 0 ]
```

You have successfully created a `Color` instance, and the instance has a `values` property, which is an array of the RGB values you passed in. That is pretty much equivalent to the following:

```
function createColor(r, g, b) {
  return {
    values: [r, g, b],
  };
}
```

The constructor's syntax is exactly the same as a normal function — which means you can use other syntaxes, like rest parameters:

```
class Color {
  constructor(...values) {
    this.values = values;
  }
}

const red = new Color(255, 0, 0);
// Creates an instance with the same shape as above.
```

Each time you call `new`, a different instance is created.

```
const red = new Color(255, 0, 0);
const anotherRed = new Color(255, 0, 0);
console.log(red === anotherRed); // false
```

Within a class constructor, the value of `this` points to the newly created instance. You can assign properties to it, or read existing properties (especially methods — which we will cover next).

The `this` value will be automatically returned as the result of `new`. You are advised to not return any value from the constructor — because if you return a non-primitive value, it will become the value of the `new` expression, and the value of `this` is dropped. (You can read more about what `new` does in its description.)

```
class MyClass {
  constructor() {
    this.myField = "foo";
    return {};
  }
}

console.log(new MyClass().myField); // undefined
```

Instance methods

If a class only has a constructor, it is not much different from a `createX` factory function which just creates plain objects. However, the power of classes is that they can be used as "templates" which automatically assign methods to instances.

For example, for `Date` instances, you can use a range of methods to get different information from a single date value, such as the year, month, day of the week, etc. You can also set those values through the `setX` counterparts like `setFullYear`.

For our own `Color` class, we can add a method called `getRed` which returns the red value of the color.

```
class Color {
  constructor(r, g, b) {
    this.values = [r, g, b];
  }
  getRed() {
    return this.values[0];
  }
}

const red = new Color(255, 0, 0);
console.log(red.getRed()); // 255
```

Without methods, you may be tempted to define the function within the constructor:

```
class Color {
  constructor(r, g, b) {
    this.values = [r, g, b];
    this.getRed = function () {
      return this.values[0];
    };
  }
}
```

This also works. However, a problem is that this creates a new function every time a `Color` instance is created, even when they all do the same thing!

```
console.log(new Color().getRed === new Color().getRed); // false
```

In contrast, if you use a method, it will be shared between all instances. A function can be shared between all instances, but still have its behavior differ when different instances call it, because the value of `this` is different. If you are curious *where* this method is stored in — it's defined on the prototype of all instances, or `Color.prototype`, which is explained in more detail in Inheritance and the prototype chain.

Similarly, we can create a new method called `setRed`, which sets the red value of the color.

```
class Color {
  constructor(r, g, b) {
    this.values = [r, g, b];
  }
  getRed() {
    return this.values[0];
  }
  setRed(value) {
    this.values[0] = value;
  }
}

const red = new Color(255, 0, 0);
red.setRed(0);
console.log(red.getRed()); // 0; of course, it should be called "black" at this stage!
```

Private fields

You might be wondering: why do we want to go to the trouble of using `getRed` and `setRed` methods, when we can directly access the `values` array on the instance?

```
class Color {
  constructor(r, g, b) {
    this.values = [r, g, b];
  }
}

const red = new Color(255, 0, 0);
red.values[0] = 0;
console.log(red.values[0]); // 0
```

There is a philosophy in object-oriented programming called "encapsulation". This means you should not access the underlying implementation of an object, but instead use well-abstracted methods to interact with it. For example, if we suddenly decided to represent colors as HSL instead:

```
class Color {
  constructor(r, g, b) {
    // values is now an HSL array!
    this.values = rgbToHSL([r, g, b]);
  }
  getRed() {
    return hslToRGB(this.values)[0];
  }
```

```
  setRed(value) {
    const rgb = hslToRGB(this.values);
    rgb[0] = value;
    this.values = rgbToHSL(rgb);
  }
}

const red = new Color(255, 0, 0);
console.log(red.values[0]); // 0; It's not 255 anymore, because the H value for pure red is 0
```

The user assumption that `values` means the RGB value suddenly collapses, and it may cause their logic to break. So, if you are an implementor of a class, you would want to hide the internal data structure of your instance from your user, both to keep the API clean and to prevent the user's code from breaking when you do some "harmless refactors". In classes, this is done through *private fields*.

A private field is an identifier prefixed with `#` (the hash symbol). The hash is an integral part of the field's name, which means a private field can never clash names with a public field or method. In order to refer to a private field anywhere in the class, you must *declare* it in the class body (you can't create a private element on the fly). Apart from this, a private field is pretty much equivalent to a normal property.

```
class Color {
  // Declare: every Color instance has a private field called #values.
  #values;
  constructor(r, g, b) {
    this.#values = [r, g, b];
  }
  getRed() {
    return this.#values[0];
  }
  setRed(value) {
    this.#values[0] = value;
  }
}

const red = new Color(255, 0, 0);
console.log(red.getRed()); // 255
```

Accessing private fields outside the class is an early syntax error. The language can guard against this because `#privateField` is a special syntax, so it can do some static analysis and find all usage of private fields before even evaluating the code.

```
console.log(red.#values); // SyntaxError: Private field '#values' must be declared in an enclosing class
```

> **Note:** Code run in the Chrome console can access private elements outside the class. This is a DevTools-only relaxation of the JavaScript syntax restriction.

Private fields in JavaScript are *hard private*: if the class does not implement methods that expose these private fields, there's absolutely no mechanism to retrieve them from outside the class. This means you are safe to do any refactors to your class's private fields, as long as the behavior of exposed methods stay the same.

After we've made the `values` field private, we can add some more logic in the `getRed` and `setRed` methods, instead of making them simple pass-through methods. For example, we can add a check in `setRed` to see if it's a valid R value:

```
class Color {
  #values;
  constructor(r, g, b) {
    this.#values = [r, g, b];
  }
  getRed() {
    return this.#values[0];
  }
  setRed(value) {
    if (value < 0 || value > 255) {
      throw new RangeError("Invalid R value");
    }
    this.#values[0] = value;
  }
}

const red = new Color(255, 0, 0);
red.setRed(1000); // RangeError: Invalid R value
```

If we leave the `values` property exposed, our users can easily circumvent that check by assigning to `values[0]` directly, and create invalid colors. But with a well-encapsulated API, we can make our code more robust and prevent logic errors downstream.

A class method can read the private fields of other instances, as long as they belong to the same class.

```
class Color {
  #values;
  constructor(r, g, b) {
    this.#values = [r, g, b];
  }
  redDifference(anotherColor) {
    // #values doesn't necessarily need to be accessed from this:
    // you can access private fields of other instances belonging
    // to the same class.
```

```
    return this.#values[0] - anotherColor.#values[0];
  }
}

const red = new Color(255, 0, 0);
const crimson = new Color(220, 20, 60);
red.redDifference(crimson); // 35
```

However, if `anotherColor` is not a Color instance, `#values` won't exist. (Even if another class has an identically named `#values` private field, it's not referring to the same thing and cannot be accessed here.) Accessing a nonexistent private element throws an error instead of returning `undefined` like normal properties do. If you don't know if a private field exists on an object and you wish to access it without using `try/catch` to handle the error, you can use the `in` operator.

```
class Color {
  #values;
  constructor(r, g, b) {
    this.#values = [r, g, b];
  }
  redDifference(anotherColor) {
    if (!(#values in anotherColor)) {
      throw new TypeError("Color instance expected");
    }
    return this.#values[0] - anotherColor.#values[0];
  }
}
```

> **Note:** Keep in mind that the `#` is a special identifier syntax, and you can't use the field name as if it's a string. `"#values" in anotherColor` would look for a property name literally called `"#values"`, instead of a private field.

There are some limitations in using private elements: the same name can't be declared twice in a single class, and they can't be deleted. Both lead to early syntax errors.

```
class BadIdeas {
  #firstName;
  #firstName; // syntax error occurs here
  #lastName;
  constructor() {
    delete this.#lastName; // also a syntax error
  }
}
```

Methods, getters, and setters can be private as well. They're useful when you have something complex that the class needs to do internally but no other part of the code should be allowed to call.

For example, imagine creating HTML custom elements that should do something somewhat complicated when clicked/tapped/otherwise activated. Furthermore, the somewhat complicated things that happen when the element is clicked should be restricted to this class, because no other part of the JavaScript will (or should) ever access it.

```
class Counter extends HTMLElement {
  #xValue = 0;
  constructor() {
    super();
    this.onclick = this.#clicked.bind(this);
  }
  get #x() {
    return this.#xValue;
  }
  set #x(value) {
    this.#xValue = value;
    window.requestAnimationFrame(this.#render.bind(this));
  }
  #clicked() {
    this.#x++;
  }
  #render() {
    this.textContent = this.#x.toString();
  }
  connectedCallback() {
    this.#render();
  }
}

customElements.define("num-counter", Counter);
```

In this case, pretty much every field and method is private to the class. Thus, it presents an interface to the rest of the code that's essentially just like a built-in HTML element. No other part of the program has the power to affect any of the internals of `Counter`.

Accessor fields

`color.getRed()` and `color.setRed()` allow us to read and write to the red value of a color. If you come from languages like Java, you will be very familiar with this pattern. However, using methods to simply access a property is still somewhat unergonomic in JavaScript. *Accessor fields* allow us to manipulate something as if it is an "actual property".

```
class Color {
  constructor(r, g, b) {
    this.values = [r, g, b];
  }
  get red() {
    return this.values[0];
  }
  set red(value) {
    this.values[0] = value;
  }
}

const red = new Color(255, 0, 0);
red.red = 0;
console.log(red.red); // 0
```

It looks as if the object has a property called `red` — but actually, no such property exists on the instance! There are only two methods, but they are prefixed with `get` and `set`, which allows them to be manipulated as if they were properties.

If a field only has a getter but no setter, it will be effectively read-only.

```
class Color {
  constructor(r, g, b) {
    this.values = [r, g, b];
  }
  get red() {
    return this.values[0];
  }
}

const red = new Color(255, 0, 0);
red.red = 0;
console.log(red.red); // 255
```

In strict mode, the `red.red = 0` line will throw a type error: "Cannot set property red of #<Color> which has only a getter". In non-strict mode, the assignment is silently ignored.

Public fields

Private fields also have their public counterparts, which allow every instance to have a property. Fields are usually designed to be independent of the constructor's parameters.

```
class MyClass {
  luckyNumber = Math.random();
}
console.log(new MyClass().luckyNumber); // 0.5
console.log(new MyClass().luckyNumber); // 0.3
```

Public fields are almost equivalent to assigning a property to `this`. For example, the above example can also be converted to:

```
class MyClass {
  constructor() {
    this.luckyNumber = Math.random();
  }
}
```

Static properties

With the `Date` example, we have also encountered the `Date.now()` method, which returns the current date. This method does not belong to any date instance — it belongs to the class itself. However, it's put on the `Date` class instead of being exposed as a global `DateNow()` function, because it's mostly useful when dealing with date instances.

> **Note:** Prefixing utility methods with what they deal with is called "namespacing" and is considered a good practice. For example, in addition to the older, unprefixed `parseInt()` method, JavaScript also later added the prefixed `Number.parseInt()` method to indicate that it's for dealing with numbers.

Static properties are a group of class features that are defined on the class itself, rather than on individual instances of the class. These features include:

- Static methods
- Static fields
- Static getters and setters

Everything also has private counterparts. For example, for our `Color` class, we can create a static method that checks whether a given triplet is a valid RGB value:

```
class Color {
  static isValid(r, g, b) {
    return r >= 0 && r <= 255 && g >= 0 && g <= 255 && b >= 0 && b <= 255;
  }
}
```

```
Color.isValid(255, 0, 0); // true
Color.isValid(1000, 0, 0); // false
```

Static properties are very similar to their instance counterparts, except that:

- They are all prefixed with `static`, and
- They are not accessible from instances.

```
console.log(new Color(0, 0, 0).isValid); // undefined
```

There is also a special construct called a *static initialization block*, which is a block of code that runs when the class is first loaded.

```
class MyClass {
  static {
    MyClass.myStaticProperty = "foo";
  }
}

console.log(MyClass.myStaticProperty); // 'foo'
```

Static initialization blocks are almost equivalent to immediately executing some code after a class has been declared. The only difference is that they have access to static private elements.

Extends and inheritance

A key feature that classes bring about (in addition to ergonomic encapsulation with private fields) is *inheritance*, which means one object can "borrow" a large part of another object's behaviors, while overriding or enhancing certain parts with its own logic.

For example, suppose our `Color` class now needs to support transparency. We may be tempted to add a new field that indicates its transparency:

```
class Color {
  #values;
  constructor(r, g, b, a = 1) {
    this.#values = [r, g, b, a];
  }
  get alpha() {
    return this.#values[3];
  }
  set alpha(value) {
    if (value < 0 || value > 1) {
      throw new RangeError("Alpha value must be between 0 and 1");
    }
    this.#values[3] = value;
  }
}
```

However, this means every instance — even the vast majority which aren't transparent (those with an alpha value of 1) — will have to have the extra alpha value, which is not very elegant. Plus, if the features keep growing, our `Color` class will become very bloated and hard to maintain.

Instead, in object-oriented programming, we would create a *derived class*. The derived class has access to all public properties of the parent class. In JavaScript, derived classes are declared with an `extends` clause, which indicates the class it extends from.

```
class ColorWithAlpha extends Color {
  #alpha;
  constructor(r, g, b, a) {
    super(r, g, b);
    this.#alpha = a;
  }
  get alpha() {
    return this.#alpha;
  }
  set alpha(value) {
    if (value < 0 || value > 1) {
      throw new RangeError("Alpha value must be between 0 and 1");
    }
    this.#alpha = value;
  }
}
```

There are a few things that have immediately come to attention. First is that in the constructor, we are calling `super(r, g, b)`. It is a language requirement to call `super()` before accessing `this`. The `super()` call calls the parent class's constructor to initialize `this` — here it's roughly equivalent to `this = new Color(r, g, b)`. You can have code before `super()`, but you cannot access `this` before `super()` — the language prevents you from accessing the uninitialized `this`.

After the parent class is done with modifying `this`, the derived class can do its own logic. Here we added a private field called `#alpha`, and also provided a pair of getter/setters to interact with them.

A derived class inherits all methods from its parent. For example, consider the `get red()` accessor we added to the `Color` in the Accessor fields section—even though we haven't declared one in `ColorWithAlpha`, we can still access `red` because this behavior is specified by the parent class:

```
const color = new ColorWithAlpha(255, 0, 0, 0.5);
console.log(color.red); // 255
```

Derived classes can also override methods from the parent class. For example, all classes implicitly inherit the `Object` class, which defines some basic methods like `toString()`. However, the base `toString()` method is notoriously useless, because it prints `[object Object]` in most cases:

```
console.log(red.toString()); // [object Object]
```

Instead, our class can override it to print the color's RGB values:

```
class Color {
  #values;
  // …
  toString() {
    return this.#values.join(", ");
  }
}

console.log(new Color(255, 0, 0).toString()); // '255, 0, 0'
```

Within derived classes, you can access the parent class's methods by using `super`. This allows you to build enhancement methods and avoid code duplication.

```
class ColorWithAlpha extends Color {
  #alpha;
  // …
  toString() {
    // Call the parent class's toString() and build on the return value
    return `${super.toString()}, ${this.#alpha}`;
  }
}

console.log(new ColorWithAlpha(255, 0, 0, 0.5).toString()); // '255, 0, 0, 0.5'
```

When you use `extends`, the static methods inherit from each other as well, so you can also override or enhance them.

```
class ColorWithAlpha extends Color {
  // …
  static isValid(r, g, b, a) {
    // Call the parent class's isValid() and build on the return value
    return super.isValid(r, g, b) && a >= 0 && a <= 1;
  }
}

console.log(ColorWithAlpha.isValid(255, 0, 0, -1)); // false
```

Derived classes don't have access to the parent class's private fields — this is another key aspect to JavaScript private fields being "hard private". Private fields are scoped to the class body itself and do not grant access to *any* outside code.

```
class ColorWithAlpha extends Color {
  log() {
    console.log(this.#values); // SyntaxError: Private field '#values' must be declared in an enclosing class
  }
}
```

A class can only extend from one class. This prevents problems in multiple inheritance like the diamond problem. However, due to the dynamic nature of JavaScript, it's still possible to achieve the effect of multiple inheritance through class composition and mixins.

Instances of derived classes are also instances of the base class.

```
const color = new ColorWithAlpha(255, 0, 0, 0.5);
console.log(color instanceof Color); // true
console.log(color instanceof ColorWithAlpha); // true
```

Why classes?

The guide has been pragmatic so far: we are focusing on *how* classes can be used, but there's one question unanswered: *why* would one use a class? The answer is: it depends.

Classes introduce a *paradigm*, or a way to organize your code. Classes are the foundations of object-oriented programming, which is built on concepts like inheritance and polymorphism (especially *subtype polymorphism*). However, many people are philosophically against certain OOP practices and don't use classes as a result.

For example, one thing that makes `Date` objects infamous is that they're *mutable*.

```
function incrementDay(date) {
  return new Date(date.setDate(date.getDate() + 1));
}
const date = new Date(); // 2019-06-19
const newDay = incrementDay(date);
console.log(newDay); // 2019-06-20
// The old date is modified as well!?
console.log(date); // 2019-06-20
```

Mutability and internal state are important aspects of object-oriented programming, but often make code hard to reason with — because any seemingly innocent operation may have unexpected side effects and change the behavior in other parts of the program.

In order to reuse code, we usually resort to extending classes, which can create big hierarchies of inheritance patterns.

However, it is often hard to describe inheritance cleanly when one class can only extend one other class. Often, we want the behavior of multiple classes. In Java, this is done through interfaces; in JavaScript, it can be done through mixins. But at the end of the day, it's still not very convenient.

On the brighter side, classes are a very powerful way to organize our code on a higher level. For example, without the `Color` class, we may need to create a dozen of utility functions:

```
function isRed(color) {
  return color.red === 255;
}
function isValidColor(color) {
  return (
    color.red >= 0 &&
    color.red <= 255 &&
    color.green >= 0 &&
    color.green <= 255 &&
    color.blue >= 0 &&
    color.blue <= 255
  );
}
// …
```

But with classes, we can congregate them all under the `Color` namespace, which improves readability. In addition, the introduction of private fields allows us to hide certain data from downstream users, creating a clean API.

In general, you should consider using classes when you want to create objects that store their own internal data and expose a lot of behavior. Take built-in JavaScript classes as examples:

- The `Map` and `Set` classes store a collection of elements and allow you to access them by key using `get()`, `set()`, `has()`, etc.
- The `Date` class stores a date as a Unix timestamp (a number) and allows you to format, update, and read individual date components.
- The `Error` class stores information about a particular exception, including the error message, stack trace, cause, etc. It's one of the few classes that come with a rich inheritance structure: there are multiple built-in classes like `TypeError` and `ReferenceError` that extend `Error`. In the case of errors, this inheritance allows refining the semantics of errors: each error class represents a specific type of error, which can be easily checked with `instanceof`.

JavaScript offers the mechanism to organize your code in a canonical object-oriented way, but whether and how to use it is entirely up to the programmer's discretion.

Using promises

- Previous
- Next

A `Promise` is an object representing the eventual completion or failure of an asynchronous operation. Since most people are consumers of already-created promises, this guide will explain consumption of returned promises before explaining how to create them.

Essentially, a promise is a returned object to which you attach callbacks, instead of passing callbacks into a function. Imagine a function, `createAudioFileAsync()`, which asynchronously generates a sound file given a configuration record and two callback functions: one called if the audio file is successfully created, and the other called if an error occurs.

Here's some code that uses `createAudioFileAsync()`:

```
function successCallback(result) {
  console.log(`Audio file ready at URL: ${result}`);
}

function failureCallback(error) {
  console.error(`Error generating audio file: ${error}`);
}

createAudioFileAsync(audioSettings, successCallback, failureCallback);
```

If `createAudioFileAsync()` were rewritten to return a promise, you would attach your callbacks to it instead:

```
createAudioFileAsync(audioSettings).then(successCallback, failureCallback);
```

This convention has several advantages. We will explore each one.

Chaining

A common need is to execute two or more asynchronous operations back to back, where each subsequent operation starts when the previous operation succeeds, with the result from the previous step. In the old days, doing several asynchronous operations in a row would lead to the classic callback hell:

```
doSomething(function (result) {
  doSomethingElse(result, function (newResult) {
    doThirdThing(newResult, function (finalResult) {
      console.log(`Got the final result: ${finalResult}`);
    }, failureCallback);
```

```
  }, failureCallback);
}, failureCallback);
```

With promises, we accomplish this by creating a promise chain. The API design of promises makes this great, because callbacks are attached to the returned promise object, instead of being passed into a function.

Here's the magic: the `then()` function returns a **new promise**, different from the original:

```
const promise = doSomething();
const promise2 = promise.then(successCallback, failureCallback);
```

This second promise (`promise2`) represents the completion not just of `doSomething()`, but also of the `successCallback` or `failureCallback` you passed in — which can be other asynchronous functions returning a promise. When that's the case, any callbacks added to `promise2` get queued behind the promise returned by either `successCallback` or `failureCallback`.

> **Note:** If you want a working example to play with, you can use the following template to create any function returning a promise:
>
> ```
> function doSomething() {
>   return new Promise((resolve) => {
>     setTimeout(() => {
>       // Other things to do before completion of the promise
>       console.log("Did something");
>       // The fulfillment value of the promise
>       resolve("https://example.com/");
>     }, 200);
>   });
> }
> ```
>
> The implementation is discussed in the Creating a Promise around an old callback API section below.

With this pattern, you can create longer chains of processing, where each promise represents the completion of one asynchronous step in the chain. In addition, the arguments to `then` are optional, and `catch(failureCallback)` is short for `then(null, failureCallback)` — so if your error handling code is the same for all steps, you can attach it to the end of the chain:

```
doSomething()
  .then(function (result) {
    return doSomethingElse(result);
  })
  .then(function (newResult) {
    return doThirdThing(newResult);
  })
  .then(function (finalResult) {
    console.log(`Got the final result: ${finalResult}`);
  })
  .catch(failureCallback);
```

You might see this expressed with arrow functions instead:

```
doSomething()
  .then((result) => doSomethingElse(result))
  .then((newResult) => doThirdThing(newResult))
  .then((finalResult) => {
    console.log(`Got the final result: ${finalResult}`);
  })
  .catch(failureCallback);
```

> **Note:** Arrow function expressions can have an implicit return; so, `() => x` is short for `() => { return x; }`.

`doSomethingElse` and `doThirdThing` can return any value — if they return promises, that promise is first waited until it settles, and the next callback receives the fulfillment value, not the promise itself. It is important to always return promises from `then` callbacks, even if the promise always resolves to `undefined`. If the previous handler started a promise but did not return it, there's no way to track its settlement anymore, and the promise is said to be "floating".

```
doSomething()
  .then((url) => {
    // Missing `return` keyword in front of fetch(url).
    fetch(url);
  })
  .then((result) => {
    // result is undefined, because nothing is returned from the previous
    // handler. There's no way to know the return value of the fetch()
    // call anymore, or whether it succeeded at all.
  });
```

By returning the result of the `fetch` call (which is a promise), we can both track its completion and receive its value when it completes.

```
doSomething()
  .then((url) => {
    // `return` keyword added
```

```
    return fetch(url);
  })
  .then((result) => {
    // result is a Response object
  });
```

Floating promises could be worse if you have race conditions — if the promise from the last handler is not returned, the next `then` handler will be called early, and any value it reads may be incomplete.

```
const listOfIngredients = [];

doSomething()
  .then((url) => {
    // Missing `return` keyword in front of fetch(url).
    fetch(url)
      .then((res) => res.json())
      .then((data) => {
        listOfIngredients.push(data);
      });
  })
  .then(() => {
    console.log(listOfIngredients);
    // listOfIngredients will always be [], because the fetch request hasn't completed yet.
  });
```

Therefore, as a rule of thumb, whenever your operation encounters a promise, return it and defer its handling to the next `then` handler.

```
const listOfIngredients = [];

doSomething()
  .then((url) => {
    // `return` keyword now included in front of fetch call.
    return fetch(url)
      .then((res) => res.json())
      .then((data) => {
        listOfIngredients.push(data);
      });
  })
  .then(() => {
    console.log(listOfIngredients);
    // listOfIngredients will now contain data from fetch call.
  });
```

Even better, you can flatten the nested chain into a single chain, which is simpler and makes error handling easier. The details are discussed in the Nesting section below.

```
doSomething()
  .then((url) => fetch(url))
  .then((res) => res.json())
  .then((data) => {
    listOfIngredients.push(data);
  })
  .then(() => {
    console.log(listOfIngredients);
  });
```

Using `async/await` can help you write code that's more intuitive and resembles synchronous code. Below is the same example using `async/await`:

```
async function logIngredients() {
  const url = await doSomething();
  const res = await fetch(url);
  const data = await res.json();
  listOfIngredients.push(data);
  console.log(listOfIngredients);
}
```

Note how the code looks exactly like synchronous code, except for the `await` keywords in front of promises. One of the only tradeoffs is that it may be easy to forget the `await` keyword, which can only be fixed when there's a type mismatch (e.g., trying to use a promise as a value).

`async/await` builds on promises — for example, `doSomething()` is the same function as before, so there's minimal refactoring needed to change from promises to `async/await`. You can read more about the `async/await` syntax in the async functions and `await` references.

> **Note:** `async/await` has the same concurrency semantics as normal promise chains. `await` within one async function does not stop the entire program, only the parts that depend on its value, so other async jobs can still run while the `await` is pending.

Error handling

You might recall seeing `failureCallback` three times in the pyramid of doom earlier, compared to only once at the end of the promise chain:

```
doSomething()
  .then((result) => doSomethingElse(result))
```

```
  .then((newResult) => doThirdThing(newResult))
  .then((finalResult) => console.log(`Got the final result: ${finalResult}`))
  .catch(failureCallback);
```

If there's an exception, the browser will look down the chain for `.catch()` handlers or `onRejected`. This is very much modeled after how synchronous code works:

```
try {
  const result = syncDoSomething();
  const newResult = syncDoSomethingElse(result);
  const finalResult = syncDoThirdThing(newResult);
  console.log(`Got the final result: ${finalResult}`);
} catch (error) {
  failureCallback(error);
}
```

This symmetry with asynchronous code culminates in the `async/await` syntax:

```
async function foo() {
  try {
    const result = await doSomething();
    const newResult = await doSomethingElse(result);
    const finalResult = await doThirdThing(newResult);
    console.log(`Got the final result: ${finalResult}`);
  } catch (error) {
    failureCallback(error);
  }
}
```

Promises solve a fundamental flaw with the callback pyramid of doom, by catching all errors, even thrown exceptions and programming errors. This is essential for functional composition of asynchronous operations. All errors are now handled by the `catch()` method at the end of the chain, and you should almost never need to use `try/catch` without using `async/await`.

Nesting

In the examples above involving `listOfIngredients`, the first one has one promise chain nested in the return value of another `then()` handler, while the second one uses an entirely flat chain. Simple promise chains are best kept flat without nesting, as nesting can be a result of careless composition.

Nesting is a control structure to limit the scope of `catch` statements. Specifically, a nested `catch` only catches failures in its scope and below, not errors higher up in the chain outside the nested scope. When used correctly, this gives greater precision in error recovery:

```
doSomethingCritical()
  .then((result) =>
    doSomethingOptional(result)
      .then((optionalResult) => doSomethingExtraNice(optionalResult))
      .catch((e) => {}),
  ) // Ignore if optional stuff fails; proceed.
  .then(() => moreCriticalStuff())
  .catch((e) => console.error(`Critical failure: ${e.message}`));
```

Note that the optional steps here are nested — with the nesting caused not by the indentation, but by the placement of the outer `(` and `)` parentheses around the steps.

The inner error-silencing `catch` handler only catches failures from `doSomethingOptional()` and `doSomethingExtraNice()`, after which the code resumes with `moreCriticalStuff()`. Importantly, if `doSomethingCritical()` fails, its error is caught by the final (outer) `catch` only, and does not get swallowed by the inner `catch` handler.

In `async/await`, this code looks like:

```
async function main() {
  try {
    const result = await doSomethingCritical();
    try {
      const optionalResult = await doSomethingOptional(result);
      await doSomethingExtraNice(optionalResult);
    } catch (e) {
      // Ignore failures in optional steps and proceed.
    }
    await moreCriticalStuff();
  } catch (e) {
    console.error(`Critical failure: ${e.message}`);
  }
}
```

> **Note:** If you don't have sophisticated error handling, you very likely don't need nested `then` handlers. Instead, use a flat chain and put the error handling logic at the end.

Chaining after a catch

It's possible to chain *after* a failure, i.e., a `catch`, which is useful to accomplish new actions even after an action failed in the chain. Read the following example:

```
doSomething()
  .then(() => {
    throw new Error("Something failed");

    console.log("Do this");
  })
  .catch(() => {
    console.error("Do that");
  })
  .then(() => {
    console.log("Do this, no matter what happened before");
  });
```

This will output the following text:

```
Do that
Do this, no matter what happened before
```

> **Note:** The text "Do this" is not displayed because the "Something failed" error caused a rejection.

In `async/await`, this code looks like:

```
async function main() {
  try {
    await doSomething();
    throw new Error("Something failed");
    console.log("Do this");
  } catch (e) {
    console.error("Do that");
  }
  console.log("Do this, no matter what happened before");
}
```

Promise rejection events

If a promise rejection event is not handled by any handler, it bubbles to the top of the call stack, and the host needs to surface it. On the web, whenever a promise is rejected, one of two events is sent to the global scope (generally, this is either the `window` or, if being used in a web worker, it's the `Worker` or other worker-based interface). The two events are:

`unhandledrejection`

: Sent when a promise is rejected but there is no rejection handler available.

`rejectionhandled`

: Sent when a handler is attached to a rejected promise that has already caused an `unhandledrejection` event.

In both cases, the event (of type `PromiseRejectionEvent`) has as members a `promise` property indicating the promise that was rejected, and a `reason` property that provides the reason given for the promise to be rejected.

These make it possible to offer fallback error handling for promises, as well as to help debug issues with your promise management. These handlers are global per context, so all errors will go to the same event handlers, regardless of source.

In Node.js, handling promise rejection is slightly different. You capture unhandled rejections by adding a handler for the Node.js `unhandledRejection` event (notice the difference in capitalization of the name), like this:

```
process.on("unhandledRejection", (reason, promise) => {
  // Add code here to examine the "promise" and "reason" values
});
```

For Node.js, to prevent the error from being logged to the console (the default action that would otherwise occur), adding that `process.on()` listener is all that's necessary; there's no need for an equivalent of the browser runtime's `preventDefault()` method.

However, if you add that `process.on` listener but don't also have code within it to handle rejected promises, they will just be dropped on the floor and silently ignored. So ideally, you should add code within that listener to examine each rejected promise and make sure it was not caused by an actual code bug.

Composition

There are four composition tools for running asynchronous operations concurrently: `Promise.all()`, `Promise.allSettled()`, `Promise.any()`, and `Promise.race()`.

We can start operations at the same time and wait for them all to finish like this:

```
Promise.all([func1(), func2(), func3()]).then(([result1, result2, result3]) => {
  // use result1, result2 and result3
});
```

If one of the promises in the array rejects, `Promise.all()` immediately rejects the returned promise. The other operations continue to run, but their outcomes are not available via the return value of `Promise.all()`. This may cause unexpected state or behavior. `Promise.allSettled()` is another composition tool that ensures all operations are complete before resolving.

These methods all run promises concurrently — a sequence of promises are started simultaneously and do not wait for each other. Sequential composition is possible using some clever JavaScript:

```
[func1, func2, func3]
  .reduce((p, f) => p.then(f), Promise.resolve())
  .then((result3) => {
    /* use result3 */
  });
```

In this example, we reduce an array of asynchronous functions down to a promise chain. The code above is equivalent to:

```
Promise.resolve()
  .then(func1)
  .then(func2)
  .then(func3)
  .then((result3) => {
    /* use result3 */
  });
```

This can be made into a reusable compose function, which is common in functional programming:

```
const applyAsync = (acc, val) => acc.then(val);
const composeAsync =
  (...funcs) =>
  (x) =>
    funcs.reduce(applyAsync, Promise.resolve(x));
```

The `composeAsync()` function accepts any number of functions as arguments and returns a new function that accepts an initial value to be passed through the composition pipeline:

```
const transformData = composeAsync(func1, func2, func3);
const result3 = transformData(data);
```

Sequential composition can also be done more succinctly with async/await:

```
let result;
for (const f of [func1, func2, func3]) {
  result = await f(result);
}
/* use last result (i.e. result3) */
```

However, before you compose promises sequentially, consider if it's really necessary — it's always better to run promises concurrently so that they don't unnecessarily block each other unless one promise's execution depends on another's result.

Cancellation

`Promise` itself has no first-class protocol for cancellation, but you may be able to directly cancel the underlying asynchronous operation, typically using `AbortController`.

Creating a Promise around an old callback API

A `Promise` can be created from scratch using its constructor. This should be needed only to wrap old APIs.

In an ideal world, all asynchronous functions would already return promises. Unfortunately, some APIs still expect success and/or failure callbacks to be passed in the old way. The most obvious example is the `setTimeout()` function:

```
setTimeout(() => saySomething("10 seconds passed"), 10 * 1000);
```

Mixing old-style callbacks and promises is problematic. If `saySomething()` fails or contains a programming error, nothing catches it. This is intrinsic to the design of `setTimeout()`.

Luckily we can wrap `setTimeout()` in a promise. The best practice is to wrap the callback-accepting functions at the lowest possible level, and then never call them directly again:

```
const wait = (ms) => new Promise((resolve) => setTimeout(resolve, ms));

wait(10 * 1000)
  .then(() => saySomething("10 seconds"))
  .catch(failureCallback);
```

The promise constructor takes an executor function that lets us resolve or reject a promise manually. Since `setTimeout()` doesn't really fail, we left out reject in this case. For more information on how the executor function works, see the `Promise()` reference.

Timing

Lastly, we will look into the more technical details, about when the registered callbacks get called.

Guarantees

In the callback-based API, when and how the callback gets called depends on the API implementor. For example, the callback may be called synchronously or asynchronously:

```
function doSomething(callback) {
  if (Math.random() > 0.5) {
    callback();
  } else {
    setTimeout(() => callback(), 1000);
  }
}
```

The above design is strongly discouraged because it leads to the so-called "state of Zalgo". In the context of designing asynchronous APIs, this means a callback is called synchronously in some cases but asynchronously in other cases, creating ambiguity for the caller. For further background, see the article Designing APIs for Asynchrony, where the term was first formally presented. This API design makes side effects hard to analyze:

```
let value = 1;
doSomething(() => {
  value = 2;
});
console.log(value); // 1 or 2?
```

On the other hand, promises are a form of inversion of control — the API implementor does not control when the callback gets called. Instead, the job of maintaining the callback queue and deciding when to call the callbacks is delegated to the promise implementation, and both the API user and API developer automatically get strong semantic guarantees, including:

- Callbacks added with `then()` will never be invoked before the completion of the current run of the JavaScript event loop.
- These callbacks will be invoked even if they were added *after* the success or failure of the asynchronous operation that the promise represents.
- Multiple callbacks may be added by calling `then()` several times. They will be invoked one after another, in the order in which they were inserted.

To avoid surprises, functions passed to `then()` will never be called synchronously, even with an already-resolved promise:

```
Promise.resolve().then(() => console.log(2));
console.log(1);
// Logs: 1, 2
```

Instead of running immediately, the passed-in function is put on a microtask queue, which means it runs later (only after the function which created it exits, and when the JavaScript execution stack is empty), just before control is returned to the event loop; i.e., pretty soon:

```
const wait = (ms) => new Promise((resolve) => setTimeout(resolve, ms));

wait(0).then(() => console.log(4));
Promise.resolve()
  .then(() => console.log(2))
  .then(() => console.log(3));
console.log(1); // 1, 2, 3, 4
```

Task queues vs. microtasks

Promise callbacks are handled as a microtask whereas `setTimeout()` callbacks are handled as task queues.

```
const promise = new Promise((resolve, reject) => {
  console.log("Promise callback");
  resolve();
}).then((result) => {
  console.log("Promise callback (.then)");
});

setTimeout(() => {
  console.log("event-loop cycle: Promise (fulfilled)", promise);
}, 0);

console.log("Promise (pending)", promise);
```

The code above will output:

```
Promise callback
Promise (pending) Promise {<pending>}
Promise callback (.then)
event-loop cycle: Promise (fulfilled) Promise {<fulfilled>}
```

For more details, refer to Tasks vs. microtasks.

When promises and tasks collide

If you run into situations in which you have promises and tasks (such as events or callbacks) which are firing in unpredictable orders, it's possible you may benefit from using a microtask to check status or balance out your promises when promises are created conditionally.

If you think microtasks may help solve this problem, see the microtask guide to learn more about how to use `queueMicrotask()` to enqueue a function as a microtask.

Working with objects

- Previous
- Next

JavaScript is designed on an object-based paradigm. An object is a collection of properties, and a property is an association between a name (or *key*) and a value. A property's value can be a function, in which case the property is known as a method.

Objects in JavaScript, just as in many other programming languages, can be compared to objects in real life. In JavaScript, an object is a standalone entity, with properties and type. Compare it with a cup, for example. A cup is an object with properties. A cup has a color, a design, weight, a material it is made of, etc. In the same way, JavaScript objects can have properties, which define their characteristics.

In addition to objects that are predefined in the browser, you can define your own objects. This chapter describes how to use objects, properties, and methods, and how to create your own objects.

Creating new objects

You can create an object using an object initializer. Alternatively, you can first create a constructor function and then instantiate an object by invoking that function with the `new` operator.

Using object initializers

Object initializers are also called *object literals*. "Object initializer" is consistent with the terminology used by C++.

The syntax for an object using an object initializer is:

```
const obj = {
  property1: value1, // property name may be an identifier
  2: value2, // or a number
  "property n": value3, // or a string
};
```

Each property name before the colon is either an identifier, a number literal, or a string literal, and each `valueN` is an expression whose value is assigned to the property name. The property name can also be an expression; computed keys need to be wrapped in square brackets. The object initializer reference contains a more detailed explanation of the syntax.

In this example, the newly created object is assigned to a variable `obj` — this is optional. If you do not need to refer to this object elsewhere, you do not need to assign it to a variable. (Note that you may need to wrap the object literal in parentheses if the object appears where a statement is expected, so as not to have the literal be confused with a block statement.)

Object initializers are expressions, and each object initializer results in a new object being created whenever the statement in which it appears is executed. Identical object initializers create distinct objects that do not compare to each other as equal.

The following statement creates an object and assigns it to the variable `x` if and only if the expression `cond` is true:

```
let x;
if (cond) {
  x = { greeting: "hi there" };
}
```

The following example creates `myHonda` with three properties. Note that the `engine` property is also an object with its own properties.

```
const myHonda = {
  color: "red",
  wheels: 4,
  engine: { cylinders: 4, size: 2.2 },
};
```

Objects created with initializers are called *plain objects*, because they are instances of `Object`, but not any other object type. Some object types have special initializer syntaxes — for example, array initializers and regex literals.

Using a constructor function

Alternatively, you can create an object with these two steps:

1. Define the object type by writing a constructor function. There is a strong convention, with good reason, to use a capital initial letter.
2. Create an instance of the object with `new`.

To define an object type, create a function for the object type that specifies its name, properties, and methods. For example, suppose you want to create an object type for cars. You want this type of object to be called `Car`, and you want it to have properties for make, model, and year. To do this, you would write the following function:

```
function Car(make, model, year) {
  this.make = make;
  this.model = model;
```

```
  this.year = year;
}
```

Notice the use of `this` to assign values to the object's properties based on the values passed to the function.

Now you can create an object called `myCar` as follows:

```
const myCar = new Car("Eagle", "Talon TSi", 1993);
```

This statement creates `myCar` and assigns it the specified values for its properties. Then the value of `myCar.make` is the string `"Eagle"`, `myCar.model` is the string `"Talon TSi"`, `myCar.year` is the integer `1993`, and so on. The order of arguments and parameters should be the same.

You can create any number of `Car` objects by calls to `new`. For example,

```
const randCar = new Car("Nissan", "300ZX", 1992);
const kenCar = new Car("Mazda", "Miata", 1990);
```

An object can have a property that is itself another object. For example, suppose you define an object called `Person` as follows:

```
function Person(name, age, sex) {
  this.name = name;
  this.age = age;
  this.sex = sex;
}
```

and then instantiate two new `Person` objects as follows:

```
const rand = new Person("Rand McKinnon", 33, "M");
const ken = new Person("Ken Jones", 39, "M");
```

Then, you can rewrite the definition of `Car` to include an `owner` property that takes a `Person` object, as follows:

```
function Car(make, model, year, owner) {
  this.make = make;
  this.model = model;
  this.year = year;
  this.owner = owner;
}
```

To instantiate the new objects, you then use the following:

```
const car1 = new Car("Eagle", "Talon TSi", 1993, rand);
const car2 = new Car("Nissan", "300ZX", 1992, ken);
```

Notice that instead of passing a literal string or integer value when creating the new objects, the above statements pass the objects `rand` and `ken` as the arguments for the owners. Then if you want to find out the name of the owner of `car2`, you can access the following property:

```
car2.owner.name;
```

You can always add a property to a previously defined object. For example, the statement

```
car1.color = "black";
```

adds a property `color` to `car1`, and assigns it a value of `"black"`. However, this does not affect any other objects. To add the new property to all objects of the same type, you have to add the property to the definition of the `Car` object type.

You can also use the `class` syntax instead of the `function` syntax to define a constructor function. For more information, see the class guide.

Using the Object.create() method

Objects can also be created using the `Object.create()` method. This method can be very useful, because it allows you to choose the prototype object for the object you want to create, without having to define a constructor function.

```
// Animal properties and method encapsulation
const animalProto = {
  type: "Invertebrates", // Default value of properties
  displayType() {
    // Method which will display the type of animal
    console.log(this.type);
  },
};

// Create a new animal type called `animal`
const animal = Object.create(animalProto);
animal.displayType(); // Logs: Invertebrates

// Create a new animal type called fish
const fish = Object.create(animalProto);
fish.type = "Fishes";
fish.displayType(); // Logs: Fishes
```

Objects and properties

A JavaScript object has properties associated with it. Object properties are basically the same as variables, except that they are associated with objects, not scopes. The properties of an object define the characteristics of the object.

For example, this example creates an object named `myCar`, with properties named `make`, `model`, and `year`, with their values set to `"Ford"`, `"Mustang"`, and `1969`:

```
const myCar = {
  make: "Ford",
  model: "Mustang",
  year: 1969,
};
```

Like JavaScript variables, property names are case sensitive. Property names can only be strings or Symbols — all keys are converted to strings unless they are Symbols. Array indices are, in fact, properties with string keys that contain integers.

Accessing properties

You can access a property of an object by its property name. Property accessors come in two syntaxes: *dot notation* and *bracket notation*. For example, you could access the properties of the `myCar` object as follows:

```
// Dot notation
myCar.make = "Ford";
myCar.model = "Mustang";
myCar.year = 1969;

// Bracket notation
myCar["make"] = "Ford";
myCar["model"] = "Mustang";
myCar["year"] = 1969;
```

An object property name can be any JavaScript string or symbol, including an empty string. However, you cannot use dot notation to access a property whose name is not a valid JavaScript identifier. For example, a property name that has a space or a hyphen, that starts with a number, or that is held inside a variable can only be accessed using the bracket notation. This notation is also very useful when property names are to be dynamically determined, i.e., not determinable until runtime. Examples are as follows:

```
const myObj = {};
const str = "myString";
const rand = Math.random();
const anotherObj = {};

// Create additional properties on myObj
myObj.type = "Dot syntax for a key named type";
myObj["date created"] = "This key has a space";
myObj[str] = "This key is in variable str";
myObj[rand] = "A random number is the key here";
myObj[anotherObj] = "This key is object anotherObj";
myObj[""] = "This key is an empty string";

console.log(myObj);
// {
//   type: 'Dot syntax for a key named type',
//   'date created': 'This key has a space',
//   myString: 'This key is in variable str',
//   '0.6398914448618778': 'A random number is the key here',
//   '[object Object]': 'This key is object anotherObj',
//   '': 'This key is an empty string'
// }
console.log(myObj.myString); // 'This key is in variable str'
```

In the above code, the key `anotherObj` is an object, which is neither a string nor a symbol. When it is added to the `myObj`, JavaScript calls the `toString()` method of `anotherObj`, and use the resulting string as the new key.

You can also access properties with a string value stored in a variable. The variable must be passed in bracket notation. In the example above, the variable `str` held `"myString"` and it is `"myString"` that is the property name. Therefore, `myObj.str` will return as undefined.

```
str = "myString";
myObj[str] = "This key is in variable str";

console.log(myObj.str); // undefined

console.log(myObj[str]); // 'This key is in variable str'
console.log(myObj.myString); // 'This key is in variable str'
```

This allows accessing any property as determined at runtime:

```
let propertyName = "make";
myCar[propertyName] = "Ford";

// access different properties by changing the contents of the variable
propertyName = "model";
myCar[propertyName] = "Mustang";
```

```
console.log(myCar); // { make: 'Ford', model: 'Mustang' }
```

However, beware of using square brackets to access properties whose names are given by external input. This may make your code susceptible to object injection attacks.

Nonexistent properties of an object have the value `undefined` (and not `null`).

```
myCar.nonexistentProperty; // undefined
```

Enumerating properties

There are three native ways to list/traverse object properties:

- `for...in` loops. This method traverses all of the enumerable string properties of an object as well as its prototype chain.
- `Object.keys()`. This method returns an array with only the enumerable own string property names ("keys") in the object `myObj`, but not those in the prototype chain.
- `Object.getOwnPropertyNames()`. This method returns an array containing all the own string property names in the object `myObj`, regardless of if they are enumerable or not.

You can use the bracket notation with `for...in` to iterate over all the enumerable properties of an object. To illustrate how this works, the following function displays the properties of the object when you pass the object and the object's name as arguments to the function:

```
function showProps(obj, objName) {
  let result = "";
  for (const i in obj) {
    // Object.hasOwn() is used to exclude properties from the object's
    // prototype chain and only show "own properties"
    if (Object.hasOwn(obj, i)) {
      result += `${objName}.${i} = ${obj[i]}\n`;
    }
  }
  console.log(result);
}
```

The term "own property" refers to the properties of the object, but excluding those of the prototype chain. So, the function call `showProps(myCar, 'myCar')` would print the following:

```
myCar.make = Ford
myCar.model = Mustang
myCar.year = 1969
```

The above is equivalent to:

```
function showProps(obj, objName) {
  let result = "";
  Object.keys(obj).forEach((i) => {
    result += `${objName}.${i} = ${obj[i]}\n`;
  });
  console.log(result);
}
```

There is no native way to list all inherited properties, including non-enumerable ones. However, this can be achieved with the following function:

```
function listAllProperties(myObj) {
  let objectToInspect = myObj;
  let result = [];

  while (objectToInspect !== null) {
    result = result.concat(Object.getOwnPropertyNames(objectToInspect));
    objectToInspect = Object.getPrototypeOf(objectToInspect);
  }

  return result;
}
```

For more information, see Enumerability and ownership of properties.

Deleting properties

You can remove a non-inherited property using the `delete` operator. The following code shows how to remove a property.

```
// Creates a new object, myObj, with two properties, a and b.
const myObj = { a: 5, b: 12 };

// Removes the a property, leaving myObj with only the b property.
delete myObj.a;
console.log("a" in myObj); // false
```

Inheritance

All objects in JavaScript inherit from at least one other object. The object being inherited from is known as the prototype, and the inherited properties can be found in the `prototype` object of the constructor. See Inheritance and the prototype chain for more information.

Defining properties for all objects of one type

You can add a property to all objects created through a certain constructor using the `prototype` property. This defines a property that is shared by all objects of the specified type, rather than by just one instance of the object. The following code adds a `color` property to all objects of type `Car`, and then reads the property's value from an instance `car1`.

```
Car.prototype.color = "red";
console.log(car1.color); // "red"
```

Defining methods

A *method* is a function associated with an object, or, put differently, a method is a property of an object that is a function. Methods are defined the way normal functions are defined, except that they have to be assigned as the property of an object. See also method definitions for more details. An example is:

```
objectName.methodName = functionName;

const myObj = {
  myMethod: function (params) {
    // do something
  },

  // this works too!
  myOtherMethod(params) {
    // do something else
  },
};
```

where `objectName` is an existing object, `methodName` is the name you are assigning to the method, and `functionName` is the name of the function.

You can then call the method in the context of the object as follows:

```
objectName.methodName(params);
```

Methods are typically defined on the `prototype` object of the constructor, so that all objects of the same type share the same method. For example, you can define a function that formats and displays the properties of the previously-defined `Car` objects.

```
Car.prototype.displayCar = function () {
  const result = `A Beautiful ${this.year} ${this.make} ${this.model}`;
  console.log(result);
};
```

Notice the use of `this` to refer to the object to which the method belongs. Then you can call the `displayCar` method for each of the objects as follows:

```
car1.displayCar();
car2.displayCar();
```

Using this for object references

JavaScript has a special keyword, `this`, that you can use within a method to refer to the current object. For example, suppose you have 2 objects, `manager` and `intern`. Each object has its own `name`, `age` and `job`. In the function `sayHi()`, notice the use of `this.name`. When added to the 2 objects, the same function will print the message with the name of the respective object it's attached to.

```
const manager = {
  name: "Karina",
  age: 27,
  job: "Software Engineer",
};
const intern = {
  name: "Tyrone",
  age: 21,
  job: "Software Engineer Intern",
};

function sayHi() {
  console.log(`Hello, my name is ${this.name}`);
}

// Add sayHi function to both objects
manager.sayHi = sayHi;
intern.sayHi = sayHi;

manager.sayHi(); // Hello, my name is Karina
intern.sayHi(); // Hello, my name is Tyrone
```

`this` is a "hidden parameter" of a function call that's passed in by specifying the object before the function that was called. For example, in `manager.sayHi()`, `this` is the `manager` object, because `manager` comes before the function `sayHi()`. If you access the same function from another object, `this` will change as well. If you use other methods to call the function, like `Function.prototype.call()` or `Reflect.apply()`, you can explicitly pass the value of `this` as an argument.

Defining getters and setters

A getter is a function associated with a property that gets the value of a specific property. A setter is a function associated with a property that sets the value of a specific property. Together, they can indirectly represent the value of a property.

Getters and setters can be either

- defined within object initializers, or
- added later to any existing object.

Within object initializers, getters and setters are defined like regular methods, but prefixed with the keywords `get` or `set`. The getter method must not expect a parameter, while the setter method expects exactly one parameter (the new value to set). For instance:

```
const myObj = {
  a: 7,
  get b() {
    return this.a + 1;
  },
  set c(x) {
    this.a = x / 2;
  },
};

console.log(myObj.a); // 7
console.log(myObj.b); // 8, returned from the get b() method
myObj.c = 50; // Calls the set c(x) method
console.log(myObj.a); // 25
```

The `myObj` object's properties are:

- `myObj.a` — a number
- `myObj.b` — a getter that returns `myObj.a` plus 1
- `myObj.c` — a setter that sets the value of `myObj.a` to half of the value `myObj.c` is being set to

Getters and setters can also be added to an object at any time after creation using the `Object.defineProperties()` method. This method's first parameter is the object on which you want to define the getter or setter. The second parameter is an object whose property names are the getter or setter names, and whose property values are objects for defining the getter or setter functions. Here's an example that defines the same getter and setter used in the previous example:

```
const myObj = { a: 0 };

Object.defineProperties(myObj, {
  b: {
    get() {
      return this.a + 1;
    },
  },
  c: {
    set(x) {
      this.a = x / 2;
    },
  },
});

myObj.c = 10; // Runs the setter, which assigns 10 / 2 (5) to the 'a' property
console.log(myObj.b); // Runs the getter, which yields a + 1 or 6
```

Which of the two forms to choose depends on your programming style and task at hand. If you can change the definition of the original object, you will probably define getters and setters through the original initializer. This form is more compact and natural. However, if you need to add getters and setters later — maybe because you did not write the particular object — then the second form is the only possible form. The second form better represents the dynamic nature of JavaScript, but it can make the code hard to read and understand.

Comparing objects

In JavaScript, objects are a reference type. Two distinct objects are never equal, even if they have the same properties. Only comparing the same object reference with itself yields true.

```
// Two variables, two distinct objects with the same properties
const fruit = { name: "apple" };
const anotherFruit = { name: "apple" };

fruit == anotherFruit; // return false
fruit === anotherFruit; // return false
```

```
// Two variables, a single object
const fruit = { name: "apple" };
const anotherFruit = fruit; // Assign fruit object reference to anotherFruit

// Here fruit and anotherFruit are pointing to same object
fruit == anotherFruit; // return true
fruit === anotherFruit; // return true
```

```
fruit.name = "grape";
console.log(anotherFruit); // { name: "grape" }; not { name: "apple" }
```

For more information about comparison operators, see equality operators.

JavaScript reference

The JavaScript reference serves as a repository of facts about the JavaScript language. The entire language is described here in detail. As you write JavaScript code, you'll refer to these pages often (thus the title "JavaScript reference").

The JavaScript language is intended to be used within some larger environment, be it a browser, server-side scripts, or similar. For the most part, this reference attempts to be environment-agnostic and does not target a web browser environment.

If you are new to JavaScript, start with the guide. Once you have a firm grasp of the fundamentals, you can use the reference to get more details on individual objects and language constructs.

Built-ins

JavaScript standard built-in objects, along with their methods and properties.

Value properties

- `globalThis`
- `Infinity`
- `NaN`
- `undefined`

Function properties

- `eval()`
- `isFinite()`
- `isNaN()`
- `parseFloat()`
- `parseInt()`
- `decodeURI()`
- `decodeURIComponent()`
- `encodeURI()`
- `encodeURIComponent()`
- `escape()`
- `unescape()`

Fundamental objects

- `Object`
- `Function`
- `Boolean`
- `Symbol`

Error objects

- `Error`
- `AggregateError`
- `EvalError`
- `RangeError`
- `ReferenceError`
- `SuppressedError`
- `SyntaxError`
- `TypeError`
- `URIError`
- `InternalError`

Numbers and dates

- `Number`
- `BigInt`
- `Math`
- `Date`
- `Temporal`

Text processing

- `String`
- `RegExp`

Indexed collections

- `Array`
- `Int8Array`
- `Uint8Array`
- `Uint8ClampedArray`
- `Int16Array`
- `Uint16Array`
- `Int32Array`
- `Uint32Array`
- `BigInt64Array`
- `BigUint64Array`
- `Float16Array`
- `Float32Array`
- `Float64Array`

Keyed collections

- `Map`
- `Set`
- `WeakMap`
- `WeakSet`

Structured data

- `ArrayBuffer`
- `SharedArrayBuffer`
- `DataView`
- `Atomics`
- `JSON`

Managing memory

- `WeakRef`
- `FinalizationRegistry`

Control abstraction objects

- `Iterator`
- `AsyncIterator`
- `Promise`
- `GeneratorFunction`
- `AsyncGeneratorFunction`
- `Generator`
- `AsyncGenerator`
- `AsyncFunction`
- `DisposableStack`
- `AsyncDisposableStack`

Reflection

- `AbstractModuleSource`
- `Reflect`
- `Proxy`

Internationalization

- `Intl`
- `Intl.Collator`
- `Intl.DateTimeFormat`
- `Intl.DisplayNames`
- `Intl.DurationFormat`
- `Intl.ListFormat`
- `Intl.Locale`
- `Intl.NumberFormat`
- `Intl.PluralRules`
- `Intl.RelativeTimeFormat`
- `Intl.Segmenter`

Statements

JavaScript statements and declarations

Control flow

- `return`

- `break`
- `continue`
- `throw`
- `if...else`
- `switch`
- `try...catch`

Declaring variables

- `var`
- `let`
- `const`
- `using`
- `await using`

Functions and classes

- `function`
- `function*`
- `async function`
- `async function*`
- `class`

Iterations

- `do...while`
- `for`
- `for...in`
- `for...of`
- `for await...of`
- `while`

Others

- Empty
- Block
- Expression statement
- `debugger`
- `export`
- `import`
- `import defer`
- `import source`
- label
- `with`

Expressions and operators

JavaScript expressions and operators.

Primary expressions

- `this`
- Literals
- `[]`
- `{}`
- `function`
- `class`
- `function*`
- `async function`
- `async function*`
- `/ab+c/i`
- `` `string` ``
- `( )`

Left-hand-side expressions

- Property accessors
- `?.`
- `new`
- `new.target`
- `import.meta`
- `super`
- `import()`
- `import.defer()`
- `import.source()`

Increment and decrement

- `A++`
- `A--`
- `++A`
- `--A`

Unary operators

- `delete`
- `void`
- `typeof`
- `+`
- `-`
- `~`

Classes

Classes are a template for creating objects. They encapsulate data with code to work on that data. Classes in JS are built on prototypes but also have some syntax and semantics that are unique to classes.

For more examples and explanations, see the Using classes guide.

Description

Defining classes

Classes are in fact "special functions", and just as you can define function expressions and function declarations, a class can be defined in two ways: a class expression or a class declaration.

```
// Declaration
class Rectangle {
  constructor(height, width) {
    this.height = height;
    this.width = width;
  }
}

// Expression; the class is anonymous but assigned to a variable
const Rectangle = class {
  constructor(height, width) {
    this.height = height;
    this.width = width;
  }
};

// Expression; the class has its own name
const Rectangle = class Rectangle2 {
  constructor(height, width) {
    this.height = height;
    this.width = width;
  }
};
```

Like function expressions, class expressions may be anonymous, or have a name that's different from the variable that it's assigned to. However, unlike function declarations, class declarations have the same temporal dead zone restrictions as `let` or `const` and behave as if they are not hoisted.

Class body

The body of a class is the part that is in curly braces `{}`. This is where you define class members, such as methods or constructor.

The body of a class is executed in strict mode even without the `"use strict"` directive.

A class element can be characterized by three aspects:

- Kind: Getter, setter, method, or field
- Location: Static or instance
- Visibility: Public or private

Together, they add up to 16 possible combinations. To divide the reference more logically and avoid overlapping content, the different elements are introduced in detail in different pages:

Method definitions

: Public instance method

getter

: Public instance getter

setter

: Public instance setter

Public class fields

: Public instance field

`static`

: Public static method, getter, setter, and field

Private elements

: Everything that's private

> **Note:** Private elements have the restriction that all private names declared in the same class must be unique. All other public properties do not have this restriction — you can have multiple public properties with the same name, and the last one overwrites the others. This is the same behavior as in object initializers.

In addition, there are two special class element syntaxes: `constructor` and static initialization blocks, with their own references.

Constructor

The `constructor` method is a special method for creating and initializing an object created with a class. There can only be one special method with the name "constructor" in a class — a `SyntaxError` is thrown if the class contains more than one occurrence of a `constructor` method.

A constructor can use the `super` keyword to call the constructor of the super class.

You can create instance properties inside the constructor:

```
class Rectangle {
  constructor(height, width) {
    this.height = height;
    this.width = width;
  }
}
```

Alternatively, if your instance properties' values do not depend on the constructor's arguments, you can define them as class fields.

Static initialization blocks

Static initialization blocks allow flexible initialization of static properties, including the evaluation of statements during initialization, while granting access to the private scope.

Multiple static blocks can be declared, and these can be interleaved with the declaration of static fields and methods (all static items are evaluated in declaration order).

Methods

Methods are defined on the prototype of each class instance and are shared by all instances. Methods can be plain functions, async functions, generator functions, or async generator functions. For more information, see method definitions.

```
class Rectangle {
  constructor(height, width) {
    this.height = height;
    this.width = width;
  }
  // Getter
  get area() {
    return this.calcArea();
  }
  // Method
  calcArea() {
    return this.height * this.width;
  }
  *getSides() {
    yield this.height;
    yield this.width;
    yield this.height;
    yield this.width;
  }
}

const square = new Rectangle(10, 10);

console.log(square.area); // 100
console.log([...square.getSides()]); // [10, 10, 10, 10]
```

Static methods and fields

The `static` keyword defines a static method or field for a class. Static properties (fields and methods) are defined on the class itself instead of each instance. Static methods are often used to create utility functions for an application, whereas static fields are useful for caches, fixed-configuration, or any other data that doesn't need to be replicated across instances.

```
class Point {
  constructor(x, y) {
    this.x = x;
    this.y = y;
  }

  static displayName = "Point";
  static distance(a, b) {
    const dx = a.x - b.x;
    const dy = a.y - b.y;

    return Math.hypot(dx, dy);
  }
}

const p1 = new Point(5, 5);
const p2 = new Point(10, 10);
p1.displayName; // undefined
p1.distance; // undefined
p2.displayName; // undefined
p2.distance; // undefined
```

```
console.log(Point.displayName); // "Point"
console.log(Point.distance(p1, p2)); // 7.0710678118654755
```

Field declarations

With the class field declaration syntax, the constructor example can be written as:

```
class Rectangle {
  height = 0;
  width;
  constructor(height, width) {
    this.height = height;
    this.width = width;
  }
}
```

Class fields are similar to object properties, not variables, so we don't use keywords such as `const` to declare them. In JavaScript, private elements use a special identifier syntax, so modifier keywords like `public` and `private` should not be used either.

As seen above, the fields can be declared with or without a default value. Fields without default values default to `undefined`. By declaring fields up-front, class definitions become more self-documenting, and the fields are always present, which help with optimizations.

See public class fields for more information.

Private elements

Using private fields, the definition can be refined as below.

```
class Rectangle {
  #height = 0;
  #width;
  constructor(height, width) {
    this.#height = height;
    this.#width = width;
  }
}
```

It's an error to reference private fields from outside of the class; they can only be read or written within the class body. By defining things that are not visible outside of the class, you ensure that your classes' users can't depend on internals, which may change from version to version.

Private fields can only be declared up-front in a field declaration. They cannot be created later through assigning to them, the way that normal properties can.

Private methods and accessors can also be defined using the same syntax as their public counterparts, but with the identifier starting with `#`.

For more information, see private elements.

Inheritance

The `extends` keyword is used in *class declarations* or *class expressions* to create a class as a child of another constructor (either a class or a function).

```
class Animal {
  constructor(name) {
    this.name = name;
  }

  speak() {
    console.log(`${this.name} makes a noise.`);
  }
}

class Dog extends Animal {
  constructor(name) {
    super(name); // call the super class constructor and pass in the name parameter
  }

  speak() {
    console.log(`${this.name} barks.`);
  }
}

const d = new Dog("Mitzie");
d.speak(); // Mitzie barks.
```

If there is a constructor present in the subclass, it needs to first call `super()` before using `this`. The `super` keyword can also be used to call corresponding methods of super class.

```
class Cat {
  constructor(name) {
    this.name = name;
  }

  speak() {
    console.log(`${this.name} makes a noise.`);
```

```
  }
}

class Lion extends Cat {
  speak() {
    super.speak();
    console.log(`${this.name} roars.`);
  }
}

const l = new Lion("Fuzzy");
l.speak();
// Fuzzy makes a noise.
// Fuzzy roars.
```

Evaluation order

When a `class` declaration or `class` expression is evaluated, its various components are evaluated in the following order:

1. The `extends` clause, if present, is first evaluated. It must evaluate to a valid constructor function or `null`, or a `TypeError` is thrown.
2. The `constructor` method is extracted, substituted with a default implementation if `constructor` is not present. However, because the `constructor` definition is only a method definition, this step is not observable.
3. The class elements' property keys are evaluated in the order of declaration. If the property key is computed, the computed expression is evaluated, with the `this` value set to the `this` value surrounding the class (not the class itself). None of the property values are evaluated yet.
4. Methods and accessors are installed in the order of declaration. Instance methods and accessors are installed on the `prototype` property of the current class, and static methods and accessors are installed on the class itself. Private instance methods and accessors are saved to be installed on the instance directly later. This step is not observable.
5. The class is now initialized with the prototype specified by `extends` and implementation specified by `constructor`. For all steps above, if an evaluated expression tries to access the name of the class, a `ReferenceError` is thrown because the class is not initialized yet.
6. The class elements' values are evaluated in the order of declaration:
   - For each instance field (public or private), its initializer expression is saved. The initializer is evaluated during instance creation, at the start of the constructor (for base classes) or immediately before the `super()` call returns (for derived classes).
   - For each static field (public or private), its initializer is evaluated with `this` set to the class itself, and the property is created on the class.
   - Static initialization blocks are evaluated with `this` set to the class itself.
7. The class is now fully initialized and can be used as a constructor function.

For how instances are created, see the `constructor` reference.

Examples

Binding this with instance and static methods

When a static or instance method is called without a value for `this`, such as by assigning the method to a variable and then calling it, the `this` value will be `undefined` inside the method. This behavior is the same even if the `"use strict"` directive isn't present, because code within the `class` body is always executed in strict mode.

```
class Animal {
  speak() {
    return this;
  }
  static eat() {
    return this;
  }
}

const obj = new Animal();
obj.speak(); // the Animal object
const speak = obj.speak;
speak(); // undefined

Animal.eat(); // class Animal
const eat = Animal.eat;
eat(); // undefined
```

If we rewrite the above using traditional function-based syntax in non–strict mode, then `this` method calls are automatically bound to `globalThis`. In strict mode, the value of `this` remains as `undefined`.

```
function Animal() {}

Animal.prototype.speak = function () {
  return this;
};

Animal.eat = function () {
  return this;
};

const obj = new Animal();
const speak = obj.speak;
speak(); // global object (in non-strict mode)

const eat = Animal.eat;
eat(); // global object (in non-strict mode)
```

constructor

The **`constructor`** method is a special method of a class for creating and initializing an object instance of that class.

> **Note:** This page introduces the `constructor` syntax. For the `constructor` property present on all objects, see `Object.prototype.constructor`.

Try it

```
class Polygon {
  constructor() {
    this.name = "Polygon";
  }
}

const poly = new Polygon();

console.log(poly.name);
// Expected output: "Polygon"
```

Syntax

```
constructor() { /* … */ }
constructor(argument0) { /* … */ }
constructor(argument0, argument1) { /* … */ }
constructor(argument0, argument1, /* …, */ argumentN) { /* … */ }
```

There are some additional syntax restrictions:

- A class method called `constructor` cannot be a getter, setter, async, or generator.
- A class cannot have more than one `constructor` method.

Description

A constructor enables you to provide any custom initialization that must be done before any other methods can be called on an instantiated object.

```
class Person {
  constructor(name) {
    this.name = name;
  }

  introduce() {
    console.log(`Hello, my name is ${this.name}`);
  }
}

const otto = new Person("Otto");

otto.introduce(); // Hello, my name is Otto
```

If you don't provide your own constructor, then a default constructor will be supplied for you. If your class is a base class, the default constructor is empty:

```
constructor() {}
```

If your class is a derived class, the default constructor calls the parent constructor, passing along any arguments that were provided:

```
constructor(...args) {
  super(...args);
}
```

> **Note:** The difference between an explicit constructor like the one above and the default constructor is that the latter doesn't actually invoke the array iterator through argument spreading.

That enables code like this to work:

```
class ValidationError extends Error {
  printCustomerMessage() {
    return `Validation failed :-( (details: ${this.message})`;
  }
}
```

```
try {
  throw new ValidationError("Not a valid phone number");
} catch (error) {
  if (error instanceof ValidationError) {
    console.log(error.name); // This is Error instead of ValidationError!
    console.log(error.printCustomerMessage());
  } else {
    console.log("Unknown error", error);
    throw error;
  }
}
```

The `ValidationError` class doesn't need an explicit constructor, because it doesn't need to do any custom initialization. The default constructor then takes care of initializing the parent `Error` from the argument it is given.

However, if you provide your own constructor, and your class derives from some parent class, then you must explicitly call the parent class constructor using `super()`. For example:

```
class ValidationError extends Error {
  constructor(message) {
    super(message); // call parent class constructor
    this.name = "ValidationError";
    this.code = "42";
  }

  printCustomerMessage() {
    return `Validation failed :-( (details: ${this.message}, code: ${this.code})`;
  }
}

try {
  throw new ValidationError("Not a valid phone number");
} catch (error) {
  if (error instanceof ValidationError) {
    console.log(error.name); // Now this is ValidationError!
    console.log(error.printCustomerMessage());
  } else {
    console.log("Unknown error", error);
    throw error;
  }
}
```

Using `new` on a class goes through the following steps:

1. (If it's a derived class) The `constructor` body before the `super()` call is evaluated. This part should not access `this` because it's not yet initialized.
2. (If it's a derived class) The `super()` call is evaluated, which initializes the parent class through the same process.
3. The current class's fields are initialized.
4. The `constructor` body after the `super()` call (or the entire body, if it's a base class) is evaluated.

Within the `constructor` body, you can access the object being created through `this` and access the class that is called with `new` through `new.target`. Note that methods (including getters and setters) and the prototype chain are already initialized on `this` before the `constructor` is executed, so you can even access methods of the subclass from the constructor of the superclass. However, if those methods use `this`, the `this` will not have been fully initialized yet. This means reading public fields of the derived class will result in `undefined`, while reading private fields will result in a `TypeError`.

```
new (class C extends class B {
  constructor() {
    console.log(this.foo());
  }
} {
  #a = 1;
  foo() {
    return this.#a; // TypeError: Cannot read private member #a from an object whose class did not declare it
    // It's not really because the class didn't declare it,
    // but because the private field isn't initialized yet
    // when the superclass constructor is running
  }
})();
```

The `constructor` method may have a return value. While the base class may return anything from its constructor, the derived class must return an object or `undefined`, or a `TypeError` will be thrown.

```
class ParentClass {
  constructor() {
    return 1;
  }
}

console.log(new ParentClass()); // ParentClass {}
// The return value is ignored because it's not an object
// This is consistent with function constructors

class ChildClass extends ParentClass {
  constructor() {
```

```
    return 1;
  }
}

console.log(new ChildClass()); // TypeError: Derived constructors may only return object or undefined
```

If the parent class constructor returns an object, that object will be used as the `this` value on which class fields of the derived class will be defined. This trick is called "return overriding", which allows a derived class's fields (including private ones) to be defined on unrelated objects.

The `constructor` follows normal method syntax, so parameter default values, rest parameters, etc. can all be used.

```
class Person {
  constructor(name = "Anonymous") {
    this.name = name;
  }
  introduce() {
    console.log(`Hello, my name is ${this.name}`);
  }
}

const person = new Person();
person.introduce(); // Hello, my name is Anonymous
```

The constructor must be a literal name. Computed properties cannot become constructors.

```
class Foo {
  // This is a computed property. It will not be picked up as a constructor.
  ["constructor"]() {
    console.log("called");
    this.a = 1;
  }
}

const foo = new Foo(); // No log
console.log(foo); // Foo {}
foo.constructor(); // Logs "called"
console.log(foo); // Foo { a: 1 }
```

Async methods, generator methods, accessors, and class fields are forbidden from being called `constructor`. Private names cannot be called `#constructor`. Any member named `constructor` must be a plain method.

Examples

Using the constructor

This code snippet is taken from the classes sample (live demo).

```
class Square extends Polygon {
  constructor(length) {
    // Here, it calls the parent class' constructor with lengths
    // provided for the Polygon's width and height
    super(length, length);
    // NOTE: In derived classes, `super()` must be called before you
    // can use `this`. Leaving this out will cause a ReferenceError.
    this.name = "Square";
  }

  get area() {
    return this.height * this.width;
  }

  set area(value) {
    this.height = value ** 0.5;
    this.width = value ** 0.5;
  }
}
```

Calling super in a constructor bound to a different prototype

`super()` calls the constructor that's the prototype of the current class. If you change the prototype of the current class itself, `super()` will call the constructor that's the new prototype. Changing the prototype of the current class's `prototype` property doesn't affect which constructor `super()` calls.

```
class Polygon {
  constructor() {
    this.name = "Polygon";
  }
}

class Rectangle {
  constructor() {
    this.name = "Rectangle";
  }
}
```

```
class Square extends Polygon {
  constructor() {
    super();
  }
}

// Make Square extend Rectangle (which is a base class) instead of Polygon
Object.setPrototypeOf(Square, Rectangle);

const newInstance = new Square();

// newInstance is still an instance of Polygon, because we didn't
// change the prototype of Square.prototype, so the prototype chain
// of newInstance is still
//   newInstance --> Square.prototype --> Polygon.prototype
console.log(newInstance instanceof Polygon); // true
console.log(newInstance instanceof Rectangle); // false

// However, because super() calls Rectangle as constructor, the name property
// of newInstance is initialized with the logic in Rectangle
console.log(newInstance.name); // Rectangle
```

- Classes
- Static initialization blocks
- `class`
- `super()`
- `Object.prototype.constructor`

extends

The **`extends`** keyword is used in class declarations or class expressions to create a class that is a child of another class.

Try it

```
class DateFormatter extends Date {
  getFormattedDate() {
    const months = [
      "Jan",
      "Feb",
      "Mar",
      "Apr",
      "May",
      "Jun",
      "Jul",
      "Aug",
      "Sep",
      "Oct",
      "Nov",
      "Dec",
    ];
    return `${this.getDate()}-${months[this.getMonth()]}-${this.getFullYear()}`;
  }
}

console.log(new DateFormatter("August 19, 1975 23:15:30").getFormattedDate());
// Expected output: "19-Aug-1975"
```

Syntax

```
class ChildClass extends ParentClass { /* … */ }
```

`ParentClass`

An expression that evaluates to a constructor function (including a class) or `null`.

Description

The `extends` keyword can be used to subclass custom classes as well as built-in objects.

Any constructor that can be called with `new` and has the `prototype` property can be the candidate for the parent class. The two conditions must both hold — for example, bound functions and `Proxy` can be constructed, but they don't have a `prototype` property, so they cannot be subclassed.

```
function OldStyleClass() {
  this.someProperty = 1;
}
OldStyleClass.prototype.someMethod = function () {};

class ChildClass extends OldStyleClass {}

class ModernClass {
  someProperty = 1;
```

```
  someMethod() {}
}

class AnotherChildClass extends ModernClass {}
```

The `prototype` property of the `ParentClass` must be an `Object` or `null`, but you would rarely worry about this in practice, because a non-object `prototype` doesn't behave as it should anyway. (It's ignored by the `new` operator.)

```
function ParentClass() {}
ParentClass.prototype = 3;

class ChildClass extends ParentClass {}
// Uncaught TypeError: Class extends value does not have valid prototype property 3

console.log(Object.getPrototypeOf(new ParentClass()));
// [Object: null prototype] {}
// Not actually a number!
```

`extends` sets the prototype for both `ChildClass` and `ChildClass.prototype`.

	Prototype of `ChildClass`	**Prototype of `ChildClass.prototype`**
`extends` clause absent	`Function.prototype`	`Object.prototype`
`extends null`	`Function.prototype`	`null`
`extends ParentClass`	`ParentClass`	`ParentClass.prototype`

```
class ParentClass {}
class ChildClass extends ParentClass {}

// Allows inheritance of static properties
Object.getPrototypeOf(ChildClass) === ParentClass;
// Allows inheritance of instance properties
Object.getPrototypeOf(ChildClass.prototype) === ParentClass.prototype;
```

The right-hand side of `extends` does not have to be an identifier. You can use any expression that evaluates to a constructor. This is often useful to create mixins. The `this` value in the `extends` expression is the `this` surrounding the class definition, and referring to the class's name is a `ReferenceError` because the class is not initialized yet. `await` and `yield` work as expected in this expression.

```
class SomeClass extends class {
  constructor() {
    console.log("Base class");
  }
} {
  constructor() {
    super();
    console.log("Derived class");
  }
}

new SomeClass();
// Base class
// Derived class
```

While the base class may return anything from its constructor, the derived class must return an object or `undefined`, or a `TypeError` will be thrown.

```
class ParentClass {
  constructor() {
    return 1;
  }
}

console.log(new ParentClass()); // ParentClass {}
// The return value is ignored because it's not an object
// This is consistent with function constructors

class ChildClass extends ParentClass {
  constructor() {
    super();
    return 1;
  }
}

console.log(new ChildClass()); // TypeError: Derived constructors may only return object or undefined
```

If the parent class constructor returns an object, that object will be used as the `this` value for the derived class when further initializing class fields. This trick is called "return overriding", which allows a derived class's fields (including private ones) to be defined on unrelated objects.

Subclassing built-ins

> **Warning:** The standard committee now holds the position that the built-in subclassing mechanism in previous spec versions is over-engineered and causes non-negligible performance and security impacts. New built-in methods consider less about subclasses, and engine implementers are investigating whether to remove

> certain subclassing mechanisms. Consider using composition instead of inheritance when enhancing built-ins.

Here are some things you may expect when extending a class:

- When calling a static factory method (like `Promise.resolve()` or `Array.from()`) on a subclass, the returned instance is always an instance of the subclass.
- When calling an instance method that returns a new instance (like `Promise.prototype.then()` or `Array.prototype.map()`) on a subclass, the returned instance is always an instance of the subclass.
- Instance methods try to delegate to a minimal set of primitive methods where possible. For example, for a subclass of `Promise`, overriding `then()` automatically causes the behavior of `catch()` to change; or for a subclass of `Map`, overriding `set()` automatically causes the behavior of the `Map()` constructor to change.

However, the above expectations take non-trivial efforts to implement properly.

- The first one requires the static method to read the value of `this` to get the constructor for constructing the returned instance. This means `[p1, p2, p3].map(Promise.resolve)` throws an error because the `this` inside `Promise.resolve` is `undefined`. A way to fix this is to fall back to the base class if `this` is not a constructor, like `Array.from()` does, but that still means the base class is special-cased.
- The second one requires the instance method to read `this.constructor` to get the constructor function. However, `new this.constructor()` may break legacy code, because the `constructor` property is both writable and configurable and is not protected in any way. Therefore, many copying built-in methods use the constructor's `[Symbol.species]` property instead (which by default just returns `this`, the constructor itself). However, `[Symbol.species]` allows running arbitrary code and creating instances of arbitrary type, which poses a security concern and greatly complicates subclassing semantics.
- The third one leads to visible invocations of custom code, which makes a lot of optimizations harder to implement. For example, if the `Map()` constructor is called with an iterable of *x* elements, then it must visibly invoke the `set()` method *x* times, instead of just copying the elements into the internal storage.

These problems are not unique to built-in classes. For your own classes, you will likely have to make the same decisions. However, for built-in classes, optimizability and security are a much bigger concern. New built-in methods always construct the base class and call as few custom methods as possible. If you want to subclass built-ins while achieving the above expectations, you need to override all methods that have the default behavior baked into them. Any addition of new methods on the base class may also break the semantics of your subclass because they are inherited by default. Therefore, a better way to extend built-ins is to use *composition*.

Extending null

`extends null` was designed to allow easy creation of objects that do not inherit from `Object.prototype`. However, due to unsettled decisions about whether `super()` should be called within the constructor, it's not possible to construct such a class in practice using any constructor implementation that doesn't return an object. The TC39 committee is working on re-enabling this feature.

```
new (class extends null {})();
// TypeError: Super constructor null of anonymous class is not a constructor

new (class extends null {
  constructor() {}
})();
// ReferenceError: Must call super constructor in derived class before accessing 'this' or returning from derived constructor

new (class extends null {
  constructor() {
    super();
  }
})();
// TypeError: Super constructor null of anonymous class is not a constructor
```

Instead, you need to explicitly return an instance from the constructor.

```
class NullClass extends null {
  constructor() {
    // Using new.target allows derived classes to
    // have the correct prototype chain
    return Object.create(new.target.prototype);
  }
}

const proto = Object.getPrototypeOf;
console.log(proto(proto(new NullClass()))); // null
```

Examples

Using extends

The first example creates a class called `Square` from a class called `Polygon`. This example is extracted from this live demo (source).

```
class Square extends Polygon {
  constructor(length) {
    // Here, it calls the parent class' constructor with lengths
    // provided for the Polygon's width and height
    super(length, length);
    // Note: In derived classes, super() must be called before you
    // can use 'this'. Leaving this out will cause a reference error.
    this.name = "Square";
  }

  get area() {
    return this.height * this.width;
  }
}
```

Extending plain objects

Classes cannot extend regular (non-constructible) objects. If you want to inherit from a regular object by making all properties of this object available on inherited instances, you can instead use `Object.setPrototypeOf()`:

```
const Animal = {
  speak() {
    console.log(`${this.name} makes a noise.`);
  },
};

class Dog {
  constructor(name) {
    this.name = name;
  }
}

Object.setPrototypeOf(Dog.prototype, Animal);

const d = new Dog("Mitzie");
d.speak(); // Mitzie makes a noise.
```

Extending built-in objects

This example extends the built-in `Date` object. This example is extracted from this live demo (source).

```
class MyDate extends Date {
  getFormattedDate() {
    const months = [
      "Jan", "Feb", "Mar", "Apr", "May", "Jun",
      "Jul", "Aug", "Sep", "Oct", "Nov", "Dec",
    ];
    return `${this.getDate()}-${months[this.getMonth()]}-${this.getFullYear()}`;
  }
}
```

Extending <code>Object</code>

All JavaScript objects inherit from `Object.prototype` by default, so writing `extends Object` at first glance seems redundant. The only difference from not writing `extends` at all is that the constructor itself inherits static methods from `Object`, such as `Object.keys()`. However, because no `Object` static method uses the `this` value, there's still no value in inheriting these static methods.

The `Object()` constructor special-cases the subclassing scenario. If it's implicitly called via `super()`, it always initializes a new object with `new.target.prototype` as its prototype. Any value passed to `super()` is ignored.

```
class C extends Object {
  constructor(v) {
    super(v);
  }
}

console.log(new C(1) instanceof Number); // false
console.log(C.keys({ a: 1, b: 2 })); // [ 'a', 'b' ]
```

Compare this behavior with a custom wrapper that does not special-case subclassing:

```
function MyObject(v) {
  return new Object(v);
}
class D extends MyObject {
  constructor(v) {
    super(v);
  }
}
console.log(new D(1) instanceof Number); // true
```

Species

You might want to return `Array` objects in your derived array class `MyArray`. The species pattern lets you override default constructors.

For example, when using methods such as `Array.prototype.map()` that return the default constructor, you want these methods to return a parent `Array` object, instead of the `MyArray` object. The `Symbol.species` symbol lets you do this:

```
class MyArray extends Array {
  // Overwrite species to the parent Array constructor
  static get [Symbol.species]() {
    return Array;
  }
}

const a = new MyArray(1, 2, 3);
const mapped = a.map((x) => x * x);
```

```
console.log(mapped instanceof MyArray); // false
console.log(mapped instanceof Array); // true
```

This behavior is implemented by many built-in copying methods. For caveats of this feature, see the subclassing built-ins discussion.

Mix-ins

Abstract subclasses or *mix-ins* are templates for classes. A class can only have a single superclass, so multiple inheritance from tooling classes, for example, is not possible. The functionality must be provided by the superclass.

A function with a superclass as input and a subclass extending that superclass as output can be used to implement mix-ins:

```
const calculatorMixin = (Base) =>
  class extends Base {
    calc() {}
  };

const randomizerMixin = (Base) =>
  class extends Base {
    randomize() {}
  };
```

A class that uses these mix-ins can then be written like this:

```
class Foo {}
class Bar extends calculatorMixin(randomizerMixin(Foo)) {}
```

Avoiding inheritance

Inheritance is a very strong coupling relationship in object-oriented programming. It means all behaviors of the base class are inherited by the subclass by default, which may not always be what you want. For example, consider the implementation of a `ReadOnlyMap`:

```
class ReadOnlyMap extends Map {
  set() {
    throw new TypeError("A read-only map must be set at construction time.");
  }
}
```

It turns out that `ReadOnlyMap` is not constructible, because the `Map()` constructor calls the instance's `set()` method.

```
const m = new ReadOnlyMap([["a", 1]]); // TypeError: A read-only map must be set at construction time.
```

We may get around this by using a private flag to indicate whether the instance is being constructed. However, a more significant problem with this design is that it breaks the Liskov substitution principle, which states that a subclass should be substitutable for its superclass. If a function expects a `Map` object, it should be able to use a `ReadOnlyMap` object as well, which will break here.

Inheritance often leads to the circle-ellipse problem, because neither type perfectly entails the behavior of the other, although they share a lot of common traits. In general, unless there's a very good reason to use inheritance, it's better to use composition instead. Composition means that a class has a reference to an object of another class, and only uses that object as an implementation detail.

```
class ReadOnlyMap {
  #data;
  constructor(values) {
    this.#data = new Map(values);
  }
  get(key) {
    return this.#data.get(key);
  }
  has(key) {
    return this.#data.has(key);
  }
  get size() {
    return this.#data.size;
  }
  *keys() {
    yield* this.#data.keys();
  }
  *values() {
    yield* this.#data.values();
  }
  *entries() {
    yield* this.#data.entries();
  }
  *[Symbol.iterator]() {
    yield* this.#data[Symbol.iterator]();
  }
}
```

In this case, the `ReadOnlyMap` class is not a subclass of `Map`, but it still implements most of the same methods. This means more code duplication, but it also means that the `ReadOnlyMap` class is not strongly coupled to the `Map` class, and does not easily break if the `Map` class is changed, avoiding the semantic issues of built-in subclassing. For example, if the `Map` class adds a new utility method (such as `getOrInsert()`) that does not call `set()`, it would cause the `ReadOnlyMap` class to no longer be read-only

unless the latter is updated accordingly to override `getOrInsert()` as well. Moreover, `ReadOnlyMap` objects do not have the `set` method at all, which is more accurate than throwing an error at runtime.

Private elements

Private elements are counterparts of the regular class elements which are public, including class fields, class methods, etc. Private elements get created by using a hash `#` prefix and cannot be legally referenced outside of the class. The privacy encapsulation of these class elements is enforced by JavaScript itself. The only way to access a private element is via dot notation, and you can only do so within the class that defines the private element.

Private elements were not native to the language before this syntax existed. In prototypal inheritance, its behavior may be emulated with `WeakMap` objects or closures, but they can't compare to the `#` syntax in terms of ergonomics.

> **Note:** On MDN, we avoid using the term "private property". A property in JavaScript has a string or symbol key, and has attributes like `writable`, `enumerable`, and `configurable`, but private elements have none. While private elements are accessed with the familiar dot notation, they cannot be proxied, enumerated, deleted, or interacted with using any `Object` method.

Syntax

```
class ClassWithPrivate {
  #privateField;
  #privateFieldWithInitializer = 42;

  #privateMethod() {
    // …
  }

  static #privateStaticField;
  static #privateStaticFieldWithInitializer = 42;

  static #privateStaticMethod() {
    // …
  }
}
```

There are some additional syntax restrictions:

- All private identifiers declared within a class must be unique. The namespace is shared between static and instance elements. The only exception is when the two declarations define a getter-setter pair.
- The private identifier cannot be `#constructor`.

Description

Most class elements have their private counterparts:

- Private fields
- Private methods
- Private static fields
- Private static methods
- Private getters
- Private setters
- Private static getters
- Private static setters

These features are collectively called *private elements*. However, constructors cannot be private in JavaScript. To prevent classes from being constructed outside of the class, you have to use a private flag.

Private elements are declared with **# names** (pronounced "hash names"), which are identifiers prefixed with `#`. The hash prefix is an inherent part of the property name — you can draw relationship with the old underscore prefix convention `_privateField` — but it's not an ordinary string property, so you can't dynamically access it with the bracket notation.

It is a syntax error to refer to `#` names from outside of the class. It is also a syntax error to refer to private elements that were not declared in the class body, or to attempt to remove declared elements with `delete`.

```
class ClassWithPrivateField {
  #privateField;

  constructor() {
    delete this.#privateField; // Syntax error
    this.#undeclaredField = 42; // Syntax error
  }
}
```

```
const instance = new ClassWithPrivateField();
instance.#privateField; // Syntax error
```

JavaScript, being a dynamic language, is able to perform this compile-time check because of the special hash identifier syntax, making it different from normal properties on the syntax level.

> **Note:** Code run in the Chrome console can access private elements outside the class. This is a DevTools-only relaxation of the JavaScript syntax restriction.

If you access a private element from an object that doesn't have the element, a `TypeError` is thrown, instead of returning `undefined` as normal properties do.

```
class C {
  #x;

  static getX(obj) {
    return obj.#x;
  }
}

console.log(C.getX(new C())); // undefined
console.log(C.getX({})); // TypeError: Cannot read private member #x from an object whose class did not declare it
```

This example also illustrates that you can access private elements within static functions too, and on externally defined instances of the class.

You can use the `in` operator to check whether an externally defined object possesses a private element. This will return `true` if the private field or method exists, and `false` otherwise.

```
class C {
  #x;
  constructor(x) {
    this.#x = x;
  }
  static getX(obj) {
    if (#x in obj) return obj.#x;

    return "obj must be an instance of C";
  }
}
console.log(C.getX(new C("foo"))); // "foo"
console.log(C.getX(new C(0.196))); // 0.196
console.log(C.getX(new C(new Date()))); // the current date and time
console.log(C.getX({})); // "obj must be an instance of C"
```

Note a corollary of private names being always pre-declared and non-deletable: if you found that an object possesses one private element of the current class (either from a `try...catch` or an `in` check), it must possess all other private elements. An object possessing the private elements of a class generally means it was constructed by that class (although not always).

Private elements are not part of the prototypical inheritance model since they can only be accessed within the current class's body and aren't inherited by subclasses. Private elements with the same name within different classes are entirely different and do not interoperate with each other. See them as external metadata attached to each instance, managed by the class. For this reason, `structuredClone()` does not clone private elements, and `Object.freeze()` and `Object.seal()` have no effect on private elements.

For more information on how and when private fields are initialized, see public class fields.

Examples

Private fields

Private fields include private instance fields and private static fields. Private fields are only accessible from inside the class declaration.

Private instance fields

Like their public counterparts, private instance fields:

- are added before the constructor runs in a base class, or immediately after `super()` is invoked in a subclass, and
- are only available on instances of the class.

```
class ClassWithPrivateField {
  #privateField;

  constructor() {
    this.#privateField = 42;
  }
}

class Subclass extends ClassWithPrivateField {
  #subPrivateField;

  constructor() {
    super();
    this.#subPrivateField = 23;
  }
```

```
}

new Subclass(); // In some dev tools, it shows Subclass {#privateField: 42, #subPrivateField: 23}
```

> **Note:** `#privateField` from the `ClassWithPrivateField` base class is private to `ClassWithPrivateField` and is not accessible from the derived `Subclass`.

Returning overriding object

A class's constructor can return a different object, which will be used as the new `this` for the derived class constructor. The derived class may then define private fields on that returned object — meaning it is possible to "stamp" private fields onto unrelated objects.

```
class Stamper extends class {
  // A base class whose constructor returns the object it's given
  constructor(obj) {
    return obj;
  }
} {
  // This declaration will "stamp" the private field onto the object
  // returned by the base class constructor
  #stamp = 42;
  static getStamp(obj) {
    return obj.#stamp;
  }
}

const obj = {};
new Stamper(obj);
// `Stamper` calls `Base`, which returns `obj`, so `obj` is
// now the `this` value. `Stamper` then defines `#stamp` on `obj`

console.log(obj); // In some dev tools, it shows {#stamp: 42}
console.log(Stamper.getStamp(obj)); // 42
console.log(obj instanceof Stamper); // false

// You cannot stamp private elements twice
new Stamper(obj); // Error: Initializing an object twice is an error with private fields
```

> **Warning:** This is a potentially very confusing thing to do. You are generally advised to avoid returning anything from the constructor — especially something unrelated to `this`.

Private static fields

Like their public counterparts, private static fields:

- are added to the class constructor at class evaluation time, and
- are only available on the class itself.

```
class ClassWithPrivateStaticField {
  static #privateStaticField = 42;

  static publicStaticMethod() {
    return ClassWithPrivateStaticField.#privateStaticField;
  }
}

console.log(ClassWithPrivateStaticField.publicStaticMethod()); // 42
```

There is a restriction on private static fields: only the class which defines the private static field can access the field. This can lead to unexpected behavior when using `this`. In the following example, `this` refers to the `Subclass` class (not the `ClassWithPrivateStaticField` class) when we try to call `Subclass.publicStaticMethod()`, and so causes a `TypeError`.

```
class ClassWithPrivateStaticField {
  static #privateStaticField = 42;

  static publicStaticMethod() {
    return this.#privateStaticField;
  }
}

class Subclass extends ClassWithPrivateStaticField {}

Subclass.publicStaticMethod(); // TypeError: Cannot read private member #privateStaticField from an object whose class did not declare it
```

This is the same if you call the method with `super`, because `super` methods are not called with the super class as `this`.

```
class ClassWithPrivateStaticField {
  static #privateStaticField = 42;

  static publicStaticMethod() {
```

```
    // When invoked through super, `this` still refers to Subclass
    return this.#privateStaticField;
  }
}

class Subclass extends ClassWithPrivateStaticField {
  static callSuperMethod() {
    return super.publicStaticMethod();
  }
}

Subclass.callSuperMethod(); // TypeError: Cannot read private member #privateStaticField from an object whose class did not declare it
```

You are advised to always access private static fields through the class name, not through `this`, so inheritance doesn't break the method.

Private methods

Private methods include private instance methods and private static methods. Private methods are only accessible from inside the class declaration.

Private instance methods

Unlike their public counterparts, private instance methods:

- are installed immediately before the instance fields are installed, and
- are only available on instances of the class, not on its `.prototype` property.

```
class ClassWithPrivateMethod {
  #privateMethod() {
    return 42;
  }

  publicMethod() {
    return this.#privateMethod();
  }
}

const instance = new ClassWithPrivateMethod();
console.log(instance.publicMethod()); // 42
```

Private instance methods may be generator, async, or async generator functions. Private getters and setters are also possible, and follow the same syntax requirements as their public getter and setter counterparts.

```
class ClassWithPrivateAccessor {
  #message;

  get #decoratedMessage() {
    return `🎬${this.#message}🔴`;
  }
  set #decoratedMessage(msg) {
    this.#message = msg;
  }

  constructor() {
    this.#decoratedMessage = "hello world";
    console.log(this.#decoratedMessage);
  }
}

new ClassWithPrivateAccessor(); // 🎬hello world🔴
```

Unlike public methods, private methods are not accessible on the `.prototype` property of their class.

```
class C {
  #method() {}

  static getMethod(x) {
    return x.#method;
  }
}

console.log(C.getMethod(new C())); // [Function: #method]
console.log(C.getMethod(C.prototype)); // TypeError: Receiver must be an instance of class C
```

Private static methods

Like their public counterparts, private static methods:

- are added to the class constructor at class evaluation time, and
- are only available on the class itself.

```
class ClassWithPrivateStaticMethod {
  static #privateStaticMethod() {
    return 42;
  }
```

```
  static publicStaticMethod() {
    return ClassWithPrivateStaticMethod.#privateStaticMethod();
  }
}

console.log(ClassWithPrivateStaticMethod.publicStaticMethod()); // 42
```

Private static methods may be generator, async, and async generator functions.

The same restriction previously mentioned for private static fields holds for private static methods, and similarly can lead to unexpected behavior when using `this`. In the following example, when we try to call `Subclass.publicStaticMethod()`, `this` refers to the `Subclass` class (not the `ClassWithPrivateStaticMethod` class) and so causes a `TypeError`.

```
class ClassWithPrivateStaticMethod {
  static #privateStaticMethod() {
    return 42;
  }

  static publicStaticMethod() {
    return this.#privateStaticMethod();
  }
}

class Subclass extends ClassWithPrivateStaticMethod {}

console.log(Subclass.publicStaticMethod()); // TypeError: Cannot read private member #privateStaticMethod from an object whose class did not declare it
```

Simulating private constructors

Many other languages include the capability to mark a constructor as private, which prevents the class from being instantiated outside of the class itself — you can only use static factory methods that create instances, or not be able to create instances at all. JavaScript does not have a native way to do this, but it can be accomplished by using a private static flag.

```
class PrivateConstructor {
  static #isInternalConstructing = false;

  constructor() {
    if (!PrivateConstructor.#isInternalConstructing) {
      throw new TypeError("PrivateConstructor is not constructable");
    }
    PrivateConstructor.#isInternalConstructing = false;
    // More initialization logic
  }

  static create() {
    PrivateConstructor.#isInternalConstructing = true;
    const instance = new PrivateConstructor();
    return instance;
  }
}

new PrivateConstructor(); // TypeError: PrivateConstructor is not constructable
PrivateConstructor.create(); // PrivateConstructor {}
```

Public class fields

Public fields are writable, enumerable, and configurable properties defined on each class instance or class constructor.

Syntax

```
class ClassWithField {
  instanceField;
  instanceFieldWithInitializer = "instance field";
  static staticField;
  static staticFieldWithInitializer = "static field";
}
```

There are some additional syntax restrictions:

- The name of a static property (field or method) cannot be `prototype`.
- The name of a class field (static or instance) cannot be `constructor`.

Description

This page introduces public instance fields in detail.

- For public static fields, see `static`.
- For private fields, see private elements.
- For public methods, see method definitions.
- For public accessors, see getter and setter.

Public instance fields exist on every created instance of a class. By declaring a public field, you can ensure the field is always present, and the class definition is more self-documenting.

Public instance fields are added to the instance either at construction time in the base class (before the constructor body runs), or just after `super()` returns in a subclass. Fields without initializers are initialized to `undefined`. Like properties, field names may be computed.

```
const PREFIX = "prefix";

class ClassWithField {
  field;
  fieldWithInitializer = "instance field";
  [`${PREFIX}Field`] = "prefixed field";
}

const instance = new ClassWithField();
console.log(Object.hasOwn(instance, "field")); // true
console.log(instance.field); // undefined
console.log(instance.fieldWithInitializer); // "instance field"
console.log(instance.prefixField); // "prefixed field"
```

Computed field names are only evaluated once, at class definition time. This means that each class always has a fixed set of field names, and two instances cannot have different field names via computed names. The `this` value in the computed expression is the `this` surrounding the class definition, and referring to the class's name is a `ReferenceError` because the class is not initialized yet. `await` and `yield` work as expected in this expression.

```
class C {
  [Math.random()] = 1;
}

console.log(new C());
console.log(new C());
// Both instances have the same field name
```

In the field initializer, `this` refers to the class instance under construction, and `super` refers to the `prototype` property of the base class, which contains the base class's instance methods, but not its instance fields.

```
class Base {
  baseField = "base field";
  anotherBaseField = this.baseField;
  baseMethod() {
    return "base method output";
  }
}

class Derived extends Base {
  subField = super.baseMethod();
}

const base = new Base();
const sub = new Derived();

console.log(base.anotherBaseField); // "base field"

console.log(sub.subField); // "base method output"
```

The field initializer expression is evaluated each time a new instance is created. (Because the `this` value is different for each instance, the initializer expression can access instance-specific properties.)

```
class C {
  obj = {};
}

const instance1 = new C();
const instance2 = new C();
console.log(instance1.obj === instance2.obj); // false
```

The expression is evaluated synchronously. You cannot use `await` or `yield` in the initializer expression. (Think of the initializer expression as being implicitly wrapped in a function.)

Because instance fields of a class are added before the respective constructor runs, you can access the fields' values within the constructor. However, because instance fields of a derived class are defined after `super()` returns, the base class's constructor does not have access to the derived class's fields.

```
class Base {
  constructor() {
    console.log("Base constructor:", this.field);
  }
}

class Derived extends Base {
  field = 1;
  constructor() {
    super();
    console.log("Derived constructor:", this.field);
    this.field = 2;
  }
}

const instance = new Derived();
// Base constructor: undefined
// Derived constructor: 1
console.log(instance.field); // 2
```

Fields are added one-by-one. Field initializers can refer to field values above it, but not below it. All instance and static methods are added beforehand and can be accessed, although calling them may not behave as expected if they refer to fields below the one being initialized.

```
class C {
  a = 1;
  b = this.c;
  c = this.a + 1;
  d = this.c + 1;
}

const instance = new C();
console.log(instance.d); // 3
console.log(instance.b); // undefined
```

> **Note:** This is more important with private fields, because accessing a non-initialized private field throws a `TypeError`, even if the private field is declared below. (If the private field is not declared, it would be an early `SyntaxError`.)

Because class fields are added using the `[[DefineOwnProperty]]` semantic (which is essentially `Object.defineProperty()`), field declarations in derived classes do not invoke setters in the base class. This behavior differs from using `this.field = …` in the constructor.

```
class Base {
  set field(val) {
    console.log(val);
  }
}

class DerivedWithField extends Base {
  field = 1;
}

const instance = new DerivedWithField(); // No log

class DerivedWithConstructor extends Base {
  constructor() {
    super();
    this.field = 1;
  }
}

const instance2 = new DerivedWithConstructor(); // Logs 1
```

> **Note:** Before the class fields specification was finalized with the `[[DefineOwnProperty]]` semantic, most transpilers, including Babel and tsc, transformed class fields to the `DerivedWithConstructor` form, which has caused subtle bugs after class fields were standardized.

Examples

Using class fields

Class fields cannot depend on arguments of the constructor, so field initializers usually evaluate to the same value for each instance (unless the same expression can evaluate to different values each time, such as `Math.random()` or object initializers).

```
class Person {
  name = nameArg; // nameArg is out of scope of the constructor
  constructor(nameArg) {}
}
```

```
class Person {
  // All instances of Person will have the same name
```

```
  name = "Dragomir";
}
```

However, even declaring an empty class field is beneficial, because it indicates the existence of the field, which allows type checkers as well as human readers to statically analyze the shape of the class.

```
class Person {
  name;
  age;
  constructor(name, age) {
    this.name = name;
    this.age = age;
  }
}
```

The code above seems repetitive, but consider the case where `this` is dynamically mutated: the explicit field declaration makes it clear which fields will definitely be present on the instance.

```
class Person {
  name;
  age;
  constructor(properties) {
    Object.assign(this, properties);
  }
}
```

Because initializers are evaluated after the base class has executed, you can access properties created by the base class constructor.

```
class Person {
  name;
  age;
  constructor(name, age) {
    this.name = name;
    this.age = age;
  }
}

class Professor extends Person {
  name = `Professor ${this.name}`;
}

console.log(new Professor("Radev", 54).name); // "Professor Radev"
```

static

The **`static`** keyword defines a static method or field for a class, or a static initialization block (see the link for more information about this usage). Static properties cannot be directly accessed on instances of the class. Instead, they're accessed on the class itself.

Static methods are often utility functions, such as functions to create or clone objects, whereas static properties are useful for caches, fixed-configuration, or any other data you don't need to be replicated across instances.

> **Note:** In the context of classes, MDN Web Docs content uses the terms properties and fields interchangeably.

Try it

```
class ClassWithStaticMethod {
  static staticProperty = "someValue";
  static staticMethod() {
    return "static method has been called.";
  }
  static {
    console.log("Class static initialization block called");
  }
}

console.log(ClassWithStaticMethod.staticProperty);
// Expected output: "someValue"
console.log(ClassWithStaticMethod.staticMethod());
// Expected output: "static method has been called."
```

Syntax

```
class ClassWithStatic {
  static staticField;
  static staticFieldWithInitializer = value;
  static staticMethod() {
    // …
  }
}
```

There are some additional syntax restrictions:

- The name of a static property (field or method) cannot be `prototype`.
- The name of a class field (static or instance) cannot be `constructor`.

Description

This page introduces public static properties of classes, which include static methods, static accessors, and static fields.

- For private static features, see private elements.
- For instance features, see methods definitions, getter, setter, and public class fields.

Public static features are declared using the `static` keyword. They are added to the class constructor at the time of class evaluation using the `[[DefineOwnProperty]]` semantic (which is essentially `Object.defineProperty()`). They are accessed again from the class constructor.

Static methods are often utility functions, such as functions to create or clone instances. Public static fields are useful when you want a field to exist only once per class, not on every class instance you create. This is useful for caches, fixed-configuration, or any other data you don't need to be replicated across instances.

Static field names can be computed. The `this` value in the computed expression is the `this` surrounding the class definition, and referring to the class's name is a `ReferenceError` because the class is not initialized yet. `await` and `yield` work as expected in this expression.

Static fields can have an initializer. Static fields without initializers are initialized to `undefined`. Public static fields are not reinitialized on subclasses, but can be accessed via the prototype chain.

```
class ClassWithStaticField {
  static staticField;
  static staticFieldWithInitializer = "static field";
}

class SubclassWithStaticField extends ClassWithStaticField {
  static subStaticField = "subclass field";
}

console.log(Object.hasOwn(ClassWithStaticField, "staticField")); // true
console.log(ClassWithStaticField.staticField); // undefined
console.log(ClassWithStaticField.staticFieldWithInitializer); // "static field"
console.log(SubclassWithStaticField.staticFieldWithInitializer); // "static field"
console.log(SubclassWithStaticField.subStaticField); // "subclass field"
```

In the field initializer, `this` refers to the current class (which you can also access through its name), and `super` refers to the base class constructor.

```
class ClassWithStaticField {
  static baseStaticField = "base static field";
  static anotherBaseStaticField = this.baseStaticField;

  static baseStaticMethod() {
    return "base static method output";
  }
}

class SubClassWithStaticField extends ClassWithStaticField {
  static subStaticField = super.baseStaticMethod();
}

console.log(ClassWithStaticField.anotherBaseStaticField); // "base static field"
console.log(SubClassWithStaticField.subStaticField); // "base static method output"
```

The expression is evaluated synchronously. You cannot use `await` or `yield` in the initializer expression. (Think of the initializer expression as being implicitly wrapped in a function.)

Static field initializers and static initialization blocks are evaluated one-by-one. Field initializers can refer to field values above it, but not below it. All static methods are added beforehand and can be accessed, although calling them may not behave as expected if they refer to fields below the one being initialized.

> **Note:** This is more important with private static fields, because accessing a non-initialized private field throws a `TypeError`, even if the private field is declared below. (If the private field is not declared, it would be an early `SyntaxError`.)

Examples

Using static members in classes

The following example demonstrates several things:

1. How a static member (method or property) is defined on a class.

2. That a class with a static member can be sub-classed.
3. How a static member can and cannot be called.

```
class Triple {
  static customName = "Tripler";
  static description = "I triple any number you provide";
  static calculate(n = 1) {
    return n * 3;
  }
}

class SquaredTriple extends Triple {
  static longDescription;
  static description = "I square the triple of any number you provide";
  static calculate(n) {
    return super.calculate(n) * super.calculate(n);
  }
}

console.log(Triple.description); // 'I triple any number you provide'
console.log(Triple.calculate()); // 3
console.log(Triple.calculate(6)); // 18

const tp = new Triple();

console.log(SquaredTriple.calculate(3)); // 81 (not affected by parent's instantiation)
console.log(SquaredTriple.description); // 'I square the triple of any number you provide'
console.log(SquaredTriple.longDescription); // undefined
console.log(SquaredTriple.customName); // 'Tripler'

// This throws because calculate() is a static member, not an instance member.
console.log(tp.calculate()); // 'tp.calculate is not a function'
```

Calling static members from another static method

In order to call a static method or property within another static method of the same class, you can use the `this` keyword.

```
class StaticMethodCall {
  static staticProperty = "static property";
  static staticMethod() {
    return `Static method and ${this.staticProperty} has been called`;
  }
  static anotherStaticMethod() {
    return `${this.staticMethod()} from another static method`;
  }
}
StaticMethodCall.staticMethod();
// 'Static method and static property has been called'

StaticMethodCall.anotherStaticMethod();
// 'Static method and static property has been called from another static method'
```

Calling static members from a class constructor and other methods

Static members are not directly accessible using the `this` keyword from non-static methods. You need to call them using the class name: `CLASSNAME.STATIC_METHOD_NAME()` / `CLASSNAME.STATIC_PROPERTY_NAME` or by calling the method as a property of the `constructor`: `this.constructor.STATIC_METHOD_NAME()` / `this.constructor.STATIC_PROPERTY_NAME`

```
class StaticMethodCall {
  constructor() {
    console.log(StaticMethodCall.staticProperty); // 'static property'
    console.log(this.constructor.staticProperty); // 'static property'
    console.log(StaticMethodCall.staticMethod()); // 'static method has been called.'
    console.log(this.constructor.staticMethod()); // 'static method has been called.'
  }

  static staticProperty = "static property";
  static staticMethod() {
    return "static method has been called.";
  }
}
```

Static initialization blocks

Static initialization blocks are declared within a `class`. It contains statements to be evaluated during class initialization. This permits more flexible initialization logic than `static` properties, such as using `try...catch` or setting multiple fields from a single value. Initialization is performed in the context of the current class declaration,

with access to private state, which allows the class to share information of its private elements with other classes or functions declared in the same scope (analogous to "friend" classes in C++).

Try it

```
class ClassWithStaticInitializationBlock {
  static staticProperty1 = "Property 1";
  static staticProperty2;
  static {
    this.staticProperty2 = "Property 2";
  }
}

console.log(ClassWithStaticInitializationBlock.staticProperty1);
// Expected output: "Property 1"
console.log(ClassWithStaticInitializationBlock.staticProperty2);
// Expected output: "Property 2"
```

Syntax

```
class ClassWithSIB {
  static {
    // …
  }
}
```

Description

Without static initialization blocks, complex static initialization might be achieved by calling a static method after the class declaration:

```
class MyClass {
  static init() {
    // Access to private static fields is allowed here
  }
}

MyClass.init();
```

However, this approach exposes an implementation detail (the `init()` method) to the user of the class. On the other hand, any initialization logic declared outside the class does not have access to private static fields. Static initialization blocks allow arbitrary initialization logic to be declared within the class and executed during class evaluation.

A `class` can have any number of `static {}` initialization blocks in its class body. These are evaluated, along with any interleaved static field initializers, in the order they are declared. Any static initialization of a super class is performed first, before that of its sub classes.

The scope of the variables declared inside the static block is local to the block. This includes `var`, `function`, `const`, and `let` declarations. `var` declarations will not be hoisted out of the static block.

```
var y = "Outer y";

class A {
  static field = "Inner y";
  static {
    // var y only hoisted inside block
    console.log(y); // undefined <-- not 'Outer y'

    var y = this.field;
  }
}

// var y defined in static block is not hoisted
// outside the block
console.log(y); // 'Outer y'
```

The `this` inside a static block refers to the constructor object of the class. `super.property` can be used to access static properties of the super class. Note however that it is a syntax error to call `super()` in a class static initialization block, or to use the `arguments` object.

The statements are evaluated synchronously. You cannot use `await` or `yield` in this block. (Think of the initialization statements as being implicitly wrapped in a function.)

The scope of the static block is nested *within* the lexical scope of the class body, and can access private names declared within the class without causing a syntax error.

Static field initializers and static initialization blocks are evaluated one-by-one. The initialization block can refer to field values above it, but not below it. All static methods are added beforehand and can be accessed, although calling them may not behave as expected if they refer to fields below the current block.

> **Note:** This is more important with private static fields, because accessing a non-initialized private field throws a `TypeError`, even if the private field is declared below. (If the private field is not declared, it would be an early `SyntaxError`.)

A static initialization block may not have decorators (the class itself may).

Examples

Multiple blocks

The code below demonstrates a class with static initialization blocks and interleaved static field initializers. The output shows that the blocks and fields are evaluated in execution order.

```
class MyClass {
  static field1 = console.log("static field1");
  static {
    console.log("static block1");
  }
  static field2 = console.log("static field2");
  static {
    console.log("static block2");
  }
}
// 'static field1'
// 'static block1'
// 'static field2'
// 'static block2'
```

Note that any static initialization of a super class is performed first, before that of its sub classes.

Using this and super

The `this` inside a static block refers to the constructor object of the class. This code shows how to access a public static field.

```
class A {
  static field = "static field";
  static {
    console.log(this.field);
  }
}
// 'static field'
```

The `super.property` syntax can be used inside a `static` block to reference static properties of a super class.

```
class A {
  static field = "static field";
}

class B extends A {
  static {
    console.log(super.field);
  }
}
// 'static field'
```

Access to private elements

This example below shows how access can be granted to a private instance field of a class from an object outside the class (example from the v8.dev blog):

```
let getDPrivateField;

class D {
  #privateField;
  constructor(v) {
    this.#privateField = v;
  }
  static {
    getDPrivateField = (d) => d.#privateField;
  }
}

console.log(getDPrivateField(new D("private"))); // 'private'
```

Deprecated and obsolete features

This page lists features of JavaScript that are deprecated (that is, still available but planned for removal) and obsolete (that is, no longer usable).

Deprecated features

These deprecated features can still be used, but should be used with caution because they are not required to be implemented by every JavaScript engine. You should work to remove their use from your code.

Some of these deprecated features are listed in the Annex B section of the ECMAScript specification. This section is described as normative optional — that is, web browser hosts must implement these features, while non-web hosts may not. These features are likely stable because removing them will cause backward compatibility issues and break legacy websites. (JavaScript has the design goal of "don't break the web".) Still, they are not cross-platform portable and may not be supported by all analysis tools, so you are advised to not use them, as the introduction of Annex B states:

> … All of the language features and behaviors specified in this annex have one or more undesirable characteristics and in the absence of legacy usage would be removed from this specification. …
>
> … Programmers should not use or assume the existence of these features and behaviors when writing new ECMAScript code. …

Some others, albeit in the main spec body, are also marked as normative optional and should not be depended on.

HTML comments

JavaScript source, if parsed as scripts, allows HTML-like comments, as if the script is part of a `<script>` tag.

The following is valid JavaScript when running in a web browser (or Node.js, which uses the V8 engine powering Chrome):

```
<!-- comment
console.log("a"); <!-- another comment
console.log("b");
--> More comment
// Logs "a" and "b"
```

`<!--` and `-->` both act like `//`, i.e., starting line comments. `-->` is only valid at the start of a line (to avoid ambiguity with a postfix decrement followed by a greater than operator), while `<!--` can occur anywhere in the line.

RegExp

The following properties are deprecated. This does not affect their use in replacement strings:

`$1–$9`

: Parenthesized substring matches, if any.

`input`, `$_`

: The string against which a regular expression is matched.

`lastMatch`, `$&`

: The last matched substring.

`lastParen`, `$+`

: The last parenthesized substring match, if any.

`leftContext`, `` $` ``

: The substring preceding the most recent match.

`rightContext`, `$'`

: The substring following the most recent match.

> **Warning:** Avoid using these static properties, as they can cause issues when interacting with external code!

The `compile()` method is deprecated. Construct a new `RegExp` instance instead.

The following regex syntaxes are deprecated and only available in Unicode-unaware mode. In Unicode-aware mode, they are all syntax errors:

- Lookahead assertions can have quantifiers.
- Backreferences that do not refer to an existing capturing group become legacy octal escapes.
- In character classes, character ranges where one boundary is a character class makes the `-` become a literal character.
- An escape sequence that's not recognized becomes an "identity escape".
- Escape sequences within character classes of the form `\cX` where X is a number or _ are decoded in the same way as those with ASCII letters: `\c0` is the same as `\cP` when taken modulo 32. In addition, if the form `\cX` is encountered anywhere where X is not one of the recognized characters, then the backslash is treated as a literal character.
- The sequence `\k` within a regex that doesn't have any named capturing groups is treated as an identity escape.
- The syntax characters `]`, `{`, and `}` may appear literally without escaping if they cannot be interpreted as the end of a character class or quantifier delimiters.

Function

- The `caller` property of functions and the `arguments.callee` property are deprecated and unavailable in strict mode.
- Instead of accessing `arguments` as a property of a function, you should use the `arguments` object inside function closures.

Object

- The `Object.prototype.__proto__` accessors are deprecated. Use `Object.getPrototypeOf` and `Object.setPrototypeOf` instead. This does not apply to the `__proto__` literal key in object literals.
- The `Object.prototype.__defineGetter__`, `Object.prototype.__defineSetter__`, `Object.prototype.__lookupGetter__`, and `Object.prototype.__lookupSetter__` methods are deprecated. Use `Object.getOwnPropertyDescriptor` and `Object.defineProperty` instead.

String

- HTML wrapper methods like `String.prototype.fontsize` and `String.prototype.big`.
- `String.prototype.substr` probably won't be removed anytime soon, but it's defined in Annex B and hence normative optional.
- `String.prototype.trimLeft` and `String.prototype.trimRight` should be replaced with `String.prototype.trimStart` and `String.prototype.trimEnd`.

Date

- The `getYear()` and `setYear()` methods are affected by the Year-2000-Problem and have been subsumed by `getFullYear` and `setFullYear`.
- The `toGMTString()` method is deprecated. Use `toUTCString()` instead.

Escape sequences

- Octal escape sequences (\ followed by one, two, or three octal digits) are deprecated in string and regular expression literals.
- The `escape()` and `unescape()` functions are deprecated. Use `encodeURI()`, `encodeURIComponent()`, `decodeURI()`, or `decodeURIComponent()` to encode and decode escape sequences for special characters.

Statements

The `with` statement is deprecated and unavailable in strict mode.

Initializers in `var` declarations of `for...in` loops headers are deprecated and produce syntax errors in strict mode. The initializer expression is evaluated and assigned to the variable, but the value would be immediately reassigned on the first iteration of the loop.

Normally, the `catch` block of a `try...catch` statement cannot contain any variable declaration with the same name as the variables bound in the `catch()`. An extension grammar allows the `catch` block to contain a `var` declared variable with the same name as the `catch`-bound identifier, but only if the `catch` binding is a simple identifier, not a destructuring pattern. However, this variable's initialization and assignment would only act on the `catch`-bound identifier, instead of the upper scope variable, and the behavior could be confusing.

```
var a = 2;
try {
  throw new Error();
} catch (a) {
  var a = 1; // This 1 is assigned to the caught `a`, not the outer `a`.
}
console.log(a); // 2

try {
  throw new Error();
  // Note: identifier changed to `err` to avoid conflict with
  // the inner declaration of `a`.
} catch (err) {
  var a = 1; // This 1 is assigned to the upper-scope `a`.
}
console.log(a); // 1
```

This is listed in Annex B of the spec and hence may not be implemented everywhere. Avoid any name conflicts between the `catch`-bound identifier and variables declared in the `catch` block.

Obsolete features

These obsolete features have been entirely removed from JavaScript and can no longer be used as of the indicated version of JavaScript.

RegExp

The following are now properties of `RegExp` instances, no longer of the `RegExp` constructor:

Property	Description
`global`	Whether or not to test the regular expression against all possible matches in a string, or only against the first.
`ignoreCase`	Whether or not to ignore case while attempting a match in a string.
`lastIndex`	The index at which to start the next match.
`multiline` (also via `RegExp.$*`)	Whether or not to search in strings across multiple lines.
`source`	The text of the pattern.

The `valueOf()` method is no longer specialized for `RegExp`. It uses `Object.prototype.valueOf()`, which returns itself.

Function

- Functions' `arity` property is obsolete. Use `length` instead.

Object

Property	Description	Alternative
`__count__`	Returns the number of enumerable properties directly available on a user-defined object.	`Object.keys()`
`__parent__`	Points to an object's context.	No direct replacement
`__iterator__`	Used with legacy iterators.	`Symbol.iterator` and the new iteration protocols
`__noSuchMethod__`	A method called when a non-existent property is called as method.	`Proxy`
`Object.prototype.eval()`	Evaluates a string of JavaScript code in the context of the specified object.	No direct replacement
`Object.observe()`	Asynchronously observing the changes to an object.	`Proxy`
`Object.unobserve()`	Remove observers.	`Proxy`
`Object.getNotifier()`	Create a notifier object that allows you to synthetically trigger a change observable with `Object.observe()`.	No direct replacement
`Object.prototype.watch()`	Attach a handler callback to a property that gets called when the property is assigned.	`Proxy`
`Object.prototype.unwatch()`	Remove watch handlers on a property.	`Proxy`

String

- Non-standard String generic methods like `String.slice(myStr, 0, 12)`, `String.replace(myStr, /\./g, "!")`, etc. have been introduced in Firefox 1.5 (JavaScript 1.6), deprecated in Firefox 53, and removed in Firefox 68. You can use methods on `String.prototype` together with `Function.call` instead.
- `String.prototype.quote` is removed from Firefox 37.
- Non-standard `flags` parameter in `String.prototype.search`, `String.prototype.match`, and `String.prototype.replace` are obsolete.

WeakMap

- `WeakMap.prototype.clear()` was added in Firefox 20 and removed in Firefox 46. It is not possible to traverse all keys in a `WeakMap`.

Date

- `Date.prototype.toLocaleFormat()`, which used a format string in the same format expected by the `strftime()` function in C, is obsolete. Use `toLocaleString()` or `Intl.DateTimeFormat` instead.

Array

- Non-standard Array generic methods like `Array.slice(myArr, 0, 12)`, `Array.forEach(myArr, myFn)`, etc. have been introduced in Firefox 1.5 (JavaScript 1.6), deprecated in Firefox 68, and removed in Firefox 71. You can use methods on `Array.prototype` together with `Function.call` instead.

Property	Description	Alternative
`Array.observe()`	Asynchronously observing changes to Arrays.	`Proxy`
`Array.unobserve()`	Remove observers.	`Proxy`

Number

- `Number.toInteger()` is obsolete. Use `Math.floor`, `Math.round`, or other methods instead.

Proxy

- `Proxy.create` and `Proxy.createFunction` are obsolete. Use the `Proxy()` constructor instead.
- The following traps are obsolete:
  - `hasOwn` (bug 980565, Firefox 33).
  - `getEnumerablePropertyKeys` (bug 783829, Firefox 37)
  - `getOwnPropertyNames` (bug 1007334, Firefox 33)
  - `keys` (bug 1007334, Firefox 33)

ParallelArray

- `ParallelArray` is obsolete.

Statements

- `for each...in` is obsolete. Use `for...of` instead.
- let blocks and let expressions are obsolete.
- Expression closures (`function () 1` as a shorthand of `function () { return 1; }`) are obsolete. Use regular `functions` or arrow functions instead.

Acquiring source text

The `toSource()` methods of arrays, numbers, strings, etc. and the `uneval()` global function are obsolete. Use `toString()`, or write your own serialization method instead.

Legacy generator and iterator

Legacy generator function statements and legacy generator function expressions are removed. The legacy generator function syntax reuses the `function` keyword, which automatically becomes a generator function when there are one or more `yield` expressions in the body — this is now a syntax error. Use `function*` statements and `function*` expressions instead.

Array comprehensions and generator comprehensions are removed.

```
// Legacy array comprehensions
[for (x of iterable) x]
[for (x of iterable) if (condition) x]
[for (x of iterable) for (y of iterable) x + y]

// Legacy generator comprehensions
(for (x of iterable) x)
(for (x of iterable) if (condition) x)
(for (x of iterable) for (y of iterable) x + y)
```

Firefox, prior to version 26, implemented another iterator protocol that is similar to the standard Iterator protocol. An object is a legacy iterator when it implements a `next()` method, which produces a value on each call and throws a `StopIteration` object at the end of iteration. This legacy iterator protocol differs from the standard iterator protocol:

- The value was returned directly as the return value of calls to `next()`, instead of the `value` property of the `IteratorResult` object.
- Iteration termination was expressed by throwing a `StopIteration` object, instead of through the `done` property of the `IteratorResult` object.

This feature, along with the `StopIteration` global constructor, was removed in Firefox 58+. For future-facing usages, consider using `for...of` loops and the iterator protocol.

Sharp variables

Sharp variables are obsolete. To create circular structures, use temporary variables instead.

JavaScript error reference

Below, you'll find a list of errors which are thrown by JavaScript. These errors can be a helpful debugging aid, but the reported problem isn't always immediately clear. The pages below will provide additional details about these errors. Each error is an object based upon the `Error` object, and has a `name` and a `message`.

Errors displayed in the Web console may include a link to the corresponding page below to help you quickly comprehend the problem in your code.

For a beginner's introductory tutorial on fixing JavaScript errors, see What went wrong? Troubleshooting JavaScript.

List of errors

In this list, each page is listed by name (the type of error) and message (a more detailed human-readable error message). Together, these two properties provide a starting point toward understanding and resolving the error. For more information, follow the links below!

- AggregateError: No Promise in Promise.any was resolved
- Error: Permission denied to access property "x"
- InternalError: too much recursion
- RangeError: argument is not a valid code point
- RangeError: BigInt division by zero
- RangeError: BigInt negative exponent
- RangeError: form must be one of 'NFC', 'NFD', 'NFKC', or 'NFKD'
- RangeError: invalid array length
- RangeError: invalid date
- RangeError: precision is out of range
- RangeError: radix must be an integer
- RangeError: repeat count must be less than infinity
- RangeError: repeat count must be non-negative
- RangeError: x can't be converted to BigInt because it isn't an integer
- ReferenceError: "x" is not defined
- ReferenceError: assignment to undeclared variable "x"
- ReferenceError: can't access lexical declaration 'X' before initialization
- ReferenceError: must call super constructor before using 'this' in derived class constructor
- ReferenceError: super() called twice in derived class constructor
- SyntaxError: 'arguments'/'eval' can't be defined or assigned to in strict mode code
- SyntaxError: "0"-prefixed octal literals are deprecated
- SyntaxError: "use strict" not allowed in function with non-simple parameters
- SyntaxError: "x" is a reserved identifier
- SyntaxError: \ at end of pattern
- SyntaxError: a declaration in the head of a for-of loop can't have an initializer
- SyntaxError: applying the 'delete' operator to an unqualified name is deprecated
- SyntaxError: arguments is not valid in fields
- SyntaxError: await is only valid in async functions, async generators and modules
- SyntaxError: await/yield expression can't be used in parameter
- SyntaxError: cannot use ?? unparenthesized within || and && expressions
- SyntaxError: character class escape cannot be used in class range in regular expression
- SyntaxError: continue must be inside loop
- SyntaxError: duplicate capture group name in regular expression
- SyntaxError: duplicate formal argument x
- SyntaxError: for-in loop head declarations may not have initializers
- SyntaxError: function statement requires a name
- SyntaxError: functions cannot be labelled
- SyntaxError: getter and setter for private name #x should either be both static or non-static
- SyntaxError: getter functions must have no arguments
- SyntaxError: identifier starts immediately after numeric literal

- SyntaxError: illegal character
- SyntaxError: import declarations may only appear at top level of a module
- SyntaxError: incomplete quantifier in regular expression
- SyntaxError: invalid assignment left-hand side
- SyntaxError: invalid BigInt syntax
- SyntaxError: invalid capture group name in regular expression
- SyntaxError: invalid character in class in regular expression
- SyntaxError: invalid class set operation in regular expression
- SyntaxError: invalid decimal escape in regular expression
- SyntaxError: invalid identity escape in regular expression
- SyntaxError: invalid named capture reference in regular expression
- SyntaxError: invalid property name in regular expression
- SyntaxError: invalid range in character class
- SyntaxError: invalid regexp group
- SyntaxError: invalid regular expression flag "x"
- SyntaxError: invalid unicode escape in regular expression
- SyntaxError: JSON.parse: bad parsing
- SyntaxError: label not found
- SyntaxError: missing : after property id
- SyntaxError: missing) after argument list
- SyntaxError: missing) after condition
- SyntaxError: missing] after element list
- SyntaxError: missing } after function body
- SyntaxError: missing } after property list
- SyntaxError: missing = in const declaration
- SyntaxError: missing formal parameter
- SyntaxError: missing name after . operator
- SyntaxError: missing variable name
- SyntaxError: negated character class with strings in regular expression
- SyntaxError: new keyword cannot be used with an optional chain
- SyntaxError: nothing to repeat
- SyntaxError: numbers out of order in {} quantifier.
- SyntaxError: octal escape sequences can't be used in untagged template literals or in strict mode code
- SyntaxError: parameter after rest parameter
- SyntaxError: private fields can't be deleted
- SyntaxError: property name __proto__ appears more than once in object literal
- SyntaxError: raw bracket is not allowed in regular expression with unicode flag
- SyntaxError: redeclaration of formal parameter "x"
- SyntaxError: reference to undeclared private field or method #x
- SyntaxError: rest parameter may not have a default
- SyntaxError: return not in function
- SyntaxError: setter functions must have one argument
- SyntaxError: string literal contains an unescaped line break

TypeError: already executing generator

The JavaScript exception "TypeError: already executing generator" occurs when a generator is continued using one of its methods (such as `next()`) while executing the generator function's body itself.

Message

```
TypeError: Generator is already running (V8-based)
TypeError: already executing generator (Firefox)
TypeError: Generator is executing (Safari)
```

Error type

`TypeError`

What went wrong?

The generator's methods, `next()`, `return()`, and `throw()`, are meant to continue the execution of a generator function when it's paused after a `yield` expression or before the first statement. If a call to one of these methods is made while executing the generator function, the error is thrown. If you want to return or throw within the generator function, use the `return` statement or the `throw` statement, respectively.

Examples

```
let it;
function* getNumbers(times) {
  if (times <= 0) {
    it.throw(new Error("times must be greater than 0"));
  }
  for (let i = 0; i < times; i++) {
    yield i;
  }
}
it = getNumbers(3);
it.next();
```

```
let it;
function* getNumbers(times) {
  if (times <= 0) {
    throw new Error("times must be greater than 0");
  }
  for (let i = 0; i < times; i++) {
    yield i;
  }
}
it = getNumbers(3);
it.next(); // { value: 0, done: false }
```

Warning: -file- is being assigned a //# sourceMappingURL, but already has one

The JavaScript warning "-file- is being assigned a //# sourceMappingURL, but already has one." occurs when a source map has been specified more than once for a given JavaScript source.

Message

```
Warning: -file- is being assigned a //# sourceMappingURL, but already has one.
```

Error type

A warning. JavaScript execution won't be halted.

What went wrong?

A source map has been specified more than once for a given JavaScript source.

JavaScript sources are often combined and minified to make delivering them from the server more efficient. With source maps, the debugger can map the code being executed to the original source files. There are two ways to assign a source map, either by using a comment or by setting a header to the JavaScript file.

Examples

Setting source maps

Setting a source map by using a comment in the file:

```
//# sourceMappingURL=http://example.com/path/to/your/sourcemap.map
```

Or, alternatively, you can set a header to your JavaScript file:

```
X-SourceMap: /path/to/file.js.map
```

SyntaxError: arguments is not valid in fields

The JavaScript exception "SyntaxError: arguments is not valid in fields" occurs when the `arguments` identifier is read in a class field initializer or in a static initialization block, outside of a non-arrow function.

Message

```
SyntaxError: 'arguments' is not allowed in class field initializer or static initialization block (V8-based)
SyntaxError: arguments is not valid in fields (Firefox)
SyntaxError: Unexpected identifier 'arguments'. Cannot reference 'arguments' in class field initializer. (Safari)
```

Error type

`SyntaxError`

What went wrong?

A class field initializer expression or a class static initialization block does not have `arguments` in its scope. Trying to access it is a syntax error.

- This is true even if `arguments` is bound in a parent scope (such as when the class is nested in a non-arrow function).
- A non-arrow function declared within this scope will still bind its own `arguments` and read it normally.

Examples

```
function makeOne() {
  class C {
    args = { ...arguments }; // SyntaxError: arguments is not valid in fields
  }
  return new C();
}
```

```
let CArgs;
class C {
  static {
    CArgs = arguments; // SyntaxError: arguments is not valid in fields
  }
}
```

```
class C {
  args = {};
  constructor() {
    this.args = arguments; // You can use arguments in constructors
  }
  myMethod() {
    this.args = arguments; // You can also use it in methods
  }
}
```

```
function makeOne() {
  const _arguments = arguments;
  class C {
    args = { ..._arguments }; // Only the identifier is forbidden
  }
```

```
  return new C();
}
```

- Static initialization blocks

TypeError: invalid Array.prototype.sort argument

The JavaScript exception "invalid Array.prototype.sort argument" occurs when the argument of `Array.prototype.sort()` (and its related methods: `Array.prototype.toSorted()`, `TypedArray.prototype.sort()`, `TypedArray.prototype.toSorted()`) isn't either `undefined` or a function that compares its operands.

Message

```
TypeError: The comparison function must be either a function or undefined (V8-based)

TypeError: invalid Array.prototype.sort argument (Firefox)
TypeError: non-function passed to Array.prototype.toSorted (Firefox)
TypeError: invalid %TypedArray%.prototype.sort argument (Firefox)

TypeError: Array.prototype.sort requires the comparator argument to be a function or undefined (Safari)
TypeError: Array.prototype.toSorted requires the comparator argument to be a function or undefined (Safari)
TypeError: TypedArray.prototype.sort requires the comparator argument to be a function or undefined (Safari)
TypeError: TypedArray.prototype.toSorted requires the comparator argument to be a function or undefined (Safari)
```

Error type

`TypeError`

What went wrong?

The argument of `Array.prototype.sort()` (and its related methods: `Array.prototype.toSorted()`, `TypedArray.prototype.sort()`, `TypedArray.prototype.toSorted()`) is expected to be either `undefined` or a function which compares its operands.

Examples

Invalid cases

```
[1, 3, 2].sort(5); // TypeError
students.toSorted("name"); // TypeError
```

Valid cases

```
[1, 3, 2].sort(); // [1, 2, 3]
[1, 3, 2].sort((a, b) => a - b); // [1, 2, 3]
students.toSorted((a, b) => a.name.localeCompare(b.name));
```

- `TypedArray.prototype.toSorted()`

SyntaxError: await/yield expression can't be used in parameter

The JavaScript exception "await expression can't be used in parameter" or "yield expression can't be used in parameter" occurs when the default parameter expression contains the `await` or `yield` keyword and has the effect of pausing default parameter evaluation.

Message

```
SyntaxError: Illegal await-expression in formal parameters of async function (V8-based)
SyntaxError: await expression can't be used in parameter (Firefox)
SyntaxError: Cannot use 'await' within a parameter default expression. (Safari)

SyntaxError: Yield expression not allowed in formal parameter (V8-based)
SyntaxError: yield expression can't be used in parameter (Firefox)
SyntaxError: Unexpected keyword 'yield'. Cannot use yield expression within parameters. (Safari)
```

Error type

`SyntaxError`

What went wrong?

The default expression must be able to evaluate *synchronously*. If it contains an `await` or `yield` expression, it will pause the evaluation of the default expression, which is not allowed.

> **Note:** This error is only generated when `await` or `yield` are valid operators in this function context. Otherwise, `await` or `yield` would be parsed as an identifier, and

> either not cause an error, or cause an error like "reserved identifier", or "unexpected token" if there's an expression following it.

Examples

Invalid cases

```
function *gen(a = yield 1) {}

async function f(a = await Promise.resolve(1)) {}
```

Valid cases

You can use the nullish coalescing assignment to provide a default value instead. If you want to treat `null` and `undefined` differently, you would need to use a condition.

```
function* gen(a) {
  a ??= yield 1;
}

async function f(a) {
  a ??= await Promise.resolve(1);
}
```

You are also allowed to use `await` or `yield` if the expression is contained in a function expression of the initializer and would not pause the evaluation of the default expression.

```
async function f(a = (async () => await Promise.resolve(1))()) {}
```

- Default parameters
- `await`
- `yield`

SyntaxError: await is only valid in async functions, async generators and modules

The JavaScript exception "await is only valid in async functions, async generators and modules" occurs when an `await` expression is used outside of async functions or modules or other async contexts.

Message

```
SyntaxError: await is only valid in async functions and the top level bodies of modules (V8-based)
SyntaxError: await is only valid in async functions, async generators and modules (Firefox)
SyntaxError: Unexpected identifier (Safari)
```

Error type

`SyntaxError`.

What went wrong?

JavaScript execution is never blocking: an `await` can never block the execution of the program. Instead, it pauses the execution of the surrounding async task, while allowing other tasks to continue running. Therefore, `await` cannot be used in sync tasks, such as functions, generator functions, or top level of scripts. It is not always apparent whether the current file is a script or a module — see the Modules guide for more information.

Examples

Top-level await

You cannot use `await` at the top level of a script:

```
<script>
  await fetch("https://example.com");
  // SyntaxError: await is only valid in async functions, async generators and modules
</script>
```

Instead, make the script a module:

```
<script type="module">
  await fetch("https://example.com");
</script>
```

Async callbacks

You cannot use `await` in a sync callback:

```
urls.forEach((url) => {
  await fetch(url);
```

```
  // SyntaxError: await is only valid in async functions, async generators and modules
});
```

Instead, make the callback async. See more explanation in the Using promises guide.

```
Promise.all(
  urls.map(async (url) => {
    await fetch(url);
  }),
);
```

See also

- `await`

SyntaxError: unlabeled break must be inside loop or switch

The JavaScript exception "unlabeled break must be inside loop or switch" occurs when a `break` statement is not inside a loop or a `switch` statement.

Message

```
SyntaxError: Illegal break statement (V8-based)
SyntaxError: unlabeled break must be inside loop or switch (Firefox)
SyntaxError: 'break' is only valid inside a switch or loop statement. (Safari)
```

Error type

`SyntaxError`.

What went wrong?

`break` statements can be used to exit a loop or a `switch` statement, and using them elsewhere is a syntax error. Alternatively, you can provide a label to the `break` statement to break out of any statement with that label — however, if the label does not reference a containing statement, another error SyntaxError: label not found will be thrown.

Examples

Unsyntactic break

`break` cannot be used outside `switch` or loops.

```
let score = 0;

function increment() {
  if (score === 100)
    break; // SyntaxError: unlabeled break must be inside loop or switch
  }
  score++;
}
```

Maybe instead of `break`, you intend to use `return` to early-terminate a function.

```
let score = 0;

function increment() {
  if (score === 100) {
    return;
  }
  score++;
}
```

Using break in callbacks

`break` cannot be used in callbacks, even if the callback is called from a loop.

```
let containingIndex = 0;
const matrix = [
  [1, 2, 3],
  [4, 5, 6],
  [7, 8, 9],
];

while (containingIndex < matrix.length) {
  matrix[containingIndex].forEach((value) => {
    if (value === 5) {
      break; // SyntaxError: unlabeled break must be inside loop or switch
    }
  });
  containingIndex++;
}
```

Instead, refactor the code so the `break` is used outside the callback.

```
let containingIndex = 0;
const matrix = [
  [1, 2, 3],
  [4, 5, 6],
  [7, 8, 9],
];

outer: while (containingIndex < matrix.length) {
  for (const value of matrix[containingIndex]) {
    if (value === 5) {
      break outer;
    }
  }
  containingIndex++;
}
```

```
let containingIndex = 0;
const matrix = [
  [1, 2, 3],
  [4, 5, 6],
  [7, 8, 9],
];

while (containingIndex < matrix.length) {
  if (matrix[containingIndex].includes(5)) {
    break;
  }
  containingIndex++;
}
```

There's no way to early-terminate a `forEach()` loop. You can use `some()` instead, or convert it to a `for...of` loop.

```
array.forEach((value) => {
  if (value === 5) {
    break; // SyntaxError: unlabeled break must be inside loop or switch
  }
  // do something with value
});
```

```
array.some((value) => {
  if (value === 5) {
    return true;
  }
  // do something with value
  return false;
});
```

```
for (const value of array) {
  if (value === 5) {
    break;
  }
  // do something with value
}
```

See also

- `break`

SyntaxError: continue must be inside loop

The JavaScript exception "continue must be inside loop" occurs when a `continue` statement is not inside a loop statement.

Message

```
SyntaxError: Illegal continue statement: no surrounding iteration statement (V8-based)
SyntaxError: Illegal continue statement: 'label' does not denote an iteration statement (V8-based)
SyntaxError: continue must be inside loop (Firefox)
SyntaxError: 'continue' is only valid inside a loop statement. (Safari)
SyntaxError: Cannot continue to the label 'label' as it is not targeting a loop. (Safari)
```

Error type

`SyntaxError`.

What went wrong?

`continue` statements can be used to continue a loop, and using them elsewhere is a syntax error. Alternatively, you can provide a label to the `continue` statement to continue any loop with that label — however, if the label does not reference a containing statement, another error SyntaxError: label not found will be thrown, and if the label references a statement that is not a loop, a syntax error is still thrown.

Examples

Using continue in callbacks

If you want to proceed with the next iteration in a `forEach()` loop, use `return` instead, or convert it to a `for...of` loop.

```
array.forEach((value) => {
  if (value === 5) {
    continue; // SyntaxError: continue must be inside loop
  }
  // do something with value
});
```

```
array.forEach((value) => {
  if (value === 5) {
    return;
  }
  // do something with value
});
```

```
for (const value of array) {
  if (value === 5) {
    continue;
  }
  // do something with value
}
```

See also

- `continue`

SyntaxError: new keyword cannot be used with an optional chain

The JavaScript exception "new keyword cannot be used with an optional chain" occurs when the constructor of a `new` expression is an optional chain, or if there's an optional chain between the constructor and the parenthesized list of arguments.

Message

```
SyntaxError: Invalid optional chain from new expression (V8-based)
SyntaxError: new keyword cannot be used with an optional chain (Firefox)
SyntaxError: Cannot call constructor in an optional chain. (Safari)
```

Error type

`SyntaxError`

What went wrong?

There are two ways to get this error. The first one is if the constructor expression is an optional chain expression, like this:

```
new Intl?.DateTimeFormat();
Number?.[parseMethod]`Hello, world!`;
```

The second one is if `?.` occurs between the constructor and the arguments list, like this:

```
new Intl.DateTimeFormat?.();
```

Optional `new` is specifically forbidden because its syntax is complicated (`new` with and without arguments), and the result is unclear (it would be the only case where `new` does not evaluate to an object value). You need to translate the optional chaining to its underlying condition (see optional chaining for more information).

```
const result =
  Intl.DateTimeFormat === null || Intl.DateTimeFormat === undefined
    ? undefined
    : new Intl.DateTimeFormat();
```

Remember that optional chaining only short-circuits within a parenthesized unit. If you parenthesize your constructor expression, the optional chaining will not cause an error, because now the constructor does not short-circuit and the result is clear (the constructor will produce `undefined` and then cause the `new` expression to throw).

```
new (Intl?.DateTimeFormat)(); // Throws if Intl?.DateTimeFormat is undefined
```

However this is a bit nonsensical anyway because optional chaining prevents errors inside the property access chain, but is then guaranteed to generate an error when calling `new`. You would probably still want to use a conditional check.

Note that optional chaining is only forbidden as the constructor expression. You can use optional chaining inside the argument list, or use optional chaining on the `new` expression as a whole.

```
new Intl.DateTimeFormat(navigator?.languages);
new Intl.DateTimeFormat().resolvedOptions?.();
```

Note that there's no needs to use `?.` on the `new` expression itself: `new a()?.b`, because `new` is guaranteed to produce a non-nullish object value.

See also

- `new`
- Optional chaining (`?.`)
- Original discussion on whether "optional new" should be allowed

SyntaxError: tagged template cannot be used with optional chain

The JavaScript exception "tagged template cannot be used with optional chain" occurs when the tag expression of a tagged template literal is an optional chain, or if there's an optional chain between the tag and the template.

Message

```
SyntaxError: Invalid tagged template on optional chain (V8-based)
SyntaxError: tagged template cannot be used with optional chain (Firefox)
SyntaxError: Cannot use tagged templates in an optional chain. (Safari)
```

Error type

`SyntaxError`

What went wrong?

There are two ways to get this error. The first one is if the tag expression is an optional chain expression, like this:

```
String?.raw`Hello, world!`;
console.log?.()`Hello, world!`;
Number?.[parseMethod]`Hello, world!`;
```

The second one is if `?.` occurs between the tag and the template, like this:

```
String.raw?.`Hello, world!`;
```

Optional chaining in the tag is specifically forbidden because there's no great use case for it, and what the result is expected to be is unclear (should it be `undefined` or the template's value as if it's untagged?). You need to translate the optional chaining to its underlying condition (see optional chaining for more information).

```
const result =
  String.raw === null || String.raw === undefined
    ? undefined
    : String.raw`Hello, world!`;
```

Remember that optional chaining only short-circuits within a parenthesized unit. If you parenthesize your tag expression, the optional chaining will not cause an error, because now the tag does not short-circuit and the result is clear (the tag will produce `undefined` and then cause the tagged template to throw).

```
(console?.log)`Hello, world!`; // Throws if console?.log is undefined
```

However this is a bit nonsensical anyway because optional chaining prevents errors inside the property access chain, but is then guaranteed to generate an error when calling the template tag. You would probably still want to use a conditional check.

Note that optional chaining is only forbidden as the tag expression. You can use optional chaining inside the embedded expressions, or use optional chaining on the tagged template expression as a whole.

```
console.log`Hello, ${true.constructor?.name}!`; // ['Hello, ', '!', raw: Array(2)] 'Boolean'
console.log`Hello`?.toString(); // undefined
```

- Template literals
- Optional chaining (`?.`)
- Original discussion on whether optional chaining should be allowed in tagged template literals

RangeError: radix must be an integer

The JavaScript exception "radix must be an integer at least 2 and no greater than 36" occurs when the optional `radix` parameter of the `Number.prototype.toString()` or the `BigInt.prototype.toString()` method was specified and is not between 2 and 36.

Message

```
RangeError: toString() radix argument must be between 2 and 36 (V8-based & Safari)
RangeError: radix must be an integer at least 2 and no greater than 36 (Firefox)
```

Error type

`RangeError`

What went wrong?

The optional `radix` parameter of the `Number.prototype.toString()` or the `BigInt.prototype.toString()` method was specified. Its value must be an integer (a number) between 2 and 36, specifying the base of the number system to be used for representing numeric values. For example, the decimal (base 10) number 169 is represented in hexadecimal (base 16) as A9.

Why is this parameter's value limited to 36? A radix that is larger than 10 uses alphabetical characters as digits; therefore, the radix can't be larger than 36, since the Latin alphabet (used by English and many other languages) only has 26 characters.

The most common radixes:

- 2 for binary numbers,
- 8 for octal numbers,
- 10 for decimal numbers,
- 16 for hexadecimal numbers.

Examples

Invalid cases

```
(42).toString(0);
(42).toString(1);
(42).toString(37);
(42).toString(150);
// You cannot use a string like this for formatting:
(12071989).toString("MM-dd-yyyy");
```

Valid cases

```
(42).toString(2); // "101010" (binary)
(13).toString(8); // "15" (octal)
(0x42).toString(10); // "66" (decimal)
(100000).toString(16); // "186a0" (hexadecimal)
```

See also

- `Number.prototype.toString()`
- `BigInt.prototype.toString()`

SyntaxError: invalid regular expression flag "x"

The JavaScript exception "invalid regular expression flag" occurs when the flags in a regular expression contain any flag that is not one of: `d`, `g`, `i`, `m`, `s`, `u`, `v`, or `y`. It may also be raised if the expression contains more than one instance of a valid flag, or when the `u` and `v` flags are used together.

Message

```
SyntaxError: Invalid flags supplied to RegExp constructor 'x' (V8-based)
SyntaxError: Invalid regular expression flags (V8-based)
SyntaxError: invalid regular expression flag x (Firefox)
SyntaxError: Invalid flags supplied to RegExp constructor. (Safari)
SyntaxError: Invalid regular expression: invalid flags (Safari)
```

Error type

`SyntaxError`

What went wrong?

The regular expression contains invalid flags, or valid flags have been used more than once in the expression.

The valid (allowed) flags are `d`, `g`, `i`, `m`, `s`, `u`, `v`, and `y`. They are introduced in more detail in Regular expressions > Advanced searching with flags.

The `u` and `v` flags are mutually exclusive, so they cannot be used together. You can read the references to understand what their behavior differences are.

Examples

In a regular expression literal, which consists of a pattern enclosed between slashes, the flags are defined after the second slash. Regular expression flags can be used separately or together in any order. This syntax shows how to declare the flags using the regular expression literal:

```
const re = /pattern/flags;
```

They can also be defined in the constructor function of the `RegExp` object (second parameter):

```
const re = new RegExp("pattern", "flags");
```

Here is an example showing use of only correct flags.

```
/foo/g;
/foo/gims;
/foo/uy;
```

Below is an example showing the use of some invalid flags `b`, `a` and `r`:

```
/foo/bar;

// SyntaxError: invalid regular expression flag "b"
```

The code below is incorrect, because `W`, `e` and `b` are not valid flags.

```
const obj = {
  url: /docs/Web,
};

// SyntaxError: invalid regular expression flag "W"
```

An expression containing two slashes is interpreted as a regular expression literal. Most likely the intent was to create a string literal, using single or double quotes as shown below:

```
const obj = {
  url: "/docs/Web",
};
```

See also

- Regular expressions guide

SyntaxError: return not in function

The JavaScript exception "return not in function" occurs when a `return` statement is called outside of a function.

Message

```
SyntaxError: Illegal return statement (V8-based)
SyntaxError: return not in function (Firefox)
SyntaxError: Return statements are only valid inside functions. (Safari)
```

Error type

`SyntaxError`.

What went wrong?

A `return` statement is called outside of a function. Maybe there are missing curly braces somewhere? The `return` statement must be in a function, because it ends function execution and specifies a value to be returned to the function caller.

Examples

Missing curly braces

```
function cheer(score) {
  if (score === 147)
    return "Maximum!";
  }
  if (score > 100) {
    return "Century!";
  }
}

// SyntaxError: return not in function
```

The curly braces look correct at a first glance, but this code snippet is missing a `{` after the first `if` statement. Correct would be:

```
function cheer(score) {
  if (score === 147) {
    return "Maximum!";
  }
  if (score > 100) {
    return "Century!";
  }
}
```

See also

- `return`

SyntaxError: 'arguments'/'eval' can't be defined or assigned to in strict mode code

The JavaScript strict mode-only exception "'arguments' can't be defined or assigned to in strict mode code" or "'eval' can't be defined or assigned to in strict mode code" occurs when attempting to create a binding called `arguments` or `eval`, or assign to such a name.

Message

```
SyntaxError: Unexpected eval or arguments in strict mode (V8-based)
SyntaxError: 'arguments' can't be defined or assigned to in strict mode code (Firefox)
SyntaxError: Cannot modify 'arguments' in strict mode. (Safari)
SyntaxError: Cannot destructure to a parameter name 'arguments' in strict mode. (Safari)
SyntaxError: Cannot declare a variable named arguments in strict mode. (Safari)
SyntaxError: Cannot declare a catch variable named 'arguments' in strict mode. (Safari)
SyntaxError: 'arguments' is not a valid function name in strict mode. (Safari)
```

Error type

`SyntaxError`

What went wrong?

In strict mode, the names `arguments` and `eval` behave as if they are reserved words: you cannot make they refer to anything other than the `arguments` object in functions or the global `eval` function.

Examples

Invalid cases

```
"use strict";

const arguments = [1, 2, 3];
console.log(Math.max(...arguments));

function foo(...arguments) {
  console.log(arguments);
}
```

Valid cases

```
"use strict";

const args = [1, 2, 3];
console.log(Math.max(...args));

function foo(...args) {
  console.log(args);
}
```

SyntaxError: super() is only valid in derived class constructors

The JavaScript exception "super() is only valid in derived class constructors" occurs when the `super()` call is used somewhere that's not the body of a constructor in a class with `extends` keyword.

Message

```
SyntaxError: 'super' keyword unexpected here (V8-based)
SyntaxError: super() is only valid in derived class constructors (Firefox)
SyntaxError: super is not valid in this context. (Safari)
```

Error type

`SyntaxError`

What went wrong?

The `super()` call is used to invoke the base constructor of a derived class, so the base class can initialize the `this` object. Using it anywhere else doesn't make sense.

`super()` can also be defined in an arrow function that's nested within the constructor. However, it cannot be defined in any other kind of function.

Examples

Invalid cases

You cannot call `super()` if the class has no `extends`, because there's no base class to call:

```
class Base {
  constructor() {
    super();
  }
}
```

You cannot call `super()` in a class method, even if that method is called from the constructor:

```
class Base {}

class Derived extends Base {
  constructor() {
    this.init();
  }

  init() {
    super();
```

```
  }
}
```

You cannot call `super()` in a function, even if the function is used as a constructor:

```
function Base(x) {
  this.x = x;
}

function Derived() {
  super(1);
}

Object.setPrototypeOf(Derived.prototype, Base.prototype);
Object.setPrototypeOf(Derived, Base);
```

Valid cases

You can call `super()` before calling any other method in the constructor:

```
class Base {}

class Derived extends Base {
  constructor() {
    super();
    this.init();
  }

  init() {
    // …
  }
}
```

You can call `super()` in an arrow function that's nested within the constructor:

```
class Base {}

class Derived extends Base {
  constructor() {
    const init = () => {
      super();
    };

    init();
  }
}
```

- `super`

SyntaxError: use of super property/member accesses only valid within methods or eval code within methods

The JavaScript exception "use of super property/member accesses only valid within methods or eval code within methods" occurs when the `super.x` or `super[x]` syntax is used outside of a method.

Message

```
SyntaxError: 'super' keyword unexpected here (V8-based)
SyntaxError: use of super property accesses only valid within methods or eval code within methods (Firefox)
SyntaxError: super is not valid in this context. (Safari)
```

Error type

`SyntaxError`

What went wrong?

The `super.x` syntax is used to access properties on the prototype of the current object. It can be used in methods of both object literals and classes, field initializers, and static initialization blocks, but not in other contexts.

Examples

Invalid cases

You can't use `super.x` outside of a method in an object:

```
const obj = {
  __proto__: { x: 1 },
  x: super.x, // SyntaxError: use of super property accesses only valid within methods or eval code within methods
};
```

You can't use `super.x` in a function, even if that function has the effect of being a method:

```
function getX() {
  return super.x; // SyntaxError: use of super property accesses only valid within methods or eval code within methods
}

const obj = {
  getX,
  getX2: function () {
    return super.x; // SyntaxError: use of super property accesses only valid within methods or eval code within methods
  },
};

class Derived extends Base {
  getX = () => super.x;
}
```

Valid cases

You can use `super.x` in a method:

```
class Base {
  x = 1;
}

class Derived extends Base {
  getX() {
    return super.x;
  }
}
```

You can use `super.x` in a field initializer:

```
class Derived extends Base {
  x = super.x;
}
```

You can use `super.x` in object methods too:

```
const obj = {
  __proto__: { x: 1 },
  getX() {
    return super.x;
  },
};
```

See also

- `super`

RangeError: BigInt division by zero

The JavaScript exception "BigInt division by zero" occurs when a `BigInt` is divided by `0n`.

Message

```
RangeError: Division by zero (V8-based)
RangeError: BigInt division by zero (Firefox)
RangeError: 0 is an invalid divisor value. (Safari)
```

Error type

`RangeError`.

What went wrong?

The divisor of a division or remainder operator is `0n`. In `Number` arithmetic, this produces `Infinity`, but there's no "infinity value" in BigInts, so an error is issued. Check if the divisor is `0n` before doing the division.

Examples

Division by 0n

```
const a = 1n;
const b = 0n;
const quotient = a / b;
// RangeError: BigInt division by zero
```

Instead, check if the divisor is `0n` first, and either issue an error with a better message, or fall back to a different value, like `Infinity` or `undefined`.

```
const a = 1n;
const b = 0n;
const quotient = b === 0n ? undefined : a / b;
```

See also

- `BigInt`
- Division (`/`)
- Remainder (`%`)

RangeError: BigInt negative exponent

The JavaScript exception "BigInt negative exponent" occurs when a `BigInt` is raised to the power of a negative BigInt value.

Message

```
RangeError: Exponent must be positive (V8-based)
RangeError: BigInt negative exponent (Firefox)
RangeError: Negative exponent is not allowed (Safari)
```

Error type

`RangeError`.

What went wrong?

The exponent of an exponentiation operation must be positive. Since negative exponents would take the reciprocal of the base, the result will be between -1 and 1 in almost all cases, which gets rounded to `0n`. To catch mistakes, negative exponents are not allowed. Check if the exponent is non-negative before doing exponentiation.

Examples

Using a negative BigInt as exponent

```
const a = 1n;
const b = -1n;
const c = a ** b;
// RangeError: BigInt negative exponent
```

Instead, check if the exponent is negative first, and either issue an error with a better message, or fall back to a different value, like `0n` or `undefined`.

```
const a = 1n;
const b = -1n;
const quotient = b >= 0n ? a ** b : 0n;
```

See also

- `BigInt`
- Exponentiation (`**`)

TypeError: BigInt value can't be serialized in JSON

The JavaScript exception "BigInt value can't be serialized in JSON" occurs when a `BigInt` is encountered in `JSON.stringify` with no custom serialization method provided.

Message

```
TypeError: Do not know how to serialize a BigInt (V8-based)
TypeError: BigInt value can't be serialized in JSON (Firefox)
TypeError: JSON.stringify cannot serialize BigInt. (Safari)
```

Error type

`TypeError`

What went wrong?

You are trying to serialize a BigInt value using `JSON.stringify`, which does not support BigInt values by default. Sometimes, JSON stringification happens implicitly in libraries, as part of data serialization. For example, sending data to the server, storing it in external storage, or transferring it between threads would all require serialization, which is often done using JSON.

There are several ways to handle this:

- If you can alter the data source, avoid using BigInt values and cast it to a number first (which may lose precision for large numbers).
- If you can alter the stringification process, pass a replacer function to `JSON.stringify` that converts BigInt values to strings or numbers.
- You can also provide a `BigInt.prototype.toJSON` method globally that gets called whenever a BigInt value is stringified.

For more information on various tradeoffs, see BigInt reference.

Examples

Providing a custom serialization method

By default, BigInt values are not serializable in JSON:

```
const data = { a: 1n };
JSON.stringify(data);
// TypeError: BigInt value can't be serialized in JSON
```

Assuming you intend for the JSON to contain a number value, here are a few approaches that work:

- Convert the BigInt to a number before stringifying:

  ```
  const data = { a: 1n };
  JSON.stringify({ ...data, a: Number(data.a) });
  // '{"a":1}'
  ```

- Provide a replacer function that converts BigInt values to numbers or raw JSON objects:

  ```
  const data = { a: 1n };
  JSON.stringify(data, (key, value) =>
    typeof value === "bigint" ? Number(value) : value,
  );
  // '{"a":1}'
  ```

  ```
  const data = { a: 1n };
  JSON.stringify(data, (key, value) =>
    typeof value === "bigint" ? JSON.rawJSON(value.toString()) : value,
  );
  // '{"a":1}'
  ```

- Provide a `BigInt.prototype.toJSON` method that gets called whenever a BigInt value is stringified:

  ```
  BigInt.prototype.toJSON = function () {
    return Number(this);
  };
  const data = { a: 1n };
  JSON.stringify(data);
  // '{"a":1}'
  ```

  ```
  BigInt.prototype.toJSON = function () {
    return JSON.rawJSON(this.toString());
  };
  const data = { a: 1n };
  JSON.stringify(data);
  // '{"a":1}'
  ```

TypeError: calling a builtin X constructor without new is forbidden

The JavaScript exception "calling a builtin X constructor without new is forbidden" occurs when you try to call a builtin constructor without using the `new` keyword. All modern constructors, such as `Promise` and `Map`, must be called with `new`.

Message

```
TypeError: Constructor X requires 'new' (V8-based)
TypeError: Promise constructor cannot be invoked without 'new' (V8-based)
TypeError: calling a builtin X constructor without new is forbidden (Firefox)
TypeError: calling X constructor without new is invalid (Safari)
```

Error type

`TypeError`

What went wrong?

In JavaScript, *calling* a function without `new` and *constructing* a function with `new` are two distinct operations, and functions can behave differently depending on how they are called.

Apart from the following legacy constructors, all modern constructors must be called with `new`:

- `Object()`
- `Function()` (and its subclasses)
- `Error()` (and its subclasses)
- `RegExp()`
- `Array()`

Some other constructors, such as `Date()`, and primitive wrappers, such as `String()`, `Number()`, and `Boolean()`, can also be called with or without `new`, but the return types differ in the two cases.

On every constructor page, you can find information about whether the constructor must be called with `new`.

Examples

Invalid cases

```
const m = Map(); // TypeError: calling a builtin Map constructor without new is forbidden
```

Valid cases

```
const m = new Map();
```

See also

- `new`

TypeError: X.prototype.y called on incompatible type

The JavaScript exception "called on incompatible target (or object)" occurs when a function (on a given object), is called with a `this` not corresponding to the type expected by the function.

Message

```
TypeError: Method Set.prototype.add called on incompatible receiver undefined (V8-based)
TypeError: Bind must be called on a function (V8-based)
TypeError: Illegal invocation (V8-based)
TypeError: Function.prototype.toString requires that 'this' be a Function (V8-based)
TypeError: this is not a Date object. (V8-based)
TypeError: this is not a typed array. (V8-based)
TypeError: Function.prototype.toString called on incompatible object (Firefox)
TypeError: Function.prototype.bind called on incompatible target (Firefox)
TypeError: 'addEventListener' called on an object that does not implement interface EventTarget. (Firefox)
TypeError: Type error (Safari)
TypeError: undefined is not an object (Safari)
```

Error type

`TypeError`

What went wrong?

When this error is thrown, a function (on a given object), is called with a `this` not corresponding to the type expected by the function.

This issue can arise when using the `Function.prototype.call()` or `Function.prototype.apply()` methods, and providing a `this` argument which does not have the expected type.

This issue can also happen when providing a function that is stored as a property of an object as an argument to another function. In this case, the object that stores the function won't be the `this` target of that function when it is called by the other function. To work-around this issue, you will either need to wrap the callback function in another function, or use the `Function.prototype.bind()` method to force the `this` argument to the expected object.

Examples

Invalid cases

```
const mySet = new Set();
["bar", "baz"].forEach(mySet.add);
// mySet.add is a function, but "mySet" is not captured as this.

function myFun() {
  console.log(this);
}
["bar", "baz"].forEach(myFun.bind);
// myFun.bind is a function, but "myFun" is not captured as this.
```

Valid cases

```
const mySet = new Set();
["bar", "baz"].forEach(mySet.add.bind(mySet));
// This works due to binding "mySet" as this.

function myFun() {
  console.log(this);
}
["bar", "baz"].forEach((x) => myFun.bind(x));
// This works using the "bind" function. It creates a new function forwarding the argument.
```

ReferenceError: can't access lexical declaration 'X' before initialization

The JavaScript exception "can't access lexical declaration 'X' before initialization" occurs when a lexical variable was accessed before it was initialized. This happens within any scope (global, module, function, or block) when `let` or `const` variables are accessed before the place where they are declared is executed.

Message

```
ReferenceError: Cannot access 'X' before initialization (V8-based)
ReferenceError: can't access lexical declaration 'X' before initialization (Firefox)
ReferenceError: Cannot access uninitialized variable. (Safari)
```

Error type

`ReferenceError`

What went wrong?

A lexical variable was accessed before it was initialized. This happens within any scope (global, module, function, or block) when variables declared with `let` or `const` are accessed before the place where they are declared has been executed.

Note that it is the execution order of access and variable declaration that matters, not the order in which the statements appear in the code. For more information, see the description of Temporal Dead Zone.

This issue does not occur for variables declared using `var`, because they are initialized with a default value of `undefined` when they are hoisted.

This error can also occur in cyclic imports when a module uses a variable that depends on the module itself being evaluated.

Examples

Invalid cases

In this case, the variable `foo` is accessed before it is declared. At this point foo has not been initialized with a value, so accessing the variable throws a reference error.

```
function test() {
  // Accessing the 'const' variable foo before it's declared
  console.log(foo); // ReferenceError: foo is not initialized
  const foo = 33; // 'foo' is declared and initialized here using the 'const' keyword
}

test();
```

In this example, the imported variable `a` is accessed but is uninitialized, because the evaluation of `a.js` is blocked by the evaluation of the current module `b.js`.

```
// -- a.js (entry module) --
import { b } from "./b.js";

export const a = 2;

// -- b.js --
import { a } from "./a.js";

console.log(a); // ReferenceError: Cannot access 'a' before initialization
export const b = 1;
```

Valid cases

In the following example, we correctly declare a variable using the `const` keyword before accessing it.

```
function test() {
  // Declaring variable foo
  const foo = 33;
  console.log(foo); // 33
}
test();
```

In this example, the imported variable `a` is asynchronously accessed, so both modules are evaluated before the access to `a` occurs.

```
// -- a.js (entry module) --
import { b } from "./b.js";

export const a = 2;

// -- b.js --
import { a } from "./a.js";

setTimeout(() => {
  console.log(a); // 2
}, 10);
export const b = 1;
```

TypeError: can't assign to property "x" on "y": not an object

The JavaScript strict mode exception "can't assign to property" occurs when attempting to create a property on primitive value such as a symbol, a string, a number or a boolean. Primitive values cannot hold any property.

Message

```
TypeError: Cannot create property 'x' on number '1' (V8-based)
TypeError: can't assign to property "x" on 1: not an object (Firefox)
TypeError: Attempted to assign to readonly property. (Safari)
```

Error type

`TypeError`.

What went wrong?

In strict mode, a `TypeError` is raised when attempting to create a property on primitive value such as a symbol, a string, a number or a boolean. Primitive values cannot hold any property.

The problem might be that an unexpected value is flowing at an unexpected place, or that an object variant of a `String` or a `Number` is expected.

Examples

Invalid cases

```
"use strict";

const foo = "my string";
// The following line does nothing if not in strict mode.
foo.bar = {}; // TypeError: can't assign to property "bar" on "my string": not an object
```

Fixing the issue

Either fix the code to prevent the primitive from being used in such places, or fix the issue by creating the object equivalent `Object`.

```
"use strict";

const foo = new String("my string");
foo.bar = {};
```

See also

- Strict mode
- primitive

RangeError: x can't be converted to BigInt because it isn't an integer

The JavaScript exception "x can't be converted to BigInt because it isn't an integer" occurs when the `BigInt()` function is used on a number that isn't an integer.

Message

```
RangeError: The number 1.5 cannot be converted to a BigInt because it is not an integer (V8-based & Firefox)
RangeError: Not an integer (Safari)
```

Error type

`RangeError`.

What went wrong?

When using the `BigInt()` function to convert a number to a BigInt, the number must be an integer (such that `Number.isInteger` returns true).

Examples

Invalid cases

```
const a = BigInt(1.5);
// RangeError: The number 1.5 cannot be converted to a BigInt because it is not an integer
const b = BigInt(NaN);
// RangeError: NaN cannot be converted to a BigInt because it is not an integer
```

Valid cases

```
const a = BigInt(1);
```

See also

- `BigInt()` constructor
- `Number.isInteger()`

TypeError: can't convert BigInt to number

The JavaScript exception "can't convert BigInt to number" occurs when an arithmetic operation involves a mix of `BigInt` and `Number` values.

Message

```
TypeError: Cannot convert a BigInt value to a number (V8-based)
TypeError: Cannot mix BigInt and other types, use explicit conversions (V8-based)
TypeError: BigInts have no unsigned right shift, use >> instead (V8-based)
TypeError: can't convert BigInt to number (Firefox)
TypeError: Conversion from 'BigInt' to 'number' is not allowed. (Safari)
TypeError: Invalid mix of BigInt and other type in addition/multiplication/…. (Safari)
TypeError: BigInt does not support >>> operator (Safari)
```

Error type

`TypeError`.

What went wrong?

The two sides of an arithmetic operator must both be BigInts or both not. If an operation involves a mix of BigInts and numbers, it's ambiguous whether the result should be a BigInt or number, since there may be loss of precision in both cases.

The error also happens when a BigInt is implicitly converted to a number via the number coercion process. For example, if a BigInt is passed to a built-in method that expects a number.

The error can also happen if the unsigned right shift operator (`>>>`) is used between two BigInts. In Firefox, the message is the same: "can't convert BigInt to number".

Examples

Mixing numbers and BigInts in operations

```
const sum = 1n + 1;
// TypeError: can't convert BigInt to number
```

Instead, explicitly coerce one side to a BigInt or number.

```
const sum = 1n + BigInt(1);
const sum2 = Number(1n) + 1;
```

Using unsigned right shift on BigInts

```
const a = 4n >>> 2n;
// TypeError: can't convert BigInt to number
```

Use normal right shift instead.

```
const a = 4n >> 2n;
```

See also

- `BigInt`

TypeError: can't convert x to BigInt

The JavaScript exception "x can't be converted to BigInt" occurs when attempting to convert a `Symbol`, `null`, or `undefined` value to a `BigInt`, or if an operation expecting a BigInt parameter receives a number.

Message

```
TypeError: Cannot convert null to a BigInt (V8-based)
TypeError: can't convert null to BigInt (Firefox)
TypeError: Invalid argument type in ToBigInt operation (Safari)
```

Error type

`TypeError`.

What went wrong?

When using the `BigInt()` function to convert a value to a BigInt, the value would first be converted to a primitive. Then, if it's not one of BigInt, string, number, and boolean, the error is thrown.

Some operations, like `BigInt.asIntN`, require the parameter to be a BigInt. Passing in a number in this case will also throw this error.

Examples

Using BigInt() on invalid values

```
const a = BigInt(null);
// TypeError: can't convert null to BigInt
const b = BigInt(undefined);
// TypeError: can't convert undefined to BigInt
const c = BigInt(Symbol("1"));
// TypeError: can't convert Symbol("1") to BigInt
```

```
const a = BigInt(1);
const b = BigInt(true);
const c = BigInt("1");
const d = BigInt(Symbol("1").description);
```

> **Note:** Simply coercing the value to a string or number using `String()` or `Number()` before passing it to `BigInt()` is usually not sufficient to avoid all errors. If the string is not a valid integer number string, a SyntaxError is thrown; if the number is not an integer (most notably, `NaN`), a RangeError is thrown. If the range of input is unknown, properly validate it before using `BigInt()`.

Passing a number to a function expecting a BigInt

```
const a = BigInt.asIntN(4, 8);
// TypeError: can't convert 8 to BigInt
const b = new BigInt64Array(3).fill(3);
// TypeError: can't convert 3 to BigInt
```

```
const a = BigInt.asIntN(4, 8n);
const b = new BigInt64Array(3).fill(3n);
```

See also

- `BigInt()` constructor

TypeError: can't define property "x": "obj" is not extensible

The JavaScript exception "can't define property "x": "obj" is not extensible" occurs when an object is marked as non-extensible, so that it will never have properties beyond the ones it had at the time it was marked as non-extensible. Objects can be made non-extensible by calling `Object.preventExtensions()`, `Object.seal()`, or `Object.freeze()`.

Message

```
TypeError: Cannot add property x, object is not extensible (V8-based)
TypeError: Cannot define property x, object is not extensible (V8-based)
TypeError: can't define property "x": Object is not extensible (Firefox)
TypeError: Attempting to define property on object that is not extensible. (Safari)
```

Error type

`TypeError`

What went wrong?

Usually, an object is extensible and new properties can be added to it. However, in this case the object isn't extensible, so that it will never have properties beyond the ones it had at the time it was marked as non-extensible. You could have marked the object as non-extensible by calling `Object.preventExtensions()`, `Object.seal()`, or `Object.freeze()`, or a library you are using could have done that for you.

Examples

Adding new properties to a non-extensible objects

In strict mode, attempting to add new properties to a non-extensible object via assignment throws a `TypeError`. In sloppy mode, the addition of the "x" property is silently ignored.

```
"use strict";

const obj = {};
Object.preventExtensions(obj);

obj.x = "foo";
// TypeError: can't define property "x": Object is not extensible
```

In both strict mode and sloppy mode, a call to `Object.defineProperty()` throws when adding a new property to a non-extensible object.

```
const obj = {};
Object.preventExtensions(obj);

Object.defineProperty(obj, "x", { value: "foo" });
// TypeError: can't define property "x": Object is not extensible
```

Non-extensible objects created by other means

The `Object.seal()` and `Object.freeze()` methods also create non-extensible objects—they just have additional restrictions on modifying existing properties as well.

```
"use strict";

const obj = { y: "bar" };
Object.seal(obj);
obj.x = "foo";
// TypeError: can't define property "x": Object is not extensible
```

Fixing the error

There are three ways to fix this error: you can remove the property addition entirely if you don't need it, you can copy the existing properties to a new extensible object, or you can add the property before making the object non-extensible.

```
"use strict";

const obj = {};
obj.x = "foo"; // add property first and only then prevent extensions

Object.preventExtensions(obj);
```

See also

- `Object.preventExtensions()`
- `Object.seal()`
- `Object.freeze()`

TypeError: property "x" is non-configurable and can't be deleted

The JavaScript exception "property is non-configurable and can't be deleted" occurs when it was attempted to delete a property, but that property is non-configurable.

Message

```
TypeError: Cannot delete property 'x' of #<Object> (V8-based)
TypeError: property "x" is non-configurable and can't be deleted (Firefox)
TypeError: Unable to delete property. (Safari)
```

Error type

`TypeError` in strict mode only.

What went wrong?

It was attempted to delete a property, but that property is non-configurable. The `configurable` attribute controls whether the property can be deleted from the object and whether its attributes (other than `writable`) can be changed.

This error happens only in strict mode code. In non-strict code, the operation returns `false`.

Examples

Attempting to delete non-configurable properties

Non-configurable properties are not super common, but they can be created using `Object.defineProperty()` or `Object.freeze()`.

```
"use strict";
const obj = Object.freeze({ name: "Elsa", score: 157 });
delete obj.score; // TypeError
```

```
"use strict";
const obj = {};
Object.defineProperty(obj, "foo", { value: 2, configurable: false });
delete obj.foo; // TypeError
```

```
"use strict";
const frozenArray = Object.freeze([0, 1, 2]);
frozenArray.pop(); // TypeError
```

There are also a few non-configurable properties built into JavaScript. Maybe you tried to delete a mathematical constant.

```
"use strict";
delete Math.PI; // TypeError
```

See also

- `delete`
- `Object.defineProperty()`
- `Object.freeze()`

SyntaxError: private fields can't be deleted

The JavaScript exception "SyntaxError: private fields can't be deleted" occurs when `delete` is used on a private element of a class or an object.

Message

```
SyntaxError: Private fields can not be deleted (V8-based)
SyntaxError: private fields can't be deleted (Firefox)
SyntaxError: Cannot delete private field X (Safari)
```

Error type

`SyntaxError`

What went wrong?

There's code trying to `delete` a private element (field or method) of an object or a class. This is forbidden by JavaScript—private elements cannot be added or removed on the fly.

Examples

```
class MyClass {
  #myPrivateField;
  deleteIt() {
    delete this.#myPrivateField; // SyntaxError: private fields can't be deleted
  }
}
```

```
class MyClass {
  #myPrivateMethod() {
  }
  #deleteIt() {
    delete this.#myPrivateMethod; // SyntaxError: private fields can't be deleted
  }
}
```

See also

- Classes
- Private elements

TypeError: can't redefine non-configurable property "x"

The JavaScript exception "can't redefine non-configurable property" occurs when it was attempted to redefine a property, but that property is non-configurable.

Message

```
TypeError: Cannot redefine property: "x" (V8-based)
TypeError: can't redefine non-configurable property "x" (Firefox)
TypeError: Attempting to change value of a readonly property. (Safari)
```

Error type

`TypeError`

What went wrong?

It was attempted to redefine a property, but that property is non-configurable. The `configurable` attribute controls whether the property can be deleted from the object and whether its attributes (other than `writable`) can be changed. Usually, properties in an object created by an object initializer are configurable. However, for example, when using `Object.defineProperty()`, the property isn't configurable by default.

Examples

Non-configurable properties created by Object.defineProperty

The `Object.defineProperty()` creates non-configurable properties if you haven't specified them as configurable.

```
const obj = Object.create({});
Object.defineProperty(obj, "foo", { value: "bar" });

Object.defineProperty(obj, "foo", { value: "baz" });
// TypeError: can't redefine non-configurable property "foo"
```

You will need to set the "foo" property to configurable, if you intend to redefine it later in the code.

```
const obj = Object.create({});
Object.defineProperty(obj, "foo", { value: "bar", configurable: true });
Object.defineProperty(obj, "foo", { value: "baz", configurable: true });
```

See also

- [[Configurable]]
- `Object.defineProperty()`

TypeError: can't set prototype of this object

The JavaScript exception "can't set prototype of this object" occurs when attempting to set the prototype of an object, but the object's prototype is frozen, either by being a built-in immutable prototype object, or by being non-extensible.

Message

```
TypeError: Immutable prototype object 'Object.prototype' cannot have their prototype set (V8-based)
TypeError: #<Object> is not extensible (V8-based)
TypeError: can't set prototype of this object (Firefox)
TypeError: Cannot set prototype of immutable prototype object (Safari)
TypeError: Attempted to assign to readonly property. (Safari)
```

Error type

`TypeError`

What went wrong?

You are using one of the prototype-mutating methods—most notably, `Object.setPrototypeOf()`—on an object whose prototype is immutable. Some built-in objects have immutable prototypes, such as `Object.prototype` and `window`, for security reasons. User objects can also prevent prototype changes by using `Object.preventExtensions()`, `Object.seal()`, or `Object.freeze()`.

Examples

Changing the prototype of a built-in object

A selected few built-in objects have immutable prototypes. For example, you cannot change the prototype of `Object.prototype`:

```
Object.setPrototypeOf(Object.prototype, {});
```

This prevents you from being able to arbitrarily change the behavior of all objects in the system. The prototype of `Object.prototype` is always `null`. However, other built-in prototype objects, such as `Function.prototype` and `Array.prototype`, are not protected by default in this regard.

Changing the prototype of a non-extensible object

If you make an object non-extensible, you cannot change its prototype either:

```
const obj = {};
Object.preventExtensions(obj);
Object.setPrototypeOf(obj, {});
// TypeError: can't set prototype of this object
```

See also

- `Object.setPrototypeOf()`
- `Object.preventExtensions()`

SyntaxError: cannot use ?? unparenthesized within || and && expressions

The JavaScript exception "cannot use `??` unparenthesized within `||` and `&&` expressions" occurs when a nullish coalescing operator is used with a logical OR or logical AND in the same expression without parentheses.

Message

```
SyntaxError: Unexpected token '??' (V8-based)
SyntaxError: cannot use `??` unparenthesized within `||` and `&&` expressions (Firefox)
SyntaxError: Unexpected token '??'. Coalescing and logical operators used together in the same expression; parentheses must be used to disambiguate.
(Safari)
```

Error type

`SyntaxError`

What went wrong?

The operator precedence chain looks like this:

```
|   >   &&   >   ||   >   =
|   >   ??   >   =
```

However, the precedence *between* `??` and `&&`/`||` is intentionally undefined, because the short circuiting behavior of logical operators can make the expression's evaluation counter-intuitive. Therefore, the following combinations are all syntax errors, because the language doesn't know how to parenthesize the operands:

```
a ?? b || c;
a || b ?? c;
a ?? b && c;
a && b ?? c;
```

Instead, make your intent clear by parenthesizing either side explicitly:

```
(a ?? b) || c;
a ?? (b && c);
```

Examples

When migrating legacy code that uses `||` and `&&` for guarding against `null` or `undefined`, you may often convert it partially:

```
function getId(user, fallback) {
  // Previously: user && user.id || fallback
  return user && user.id ?? fallback; // SyntaxError: cannot use `??` unparenthesized within `||` and `&&` expressions
}
```

Instead, consider parenthesizing the `&&`:

```
function getId(user, fallback) {
  return (user && user.id) ?? fallback;
}
```

Even better, consider using optional chaining instead of `&&`:

```
function getId(user, fallback) {
  return user?.id ?? fallback;
}
```

TypeError: class constructors must be invoked with 'new'

The JavaScript exception "class constructors must be invoked with 'new'" occurs when a class constructor is called without the `new` keyword. All class constructors must be called with `new`.

Message

```
TypeError: Class constructor X cannot be invoked without 'new' (V8-based)
TypeError: Class constructors cannot be invoked without 'new' (V8-based)
TypeError: class constructors must be invoked with 'new' (Firefox)
TypeError: Cannot call a class constructor without |new| (Safari)
```

Error type

`TypeError`

What went wrong?

In JavaScript, *calling* a function without `new` and *constructing* a function with `new` are two distinct operations, and functions can behave differently depending on how they are called.

Traditionally, JavaScript functions have been used as both constructors and normal functions, and can detect how they were called using `new.target`. However, class constructors are always constructors and cannot be called as normal functions.

Examples

Invalid cases

```
class X {}

X(); // TypeError: class constructors must be invoked with 'new'
```

Valid cases

```
class X {}

new X();
```

See also

- Classes
- `new`

TypeError: Iterator/AsyncIterator constructor can't be used directly

The JavaScript exception "Iterator constructor can't be used directly" or "AsyncIterator constructor can't be used directly" occurs when you try to use the `Iterator()` or `AsyncIterator` constructors directly to create instances. These constructors are *abstract classes* and should only be inherited from.

Message

```
TypeError: Abstract class Iterator not directly constructable (V8-based)
TypeError: Iterator constructor can't be used directly (Firefox)
TypeError: Iterator cannot be constructed directly (Safari)
```

```
TypeError: Abstract class AsyncIterator not directly constructable (V8-based)
TypeError: AsyncIterator constructor can't be used directly (Firefox)
TypeError: AsyncIterator cannot be constructed directly (Safari)
```

Error type

`TypeError`

What went wrong?

The `Iterator` and `AsyncIterator` constructors are abstract classes and should not be used directly. They check the value of `new.target` and throw if it is the same as the constructor itself. The only way to use these constructors is to inherit from them in a subclass and call `super()` in the subclass constructor. The subclass must also define a `next()` method to be useful.

Examples

Invalid cases

```
new Iterator();
```

Valid cases

```
class MyIterator extends Iterator {
  #step;
  #end;
  constructor(start, end) {
    // Implicitly calls new Iterator(), but with a different `new.target`
    super();
    this.#step = start;
    this.#end = end;
  }
  next() {
    if (this.#step >= this.#end) {
      return { done: true };
    }
    return { value: this.#step++, done: false };
  }
}

new MyIterator();
```

See also

- `AsyncIterator`
- `Iterator`

TypeError: cyclic object value

The JavaScript exception "cyclic object value" occurs when object references were found in JSON. `JSON.stringify()` doesn't try to solve them and fails accordingly.

Message

```
TypeError: Converting circular structure to JSON (V8-based)
TypeError: cyclic object value (Firefox)
TypeError: JSON.stringify cannot serialize cyclic structures. (Safari)
```

Error type

`TypeError`

What went wrong?

The JSON format per se doesn't support object references (although an IETF draft exists), hence `JSON.stringify()` doesn't try to solve them and fails accordingly.

Examples

Circular references

In a circular structure like the following:

```
const circularReference = { otherData: 123 };
circularReference.myself = circularReference;
```

`JSON.stringify()` will fail

```
JSON.stringify(circularReference);
// TypeError: cyclic object value
```

To serialize circular references you can use a library that supports them (e.g., cycle.js) or implement a solution by yourself, which will require finding and replacing (or removing) the cyclic references by serializable values.

The snippet below illustrates how to find and filter (thus causing data loss) a cyclic reference by using the `replacer` parameter of `JSON.stringify()`:

```
function getCircularReplacer() {
  const ancestors = [];
  return function (key, value) {
    if (typeof value !== "object" || value === null) {
      return value;
    }
    // `this` is the object that value is contained in,
    // i.e., its direct parent.
    while (ancestors.length > 0 && ancestors.at(-1) !== this) {
      ancestors.pop();
    }
    if (ancestors.includes(value)) {
      return "[Circular]";
    }
    ancestors.push(value);
    return value;
  };
}

JSON.stringify(circularReference, getCircularReplacer());
// {"otherData":123,"myself":"[Circular]"}

const o = {};
const notCircularReference = [o, o];
JSON.stringify(notCircularReference, getCircularReplacer());
// [{},{}]
```

See also

- `JSON.stringify()`
- cycle.js on GitHub

TypeError: can't set prototype: it would cause a prototype chain cycle

The JavaScript exception "TypeError: can't set prototype: it would cause a prototype chain cycle" occurs when an object's prototype is set to an object such that the prototype chain becomes circular (`a` and `b` both have each other in their prototype chains).

Message

```
TypeError: Cyclic __proto__ value (V8-based)
TypeError: can't set prototype: it would cause a prototype chain cycle (Firefox)
TypeError: cyclic __proto__ value (Safari)
```

Error type

`TypeError`

What went wrong?

A loop, also called a cycle, was introduced in a prototype chain. That means that when walking this prototype chain, the same place would be accessed over and over again, instead of eventually reaching `null`.

This error is thrown at the time of setting the prototype. In an operation like `Object.setPrototypeOf(a, b)`, if `a` already exists in the prototype chain of `b`, this error will be thrown.

Examples

```
const a = {};
Object.setPrototypeOf(a, a);
// TypeError: can't set prototype: it would cause a prototype chain cycle
```

```
const a = {};
const b = {};
const c = {};
Object.setPrototypeOf(a, b);
Object.setPrototypeOf(b, c);
Object.setPrototypeOf(c, a);
// TypeError: can't set prototype: it would cause a prototype chain cycle
```

- Object Prototypes
- Inheritance and the prototype chain

SyntaxError: applying the 'delete' operator to an unqualified name is deprecated

The JavaScript strict mode-only exception "applying the 'delete' operator to an unqualified name is deprecated" occurs when variables are attempted to be deleted using the `delete` operator.

Message

```
SyntaxError: Delete of an unqualified identifier in strict mode. (V8-based)
SyntaxError: applying the 'delete' operator to an unqualified name is deprecated (Firefox)
```

```
SyntaxError: Cannot delete unqualified property 'a' in strict mode. (Safari)
```

Error type

`SyntaxError` in strict mode only.

What went wrong?

Normal variables in JavaScript can't be deleted using the `delete` operator. In strict mode, an attempt to delete a variable will throw an error and is not allowed.

The `delete` operator can only delete properties on an object. Object properties are "qualified" if they are configurable.

Unlike what common belief suggests, the `delete` operator has **nothing** to do with directly freeing memory. Memory management is done indirectly via breaking references, see the memory management page and the `delete` operator page for more details.

This error only happens in strict mode code. In non-strict code, the operation just returns `false`.

Examples

Freeing the contents of a variable

Attempting to delete a plain variable throws an error in strict mode:

```
"use strict";

var x;

// …

delete x;

// SyntaxError: applying the 'delete' operator to an unqualified name
// is deprecated
```

To free the contents of a variable, you can set it to `null`:

```
"use strict";

var x;

// …

x = null;

// x can be garbage collected
```

See also

- `delete`
- Memory management
- TypeError: property "x" is non-configurable and can't be deleted

TypeError: 'caller', 'callee', and 'arguments' properties may not be accessed

The JavaScript strict mode-only exception "'caller', 'callee', and 'arguments' properties may not be accessed on strict mode functions or the arguments objects for calls to them" occurs when the deprecated `arguments.callee`, `Function.prototype.caller`, or `Function.prototype.arguments` properties are used.

Message

```
TypeError: 'caller', 'callee', and 'arguments' properties may not be accessed on strict mode functions or the arguments objects for calls to them (V8-
based & Firefox)
TypeError: 'arguments', 'callee', and 'caller' cannot be accessed in this context. (Safari)
```

Error type

`TypeError` in strict mode only.

What went wrong?

In strict mode, the `arguments.callee`, `Function.prototype.caller`, or `Function.prototype.arguments` properties are used and shouldn't be. They are deprecated, because they leak the function caller, are non-standard, hard to optimize and potentially a performance-harmful feature.

Examples

Deprecated function.caller or arguments.callee

`Function.prototype.caller` and `arguments.callee` are deprecated (see the reference articles for more information).

```
"use strict";

function myFunc() {
  if (myFunc.caller === null) {
    return "The function was called from the top!";
```

```
  }
  return `This function's caller was ${myFunc.caller}`;
}

myFunc();
// TypeError: 'caller', 'callee', and 'arguments' properties may not be accessed on strict mode functions or the arguments objects for calls to them
```

Function.prototype.arguments

`Function.prototype.arguments` is deprecated (see the reference article for more information).

```
"use strict";

function f(n) {
  g(n - 1);
}

function g(n) {
  console.log(`before: ${g.arguments[0]}`);
  if (n > 0) {
    f(n);
  }
  console.log(`after: ${g.arguments[0]}`);
}

f(2);

console.log(`returned: ${g.arguments}`);
// TypeError: 'caller', 'callee', and 'arguments' properties may not be accessed on strict mode functions or the arguments objects for calls to them
```

SyntaxError: octal escape sequences can't be used in untagged template literals or in strict mode code

The JavaScript exception "octal escape sequences can't be used in untagged template literals or in strict mode code" occurs when octal escape sequences are used in strict mode string literals or untagged template literals.

Message

```
SyntaxError: Octal escape sequences are not allowed in strict mode. (V8-based)
SyntaxError: \8 and \9 are not allowed in strict mode. (V8-based)
SyntaxError: Octal escape sequences are not allowed in template strings. (V8-based)
SyntaxError: \8 and \9 are not allowed in template strings. (V8-based)
SyntaxError: octal escape sequences can't be used in untagged template literals or in strict mode code (Firefox)
SyntaxError: the escapes \8 and \9 can't be used in untagged template literals or in strict mode code (Firefox)
SyntaxError: The only valid numeric escape in strict mode is '\0' (Safari)
```

Error type

`SyntaxError`

What went wrong?

The string escape sequence of the form `\` followed by any number of digits, except a single `0`, is deprecated. If you want to represent a character by its code point value, you should use the `\x` or `\u` escape sequence instead, such as `\x01` or `\u0001` instead of `\1`.

Untagged template literals are never allowed to contain octal escape sequences, whether in strict mode or not. However, *tagged* template literals can contain any form of escape sequence, and will cause the template array received by the tag function to contain `undefined`.

Examples

Octal escape sequences

```
"use strict";

"\251";

// SyntaxError: octal escape sequences can't be used in untagged template literals or in strict mode code
```

Valid octal numbers

For octal escape sequences, you can use hexadecimal escape sequences instead:

```
"\xA9";
```

If you want to represent some source text literally without interpreting any escape sequence, use `String.raw`:

```
String.raw`\251`; // A string containing four characters
```

See also

- Lexical grammar

SyntaxError: "0"-prefixed octal literals are deprecated

The JavaScript strict mode-only exception "0-prefixed octal literals are deprecated; use the "0o" prefix instead" occurs when deprecated octal literals (`0` followed by digits) are used.

Message

```
SyntaxError: Octal literals are not allowed in strict mode. (V8-based)
SyntaxError: Decimals with leading zeros are not allowed in strict mode. (V8-based)
SyntaxError: Unexpected number (V8-based)
SyntaxError: "0"-prefixed octal literals are deprecated; use the "0o" prefix instead (Firefox)
SyntaxError: Decimal integer literals with a leading zero are forbidden in strict mode (Safari)
```

Error type

`SyntaxError` in strict mode only.

What went wrong?

Octal literals are deprecated. When you prefix a decimal integer with `0`, you actually change it to an octal literal, which may be surprising. The standardized syntax uses a leading zero followed by a lowercase or uppercase Latin letter "O" (`0o` or `0O`).

Leading zeros are always forbidden, even when the literal is not valid octal literal syntax (such as when the literal contains the digits `8` or `9`, or it has a decimal point). A number literal may only start with `0` if that 0 is its units place.

Examples

"0"-prefixed octal literals

```
"use strict";

03;

// SyntaxError: "0"-prefixed octal literals are deprecated; use the "0o" prefix instead
```

Valid octal numbers

Use a leading zero followed by the letter "o" or "O":

```
0o3;
```

See also

- Lexical grammar

SyntaxError: Using //@ to indicate sourceURL pragmas is deprecated. Use //# instead

The JavaScript warning "Using `//@` to indicate sourceURL pragmas is deprecated. Use `//#` instead" occurs when there is a deprecated source map syntax in a JavaScript source.

Message

```
Warning: SyntaxError: Using //@ to indicate sourceURL pragmas is deprecated. Use //# instead

Warning: SyntaxError: Using //@ to indicate sourceMappingURL pragmas is deprecated. Use //# instead
```

Error type

A warning that a `SyntaxError` occurred. JavaScript execution won't be halted.

What went wrong?

There is a deprecated source map syntax in a JavaScript source.

JavaScript sources are often combined and minified to make delivering them from the server more efficient. With source maps, the debugger can map the code being executed to the original source files.

The source map specification changed the syntax due to a conflict with IE whenever it was found in the page after `//@cc_on` was interpreted to turn on conditional compilation in the IE JScript engine. The conditional compilation comment in IE is a little known feature, but it broke source maps with jQuery and other libraries.

Examples

Deprecated syntax

Syntax with the "@" sign is deprecated.

```
//@ sourceMappingURL=http://example.com/path/to/your/sourcemap.map
```

Standard syntax

Use the "#" sign instead.

```
//# sourceMappingURL=http://example.com/path/to/your/sourcemap.map
```

Or, alternatively, you can set a `SourceMap` header to your JavaScript file to avoid having a comment at all:

```
SourceMap: /path/to/file.js.map
```

See also

- Use a source map in the Firefox source docs
- Introduction to JavaScript source maps on developer.chrome.com (2012)

SyntaxError: duplicate formal argument x

The JavaScript exception "duplicate formal argument x" or "duplicate argument names not allowed in this context" occurs when a function creates two or more parameter bindings with the same name, and the function is not a non-strict function with only simple parameters.

Message

```
SyntaxError: Duplicate parameter name not allowed in this context (V8-based)
SyntaxError: duplicate formal argument x (Firefox)
SyntaxError: duplicate argument names not allowed in this context (Firefox)
SyntaxError: Cannot declare a parameter named 'x' in strict mode as it has already been declared. (Safari)
SyntaxError: Duplicate parameter 'x' not allowed in function with default parameter values. (Safari)
SyntaxError: Duplicate parameter 'x' not allowed in function with a rest parameter. (Safari)
SyntaxError: Duplicate parameter 'x' not allowed in function with destructuring parameters. (Safari)
```

Error type

`SyntaxError`

What went wrong?

Having two formal parameters of the same name is likely a mistake—the second occurrence would cause the first occurrence to be inaccessible through the parameter name. In legacy JavaScript, this was allowed. Therefore, to not break existing code, this is only an error if the code is guaranteed to not be legacy—either because it is in strict mode or it uses modern parameter syntax (rest, default, or destructured parameters).

Examples

Invalid cases

```
"use strict";

function add(x, x) {
  // How can you access both "x" parameters?
  // SyntaxError: duplicate formal argument x
}
```

```
function doSomething(name, { name }) {
  // How can you access both "name" parameters?
  // SyntaxError: duplicate argument names not allowed in this context
}
```

Valid cases

```
function doSomething(operationName, { name: userName }) {
  // You can access both "operationName" and "userName" parameters.
}

function doSomething(name, user) {
  // You can access both "name" and "user.name" parameters.
}
```

- Functions
- Strict mode

SyntaxError: property name __proto__ appears more than once in object literal

The JavaScript exception "property name __proto__ appears more than once in object literal" occurs when an object literal contains multiple occurrences of the `__proto__` field, which is used to set the prototype of this new object.

Message

```
SyntaxError: Duplicate __proto__ fields are not allowed in object literals (V8-based)
SyntaxError: property name __proto__ appears more than once in object literal (Firefox)
SyntaxError: Attempted to redefine __proto__ property. (Safari)
```

Error type

`SyntaxError`

What went wrong?

The `__proto__` key, unlike other property keys, is a special syntax in an object literal. It is used to set the prototype of the object being created and is not allowed to appear more than once in an object literal. Note that this restriction only applies to the `__proto__` prototype setter syntax: if it actually has the effect of creating a property called `__proto__`, then it can appear multiple times. See prototype setter for the exact syntax restrictions.

Worth noting that the `__proto__` key in object literals is a special syntax and is not deprecated, unlike the `Object.prototype.__proto__` accessor property.

Examples

Invalid cases

```
const obj = { __proto__: {}, __proto__: { a: 1 } };
```

Valid cases

```
// Only setting the prototype once
const obj = { __proto__: { a: 1 } };

// These syntaxes all create a property called "__proto__" and can coexist
// They would overwrite each other and the last one is actually used
const __proto__ = null;
const obj2 = {
  ["__proto__"]: {},
  __proto__,
  __proto__() {},
  get __proto__() {
    return 1;
  },
};
```

See also

- Object initializer
- Inheritance and the prototype chain

SyntaxError: getter and setter for private name #x should either be both static or non-static

The JavaScript exception "mismatched placement" occurs when a private getter and setter are mismatched in whether or not they are `static`.

Message

```
SyntaxError: Identifier '#x' has already been declared (V8-based)
SyntaxError: getter and setter for private name #x should either be both static or non-static (Firefox)
SyntaxError: Cannot declare a private non-static getter if there is a static private setter with used name. (Safari)
```

Error type

`SyntaxError`

What went wrong?

Private getters and setters for the same name must either be both `static`, or both non-static. This limitation does not exist for public methods.

Examples

Mismatched placement

```
class Test {
  static set #foo(_) {}
  get #foo() {}
}

// SyntaxError: getter and setter for private name #foo should either be both static or non-static
```

Since `foo` is private, the methods must be either both `static`:

```
class Test {
  static set #foo(_) {}
  static get #foo() {}
}
```

or non-static:

```
class Test {
  set #foo(_) {}
  get #foo() {}
}
```

See also

- `get`
- `set`
- `static`

RangeError: form must be one of 'NFC', 'NFD', 'NFKC', or 'NFKD'

The JavaScript exception "form must be one of 'NFC', 'NFD', 'NFKC', or 'NFKD'" occurs when an unrecognized string is passed to the `String.prototype.normalize()` method.

Message

```
RangeError: The normalization form should be one of NFC, NFD, NFKC, NFKD. (V8-based)
RangeError: form must be one of 'NFC', 'NFD', 'NFKC', or 'NFKD' (Firefox)
RangeError: argument does not match any normalization form (Safari)
```

Error type

`RangeError`

What went wrong?

The `String.prototype.normalize()` method only accepts the following four values as its `form` argument: `"NFC"`, `"NFD"`, `"NFKC"`, or `"NFKD"`. If you pass any other value, an error will be thrown. Read the reference of `normalize()` to learn about different normalization forms.

Examples

Invalid cases

```
"foo".normalize("nfc"); // RangeError
"foo".normalize(" NFC "); // RangeError
```

Valid cases

```
"foo".normalize("NFC"); // 'foo'
```

See also

- `String.prototype.normalize()`

SyntaxError: functions cannot be labelled

The JavaScript exception "functions cannot be labelled" occurs when a `function` declaration has a label before it.

Message

```
SyntaxError: In non-strict mode code, functions can only be declared at top level, inside a block, or as the body of an if statement. (V8-based)
SyntaxError: In strict mode code, functions can only be declared at top level or inside a block. (V8-based)
SyntaxError: Generators can only be declared at the top level or inside a block. (V8-based)
SyntaxError: Async functions can only be declared at the top level or inside a block. (V8-based)

SyntaxError: functions can only be labelled inside blocks (Firefox)
SyntaxError: functions cannot be labelled (Firefox)
SyntaxError: generator functions cannot be labelled (Firefox)
SyntaxError: async function declarations can't appear in single-statement context (Firefox)

SyntaxError: Unexpected keyword 'function'. Function declarations are only allowed inside block statements or at the top level of a program. (Safari)
SyntaxError: Function declarations are only allowed inside blocks or switch statements in strict mode. (Safari)
SyntaxError: Unexpected token '*'. Cannot use generator function declaration in single-statement context. (Safari)
SyntaxError: Unexpected keyword 'function'. Cannot use async function declaration in single-statement context. (Safari)
```

Error type

`SyntaxError`

What went wrong?

Function declarations are never supposed to be labeled, because labels should only apply to statements, not declarations. There's no way to actually jump to this label. However, due to some legacy JavaScript syntax rules, the error condition is a bit more complicated than necessary:

- In strict mode, function declarations are never allowed to be labeled.
- In non-strict mode, function declarations are allowed to be labeled, but not when the function is the sole statement of an `if` statement (which itself is a deprecated feature).
- Async functions, generator functions, and async generator functions are never allowed to be labeled.

The error message may say something along the lines of "invalid place for a function declaration to appear", because when the parser sees a label, it expects a statement to follow, and a function declaration is not a statement. It depends on whether the error's perspective is that a label cannot be followed by a function, or that a function cannot be preceded by a label.

Examples

Misparsed object literal

While it's possible that you actually expect the label to do *something* along the lines of being a jump target, usually you didn't intend for it to be a label. The most common case is you actually want it to be a property key in an object literal:

```
const createObj = () => {
  greet: function greet() { // SyntaxError: functions cannot be labelled
    console.log("Hello");
  }
};
```

Here, `{...}` is actually not an object literal, but is instead the block body of the arrow function, so `greet:` becomes a label. To fix this, you need to wrap the object literal in parentheses:

```
const createObj = () => ({
  greet: function greet() {
    console.log("Hello");
  },
});
```

You may also want to use the method syntax for object literals, which avoids this pitfall:

```
const createObj = () => ({
  greet() {
    console.log("Hello");
  },
});
```

TypeError: can't access/set private field or method: object is not the right class

The JavaScript exception "can't access private field or method: object is not the right class" or "can't set private field: object is not the right class" occurs when a private field or method is get or set on an object that does not have this private element defined.

Message

```
TypeError: Cannot read private member #x from an object whose class did not declare it (V8-based)
TypeError: Cannot write private member #x to an object whose class did not declare it (V8-based)
TypeError: can't access private field or method: object is not the right class (Firefox)
TypeError: can't set private field: object is not the right class (Firefox)
TypeError: Cannot access invalid private field (evaluating 'this.#x') (Safari)
```

Error type

`TypeError`

What went wrong?

You are trying to get or set a private field or method on an object, but that object does not contain this private element. Private instance properties can only be accessed on instances of the class (including its subclasses) that declares them; private static properties can only be accessed on the class itself that declares them, and not on subclasses.

This error occurs when the private name exists in the class scope but the object it's accessed on is invalid. If the private name does not exist, you will get a syntax error instead.

Examples

Mismatched static/instance fields

You may have declared the field as a static field, but are trying to access it on an instance, or vice versa.

```
class MyClass {
  static #x = 0;
  doSomething() {
    console.log(this.#x);
  }
}

const obj = new MyClass();
```

```
obj.doSomething();
// TypeError: can't access private field: object is not the right class
```

To fix this, either change the field to be an instance field, or access the field on the class itself, or declare another field on the instance. Note that the private namespace is shared between static and instance properties, so you cannot have a static and instance private element with the same name.

```
class MyClass {
  #x = 0;
  doSomething() {
    console.log(this.#x);
  }
}

class MyClass2 {
  static #x = 0;
  doSomething() {
    console.log(MyClass2.#x);
  }
}
```

Wrong object used

Perhaps you have a method that access `this.#x`, but it is called with another `this` value.

```
class JSONReplacer {
  #count = 0;
  func(key, value) {
    if (typeof value === "object") {
      this.#count++;
    }
    return value;
  }
}

JSON.stringify({ a: 1, b: { c: 2 } }, new JSONReplacer().func);
// TypeError: can't access private field: object is not the right class
```

This is because `JSON.stringify()` calls the replacer function with the object containing `value` as `this`, so the private field is not accessible. To fix this, you can bind the method to the object, or use an arrow function, to ensure that `replacer.func` is called with the correct `this` value.

```
const replacer = new JSONReplacer();
JSON.stringify({ a: 1, b: { c: 2 } }, replacer.func.bind(replacer));
JSON.stringify({ a: 1, b: { c: 2 } }, (...args) => replacer.func(...args));
```

Most of the time, if you accidentally unbound a method, the method would be called with `undefined` as `this`, which would result in a different error (TypeError: can't convert undefined to object). This error only occurs when the method is called with a different object as `this`, either by using `call()` or `apply()`, or by passing the method as a callback to a function that calls it with a different `this` value.

If you don't know for sure that the object will contain the private element, as in the following code:

```
class MyClass {
  #x = 0;
  static doSomething(obj) {
    console.log(obj.#x); // Throws if obj is not an instance of MyClass
  }
}
```

You can use the `in` operator to perform a *branded check* first.

```
class MyClass {
  #x = 0;
  static doSomething(obj) {
    if (!(#x in obj)) {
      return;
    }
    console.log(obj.#x);
  }
}
```

Accessing static elements on subclasses

If you have a private static property, you can only access it on the class that declares it, not on subclasses.

```
class MyClass {
  static #x = 0;
  doSomething() {
    console.log(this.#x);
  }
}

class MySubClass extends MyClass {}
```

```
MySubClass.doSomething();
// TypeError: can't access private field: object is not the right class
```

To fix this, never access private static properties through `this`. Instead, always explicitly specify the class's name.

```
class MyClass {
  static #x = 0;
  doSomething() {
    console.log(MyClass.#x);
  }
}
```

Accessing same-name private elements on another class

Unlike normal string or symbol properties, private names are not shared between classes. If you have a private element with the same name in two classes, they are still not the same element, and you cannot access one class's private element from another class.

```
class MyClass {
  #x = 0;
}

class MyOtherClass {
  #x = 1;
  doSomething(o) {
    console.log(o.#x);
  }
}

const obj = new MyClass();
new MyOtherClass().doSomething(obj);
// TypeError: can't access private field: object is not the right class
```

Adding private elements to unrelated objects

You cannot dynamically *add* private elements to unrelated objects.

```
class MyClass {
  #x = 0;
  static stamp(obj) {
    obj.#x = 1;
  }
}

MyClass.stamp({});
// TypeError: can't set private field: object is not the right class
```

If you really want to do this, consider the return override trick. However, in general, you would probably want to use a `WeakMap` instead.

```
class MyClass {
  static #objToX = new WeakMap();
  static stamp(obj) {
    MyClass.#objToX.set(obj, 1);
  }
}

MyClass.stamp({});
```

SyntaxError: getter functions must have no arguments

The JavaScript exception "getter functions must have no arguments" occurs when a getter is declared and the parameter list is non-empty.

Message

```
SyntaxError: Getter must not have any formal parameters. (V8-based)
SyntaxError: getter functions must have no arguments (Firefox)
SyntaxError: Unexpected identifier 'x'. getter functions must have no parameters. (Safari)
```

Error type

`SyntaxError`

What went wrong?

The `get` property syntax looks like a function, but it is stricter and not all function syntax is allowed. A getter is always invoked with no arguments, so defining it with any parameter is likely an error.

Note that this error only applies to property getters using the `get` syntax. If you define the getter using `Object.defineProperty()`, etc., the getter is defined as a normal function, although it's likely still an error if the getter expects any arguments, as it will be called without any.

Examples

Invalid cases

```
const obj = {
  get value(type) {
    return type === "string" ? String(Math.random()) : Math.random();
  },
};
```

Valid cases

```
// Remove the parameter
const obj = {
  get value() {
    return Math.random();
  },
};

// Use a normal method, if you need a parameter
const obj = {
  getValue(type) {
    return type === "string" ? String(Math.random()) : Math.random();
  },
};
```

- `get`

TypeError: setting getter-only property "x"

The JavaScript strict mode-only exception "setting getter-only property" occurs when there is an attempt to set a new value to a property for which only a getter is specified, or when setting a private accessor property that similarly only has a getter defined.

Message

```
TypeError: Cannot set property x of #<Object> which has only a getter (V8-based)
TypeError: '#x' was defined without a setter (V8-based)
TypeError: setting getter-only property "x" (Firefox)
TypeError: Attempted to assign to readonly property. (Safari)
TypeError: Trying to access an undefined private setter (Safari)
```

Error type

`TypeError` in strict mode only.

What went wrong?

There is an attempt to set a new value to a property for which only a getter is specified. While this will be silently ignored in non-strict mode, it will throw a `TypeError` in strict mode. Classes are always in strict mode, so assigning to a getter-only private element always throws this error.

Examples

Property with no setter

The example below shows how to set a getter for a property. It doesn't specify a setter, so a `TypeError` will be thrown upon trying to set the `temperature` property to `30`. For more details see also the `Object.defineProperty()` page.

```
"use strict";

function Archiver() {
  const temperature = null;
  Object.defineProperty(this, "temperature", {
    get() {
      console.log("get!");
      return temperature;
    },
  });
}

const arc = new Archiver();
arc.temperature; // 'get!'

arc.temperature = 30;
// TypeError: setting getter-only property "temperature"
```

To fix this error, you will either need to remove the `arc.temperature = 30` line, which attempts to set the temperature property, or you will need to implement a setter for it, for example like this:

```
"use strict";
```

```
function Archiver() {
  let temperature = null;
  const archive = [];

  Object.defineProperty(this, "temperature", {
    get() {
      console.log("get!");
      return temperature;
    },
    set(value) {
      temperature = value;
      archive.push({ val: temperature });
    },
  });

  this.getArchive = function () {
    return archive;
  };
}

const arc = new Archiver();
arc.temperature; // 'get!'
arc.temperature = 11;
arc.temperature = 13;
arc.getArchive(); // [{ val: 11 }, { val: 13 }]
```

SyntaxError: Unexpected '#' used outside of class body

The JavaScript exception "Unexpected '#' used outside of class body" occurs when a hash ("#") is encountered in an unexpected context, most notably outside of a class declaration. Hashes are valid at the beginning of a file as a hashbang comment, or inside of a class as part of a private field. You may encounter this error if you forget the quotation marks when trying to access a DOM identifier as well.

Message

```
SyntaxError: Unexpected '#' used outside of class body.
```

Error type

`SyntaxError`

What went wrong?

We encountered a `#` somewhere unexpected. This may be due to code moving around and no longer being part of a class, a hashbang comment found on a line other than the first line of a file, or accidentally forgetting the quotation marks around a DOM identifier.

Examples

Missing quotation marks

For each case, there might be something slightly wrong. For example

```
document.querySelector(#some-element)
```

This can be fixed via

```
document.querySelector("#some-element");
```

Outside of a class

```
class ClassWithPrivateField {
  #privateField;

  constructor() {}
}

this.#privateField = 42;
```

This can be fixed by moving the private field back into the class

```
class ClassWithPrivateField {
  #privateField;

  constructor() {
    this.#privateField = 42;
  }
}
```

SyntaxError: identifier starts immediately after numeric literal

The JavaScript exception "identifier starts immediately after numeric literal" occurs when an identifier started with a digit. Identifiers can only start with a letter, underscore (_), or dollar sign ($).

Message

```
SyntaxError: Invalid or unexpected token (V8-based)
SyntaxError: identifier starts immediately after numeric literal (Firefox)
SyntaxError: No identifiers allowed directly after numeric literal (Safari)
```

Error type

`SyntaxError`

What went wrong?

The names of variables, called identifiers, conform to certain rules, which your code must adhere to!

A JavaScript identifier must start with a letter, underscore (_), or dollar sign ($). They can't start with a digit! Only subsequent characters can be digits (0-9).

Examples

Variable names starting with numeric literals

Variable names can't start with numbers in JavaScript. The following fails:

```
const 1life = "foo";
// SyntaxError: identifier starts immediately after numeric literal

const foo = 1life;
// SyntaxError: identifier starts immediately after numeric literal
```

You will need to rename your variable to avoid the leading number.

```
const life1 = "foo";
const foo = life1;
```

In JavaScript, there is a syntactic peculiarity when calling properties or methods on numbers. If you want to call a method on an integer, you cannot immediately use a dot after the number because the dot is interpreted as the start of a decimal fraction, causing the parser to see the method's name as an identifier immediately after a number literal. To avoid this, you need to either wrap the number in parentheses or use a double dot, where the first dot is a decimal point for the number literal and the second dot is the property accessor.

```
alert(typeof 1.toString())
// SyntaxError: identifier starts immediately after numeric literal
```

Correct ways to call methods on numbers:

```
// Wrap the number in parentheses
alert(typeof (1).toString());

// Add an extra dot for the number literal
alert(typeof 2..toString());

// Use square brackets
alert(typeof 3["toString"]());
```

SyntaxError: illegal character

The JavaScript exception "illegal character" occurs when the lexer reads a character that's not part of a string literal, and the character cannot constitute a valid token in the language.

Message

```
SyntaxError: Invalid or unexpected token (V8-based)
SyntaxError: illegal character U+201C (Firefox)
SyntaxError: Invalid character '\u201c' (Safari)
```

Error type

`SyntaxError`

What went wrong?

There is an invalid character that the interpreter doesn't understand. You should either put it in a string literal or replace it with another character. Use an editor that supports syntax highlighting and carefully check your code against mismatches like a minus sign (-) versus a dash (–) or simple quotes (") versus non-standard quotation marks (“).

Examples

Mismatched characters

Some characters look similar, but will cause the parser to fail interpreting your code. Famous examples of this are quotes, the minus or semicolon (greek question mark (U+37e) looks same).

```
“This looks like a string”; // SyntaxError: illegal character
// “ and ” are not " but look like it

42 – 13; // SyntaxError: illegal character
// – (en-dash) is not - but looks like it

const foo = "bar"; // SyntaxError: illegal character
// <37e> is not ; but looks like it
```

This should work:

```
"This is actually a string";
42 - 13;
const foo = "bar";
```

Some editors and IDEs will notify you or at least use a slightly different highlighting for it, but not all. When something like this happens to your code and you're not able to find the source of the problem, it's often best to just delete the problematic line and retype it.

Forgotten characters

It's easy to forget a character here or there.

```
const operators = ["+", "-", ×", "÷"];
// SyntaxError: illegal character U+00D7
```

Add the missing quote for `"×"`.

```
const operators = ["+", "-", "×", "÷"];
```

Hidden characters

When copy pasting code from external sources, there might be invalid characters. Watch out!

```
const foo = "bar";
// SyntaxError: illegal character
```

When inspecting this code in an editor like VIM, you can see that there is actually a zero-width space (ZWSP) (U+200B) character.

```
const foo = "bar";<200b>
```

SyntaxError: import declarations may only appear at top level of a module

The JavaScript exception "import declarations may only appear at top level of a module" occurs when an import declaration is not at the top level of a module. This might be because the import declaration is nested in other constructs (functions, blocks, etc.), or more often because the current file is not treated as a module.

Message

```
SyntaxError: Cannot use import statement outside a module (V8-based)
SyntaxError: import declarations may only appear at top level of a module (Firefox)
SyntaxError: Unexpected identifier 'x'. import call expects one or two arguments. (Safari)
```

Error type

`SyntaxError`

What went wrong?

You may have an `import` declaration that's nested in another construct, such as a function or a block. The `import` declaration must be at the top level of the module. If you want to conditionally import a module, or lazily import it on demand, use dynamic import instead.

If the `import` is already at the top level of the code, it may be because the file is not interpreted as a module. Runtimes require external hints to determine whether a file is a module or not, and here are several ways to provide such hints:

- If the file is directly loaded from HTML, make sure the `<script>` tag has the `type="module"` attribute.
- If the file is run in Node, make sure either the file has the `.mjs` extension, or the closest `package.json` file has the `"type": "module"` field.
- If the file is run as a worker, make sure you call the `Worker()` constructor with the `type: "module"` option.

- Import this file from another module.

One other cause might be when you are writing `import` with a compiler (such as TypeScript) and you accidentally ran the source file. Since `import` declarations usually appear at the very start of the program, they are the first thing the parser sees and then complains about. Make sure to compile the source file and execute the compiled file instead.

Examples

Conditional imports

You cannot use `import` inside other constructs, like you might do in Python.

```
if (writeOutput) {
  import fs from "fs"; // SyntaxError
}
```

Either move the `import` to the top level, or use dynamic import.

```
if (writeOutput) {
  import("fs").then((fs) => {
    // use fs
  });
}
```

Importing in a non-module script

If you are loading the script from HTML, make sure to add the `type="module"` attribute to the `<script>` tag.

```
<script type="module" src="https://developer.mozilla.org/en-US/docs/Web/JavaScript/Reference/Errors/import_decl_module_top_level/main.js"></script>
```

If for some reason you cannot migrate the script to a module, you can use dynamic import.

```
async function main() {
  const myModule = await import("./my-module.js");
  // use myModule
}

main();
```

TypeError: cannot use 'in' operator to search for 'x' in 'y'

The JavaScript exception "right-hand side of 'in' should be an object" occurs when the `in` operator was used to search in strings, or in numbers, or other primitive types. It can only be used to check if a property is in an object.

Message

```
TypeError: Cannot use 'in' operator to search for 'x' in 'y' (V8-based & Firefox)
TypeError: right-hand side of 'in' should be an object, got null (Firefox)
TypeError: "y" is not an Object. (evaluating '"x" in "y"') (Safari)
```

Error type

`TypeError`

What went wrong?

The `in` operator can only be used to check if a property is in an object. You can't search in strings, or in numbers, or other primitive types.

Examples

Searching in strings

Unlike in other programming languages (e.g., Python), you can't search in strings using the `in` operator.

```
"Hello" in "Hello World";
// TypeError: cannot use 'in' operator to search for 'Hello' in 'Hello World'
```

Instead you will need to use `String.prototype.includes()`, for example.

```
"Hello World".includes("Hello");
// true
```

The operand can't be null or undefined

Make sure the object you are inspecting isn't actually `null` or `undefined`.

```
const foo = null;
"bar" in foo;
// TypeError: cannot use 'in' operator to search for 'bar' in 'foo' (Chrome)
// TypeError: right-hand side of 'in' should be an object, got null (Firefox)
```

The `in` operator always expects an object.

```
const foo = { baz: "bar" };
"bar" in foo; // false

"PI" in Math; // true
"pi" in Math; // false
```

Searching in arrays

Be careful when using the `in` operator to search in `Array` objects. The `in` operator checks the index number, not the value at that index.

```
const trees = ["redwood", "bay", "cedar", "oak", "maple"];
3 in trees; // true
"oak" in trees; // false
```

See also

- `in`

RangeError: invalid array length

The JavaScript exception "Invalid array length" occurs when specifying an array length that is either negative, a floating number or exceeds the maximum supported by the platform (i.e., when creating an `Array` or `ArrayBuffer`, or when setting the `length` property).

The maximum allowed array length depends on the platform, browser and browser version. For `Array` the maximum length is 2^{32}-1. For `ArrayBuffer` the maximum is 2^{31}-1 (2GiB-1) on 32-bit systems. From Firefox version 89 the maximum value of `ArrayBuffer` is 2^{33} (8GiB) on 64-bit systems.

> **Note:** `Array` and `ArrayBuffer` are independent data structures (the implementation of one does not affect the other).

Message

```
RangeError: invalid array length (V8-based & Firefox)
RangeError: Array size is not a small enough positive integer. (Safari)

RangeError: Invalid array buffer length (V8-based)
RangeError: length too large (Safari)
```

Error type

`RangeError`

What went wrong?

The error might appear when attempting to produce an `Array` or `ArrayBuffer` with an invalid length, which includes:

- Negative length, via the constructor or setting the `length` property.
- Non-integer length, via the constructor or setting the `length` property. (The `ArrayBuffer` constructor coerces the length to an integer, but the `Array` constructor does not.)
- Exceeding the maximum length supported by the platform. For arrays, the maximum length is 2^{32}-1. For `ArrayBuffer`, the maximum length is 2^{31}-1 (2GiB-1) on 32-bit systems, or 2^{33} (8GiB) on 64-bit systems. This can happen via the constructor, setting the `length` property, or array methods that implicitly set the length property (such as `push` and `concat`).

If you are creating an `Array` using the constructor, you probably want to use the literal notation instead, as the first argument is interpreted as the length of the `Array`. Otherwise, you might want to clamp the length before setting the length property, or using it as an argument of the constructor.

Examples

Invalid cases

```
new Array(2 ** 40);
new Array(-1);
new ArrayBuffer(2 ** 32); // 32-bit system
new ArrayBuffer(-1);

const a = [];
a.length -= 1; // set the length property to -1

const b = new Array(2 ** 32 - 1);
b.length += 1; // set the length property to 2^32
b.length = 2.5; // set the length property to a floating-point number

const c = new Array(2.5); // pass a floating-point number

// Concurrent modification that accidentally grows the array infinitely
```

```
const arr = [1, 2, 3];
for (const e of arr) {
  arr.push(e * 10);
}
```

Valid cases

```
[2 ** 40]; // [ 1099511627776 ]
[-1]; // [ -1 ]
new ArrayBuffer(2 ** 31 - 1);
new ArrayBuffer(2 ** 33); // 64-bit systems after Firefox 89
new ArrayBuffer(0);

const a = [];
a.length = Math.max(0, a.length - 1);

const b = new Array(2 ** 32 - 1);
b.length = Math.min(0xffffffff, b.length + 1);
// 0xffffffff is the hexadecimal notation for 2^32 - 1
// which can also be written as (-1 >>> 0)

b.length = 3;

const c = new Array(3);

// Because array methods save the length before iterating, it is safe to grow
// the array during iteration
const arr = [1, 2, 3];
arr.forEach((e) => arr.push(e * 10));
```

See also

- `Array`
- `length`
- `ArrayBuffer`

SyntaxError: invalid assignment left-hand side

The JavaScript exception "invalid assignment left-hand side" occurs when there was an unexpected assignment somewhere. It may be triggered when a single `=` sign was used instead of `==` or `===`.

Message

```
SyntaxError: Invalid left-hand side in assignment (V8-based)
SyntaxError: invalid assignment left-hand side (Firefox)
SyntaxError: Left side of assignment is not a reference. (Safari)

ReferenceError: Invalid left-hand side in assignment (V8-based)
ReferenceError: cannot assign to function call (Firefox)
ReferenceError: Left side of assignment is not a reference. (Safari)
```

Error type

`SyntaxError` or `ReferenceError`, depending on the syntax.

What went wrong?

There was an unexpected assignment somewhere. This might be due to a mismatch of an assignment operator and an equality operator, for example. While a single `=` sign assigns a value to a variable, the `==` or `===` operators compare a value.

Examples

Typical invalid assignments

```
if (Math.PI + 1 = 3 || Math.PI + 1 = 4) {
  console.log("no way!");
}
// SyntaxError: invalid assignment left-hand side

const str = "Hello, "
+= "is it me "
+= "you're looking for?";
// SyntaxError: invalid assignment left-hand side
```

In the `if` statement, you want to use an equality operator (`===`), and for the string concatenation, the plus (`+`) operator is needed.

```
if (Math.PI + 1 === 3 || Math.PI + 1 === 4) {
  console.log("no way!");
}

const str = "Hello, "
  + "from the "
  + "other side!";
```

Assignments producing ReferenceErrors

Invalid assignments don't always produce syntax errors. Sometimes the syntax is almost correct, but at runtime, the left-hand side expression evaluates to a *value* instead of a *reference*, so the assignment is still invalid. Such errors occur later in execution, when the statement is actually executed.

```
function foo() {
  return { a: 1 };
}
foo() = 1; // ReferenceError: invalid assignment left-hand side
```

Function calls, `new` calls, `super()`, and `this` are all values instead of references. If you want to use them on the left-hand side, the assignment target needs to be a property of their produced values instead.

```
function foo() {
  return { a: 1 };
}
foo().a = 1;
```

> **Note:** In Firefox and Safari, the first example produces a `ReferenceError` in non-strict mode, and a `SyntaxError` in strict mode. Chrome throws a runtime `ReferenceError` for both strict and non-strict modes.

Using optional chaining as assignment target

Optional chaining is not a valid target of assignment.

```
obj?.foo = 1; // SyntaxError: invalid assignment left-hand side
```

Instead, you have to first guard the nullish case.

```
if (obj) {
  obj.foo = 1;
}
```

- Assignment operators
- Equality operators

SyntaxError: invalid BigInt syntax

The JavaScript exception "invalid BigInt syntax" occurs when a string value is being coerced to a `BigInt` but it failed to be parsed as an integer.

Message

```
SyntaxError: Cannot convert x to a BigInt (V8-based)
SyntaxError: invalid BigInt syntax (Firefox)
SyntaxError: Failed to parse String to BigInt (Safari)
```

Error type

`SyntaxError`.

What went wrong?

When using the `BigInt()` function to convert a string to a BigInt, the string will be parsed in the same way as source code, and the resulting value must be an integer value.

Examples

Invalid cases

```
const a = BigInt("1.5");
const b = BigInt("1n");
const c = BigInt.asIntN(4, "8n");
// SyntaxError: invalid BigInt syntax
```

Valid cases

```
const a = BigInt("1");
const b = BigInt("  1   ");
const c = BigInt.asIntN(4, "8");
```

See also

- `BigInt`

TypeError: invalid assignment to const "x"

The JavaScript exception "invalid assignment to const" occurs when it was attempted to alter a constant value. JavaScript `const` declarations can't be re-assigned or redeclared.

Message

```
TypeError: Assignment to constant variable. (V8-based)
TypeError: invalid assignment to const 'x' (Firefox)
TypeError: Attempted to assign to readonly property. (Safari)
```

Error type

`TypeError`

What went wrong?

A constant is a value that cannot be altered by the program during normal execution. It cannot change through re-assignment, and it can't be redeclared. In JavaScript, constants are declared using the `const` keyword.

Examples

Invalid redeclaration

Assigning a value to the same constant name in the same block-scope will throw.

```
const COLUMNS = 80;

// …

COLUMNS = 120; // TypeError: invalid assignment to const `COLUMNS'
```

Fixing the error

There are multiple options to fix this error. Check what was intended to be achieved with the constant in question.

Rename

If you meant to declare another constant, pick another name and re-name. This constant name is already taken in this scope.

```
const COLUMNS = 80;
const WIDE_COLUMNS = 120;
```

const, let or var?

Do not use const if you weren't meaning to declare a constant. Maybe you meant to declare a block-scoped variable with `let` or global variable with `var`.

```
let columns = 80;

// …

columns = 120;
```

Scoping

Check if you are in the correct scope. Should this constant appear in this scope or was it meant to appear in a function, for example?

```
const COLUMNS = 80;

function setupBigScreenEnvironment() {
  const COLUMNS = 120;
}
```

const and immutability

The `const` declaration creates a read-only reference to a value. It does **not** mean the value it holds is immutable, just that the variable identifier cannot be reassigned. For instance, in case the content is an object, this means the object itself can still be altered. This means that you can't mutate the value stored in a variable:

```
const obj = { foo: "bar" };
obj = { foo: "baz" }; // TypeError: invalid assignment to const `obj'
```

But you can mutate the properties in a variable:

```
obj.foo = "baz";
obj; // { foo: "baz" }
```

RangeError: invalid date

The JavaScript exception "invalid date" occurs when an invalid date is attempted to be converted to an ISO date string.

Message

```
RangeError: Invalid time value (V8-based)
RangeError: invalid date (Firefox)
RangeError: Invalid Date (Safari)
```

Error type

`RangeError`

What went wrong?

You are converting an invalid date value to an ISO date string by calling the `toISOString()` method.

An *invalid date* is produced when you attempt to parse an invalid date string, or set the timestamp to an out-of-bounds value. Invalid dates usually cause all date methods to return `NaN` or other special values. However, such dates do not have valid ISO string representations, so an error is thrown when you attempt to do so.

> **Note:** `toJSON()` does not throw this error. It checks whether the date is finite before formatting it, and returns `null` for an invalid date instead of calling `toISOString()`. `JSON.stringify()`, which calls `toJSON()`, therefore serializes an invalid date as `null` rather than throwing.

Examples

Invalid cases

```
const invalid = new Date("nothing");
invalid.toISOString(); // RangeError: invalid date
```

However, most other methods return special values:

```
invalid.toString(); // "Invalid Date"
invalid.getDate(); // NaN
invalid.toJSON(); // null
JSON.stringify({ date: invalid }); // '{"date":null}'
```

For more details, see the `Date.parse()` documentation.

Valid cases

```
new Date("05 October 2011 14:48 UTC").toISOString(); // "2011-10-05T14:48:00.000Z"
new Date(1317826080).toISOString(); // "2011-10-05T14:48:00.000Z"
```

See also

- `Date`
- `Date.prototype.parse()`
- `Date.prototype.toISOString()`

TypeError: derived class constructor returned invalid value x

The JavaScript exception "derived class constructor returned invalid value x" occurs when a derived class constructor returns a value that is not an object or `undefined`.

Message

```
TypeError: Derived constructors may only return object or undefined (V8-based)
TypeError: derived class constructor returned invalid value 1 (Firefox)
TypeError: Cannot return a non-object type in the constructor of a derived class. (Safari)
```

Error type

`TypeError`

What went wrong?

Typically, a constructor does not need to return anything—the value of `this` is automatically returned when the class is constructed. A constructor can also return an object, and this object will override `this` as the newly constructed instance. However, returning something that's neither an object nor `undefined` is usually a mistake, because that value is ignored. In base classes and function constructors (using the `function` syntax), returning such a value is silently ignored, while in derived classes, it throws an error.

Examples

Invalid cases

```
class Base {
  constructor() {}
}

class Derived extends Base {
  constructor() {
    return 2;
```

```
  }
}

new Derived(); // TypeError: derived class constructor returned invalid value 2
```

Valid cases

```
class Base {
  constructor() {}
}

class Derived extends Base {
  constructor() {
    return { x: 1 };
  }
}

new Derived(); // { x: 1 }
```

- `new`

SyntaxError: for-in loop head declarations may not have initializers

The JavaScript strict mode-only exception "for-in loop head declarations may not have initializers" occurs when the head of a for...in contains an initializer expression, such as `for (var i = 0 in obj)`. This is not allowed in for-in loops in strict mode. In addition, lexical declarations with initializers like `for (const i = 0 in obj)` are not allowed outside strict mode either.

Message

```
SyntaxError: for-in loop variable declaration may not have an initializer. (V8-based)
SyntaxError: for-in loop head declarations may not have initializers (Firefox)
SyntaxError: a lexical declaration in the head of a for-in loop can't have an initializer (Firefox)
SyntaxError: Cannot assign to the loop variable inside a for-in loop header. (Safari)
```

Error type

`SyntaxError`.

What went wrong?

The head of a for...in loop contains an initializer expression. That is, a variable is declared and assigned a value `for (var i = 0 in obj)`. In non-strict mode, this head declaration is silently ignored and behaves like `for (var i in obj)`. In strict mode, however, a `SyntaxError` is thrown. In addition, lexical declarations with initializers like `for (const i = 0 in obj)` are not allowed outside strict mode either, and will always produce a `SyntaxError`.

Examples

This example throws a `SyntaxError`:

```
const obj = { a: 1, b: 2, c: 3 };

for (const i = 0 in obj) {
  console.log(obj[i]);
}

// SyntaxError: for-in loop head declarations may not have initializers
```

Valid for-in loop

You can remove the initializer (`i = 0`) in the head of the for-in loop.

```
const obj = { a: 1, b: 2, c: 3 };

for (const i in obj) {
  console.log(obj[i]);
}
```

Array iteration

The for...in loop shouldn't be used for Array iteration. Did you intend to use a `for` loop instead of a `for-in` loop to iterate an `Array`? The `for` loop allows you to set an initializer then as well:

```
const arr = ["a", "b", "c"];

for (let i = 2; i < arr.length; i++) {
  console.log(arr[i]);
}

// "c"
```

SyntaxError: a declaration in the head of a for-of loop can't have an initializer

The JavaScript exception "a declaration in the head of a for-of loop can't have an initializer" occurs when the head of a for...of loop contains an initializer expression such as `for (const i = 0 of iterable)`. This is not allowed in for-of loops.

Message

```
SyntaxError: for-of loop variable declaration may not have an initializer. (V8-based)
SyntaxError: a declaration in the head of a for-of loop can't have an initializer (Firefox)
SyntaxError: Cannot assign to the loop variable inside a for-of loop header. (Safari)
```

Error type

`SyntaxError`

What went wrong?

The head of a for...of loop contains an initializer expression. That is, a variable is declared and assigned a value `for (const i = 0 of iterable)`. This is not allowed in for-of loops. You might want a `for` loop that does allow an initializer.

Examples

Invalid for-of loop

```
const iterable = [10, 20, 30];

for (const value = 50 of iterable) {
  console.log(value);
}

// SyntaxError: a declaration in the head of a for-of loop can't
// have an initializer
```

Valid for-of loop

You need to remove the initializer (`value = 50`) in the head of the `for-of` loop. Maybe you intended to make 50 an offset value, in that case you could add it to the loop body, for example.

```
const iterable = [10, 20, 30];

for (let value of iterable) {
  value += 50;
  console.log(value);
}
// 60
// 70
// 80
```

See also

- `for...of`
- `for...in`

TypeError: invalid 'instanceof' operand 'x'

The JavaScript exception "invalid 'instanceof' operand" occurs when the right-hand side operands of the `instanceof` operator isn't used with a constructor object, i.e., an object which has a `prototype` property and is callable.

Message

```
TypeError: Right-hand side of 'instanceof' is not an object (V8-based)
TypeError: invalid 'instanceof' operand "x" (Firefox)
TypeError: Right hand side of instanceof is not an object (Safari)

TypeError: Right-hand side of 'instanceof' is not callable (V8-based)
TypeError: x is not a function (Firefox)
TypeError: x is not a function. (evaluating 'x instanceof y') (Safari)

TypeError: Function has non-object prototype 'undefined' in instanceof check (V8-based)
TypeError: 'prototype' property of x is not an object (Firefox)
TypeError: instanceof called on an object with an invalid prototype property. (Safari)
```

Error type

`TypeError`

What went wrong?

The `instanceof` operator expects the right-hand-side operands to be a constructor object, i.e., an object which has a `prototype` property and is callable. It can also be an object with a `Symbol.hasInstance` method. This error can occur if:

- The right-hand side operand is not an object.
- The right-hand side operand is not a callable and it has no `Symbol.hasInstance` method.
- The right-hand side operand is a callable, but its `prototype` property is not an object. (For example, arrow functions do not have a `prototype` property.)

Examples

instanceof vs. typeof

```
"test" instanceof ""; // TypeError: invalid 'instanceof' operand ""
42 instanceof 0; // TypeError: invalid 'instanceof' operand 0

function Foo() {}
const f = Foo(); // Foo() is called and returns undefined
const x = new Foo();

x instanceof f; // TypeError: invalid 'instanceof' operand f
x instanceof x; // TypeError: x is not a function
```

To fix these errors, you will either need to replace the `instanceof` operator with the `typeof` operator, or to make sure you use the function name, instead of the result of its evaluation.

```
typeof "test" === "string"; // true
typeof 42 === "number"; // true

function Foo() {}
const f = Foo; // Do not call Foo.
const x = new Foo();

x instanceof f; // true
x instanceof Foo; // true
```

See also

- `instanceof`
- `typeof`

TypeError: 'x' is not iterable

The JavaScript exception "is not iterable" occurs when the value which is spread into an array or function call, given as the right-hand side of `for...of`, as an argument of a function such as `Promise.all` or `Set()`, or as the right-hand side of an array destructuring, is not an iterable object. This error is also encountered when `Array.fromAsync()` or `for await...of` is used with a non-async iterable.

Message

```
TypeError: Spread syntax requires ...iterable[Symbol.iterator] to be a function (V8-based & Safari)
TypeError: %Array%.from requires that the property of the first argument, items[Symbol.iterator], when exists, be a function (V8-based & Safari)
TypeError: Array.fromAsync requires that the property of the first argument, items[Symbol.asyncIterator], when exists, be a function (V8-based & Safari)
TypeError: object is not iterable (cannot read property Symbol(Symbol.iterator)) (V8-based)
TypeError: x is not async iterable (V8-based)
TypeError: x is not iterable (V8-based & Firefox)
TypeError: undefined is not a function (near '...y of x...') (Safari)
TypeError: Array.from: no function (Safari)
TypeError: Type error (Safari)
```

Error type

`TypeError`

What went wrong?

The value which is spread into an array or function call, given as the right-hand side of `for...of`, or as an argument of a function such as `Promise.all` or `Set()`, or as the source of an array destructuring pattern, is not an iterable object. An iterable can be a built-in iterable type such as `Array`, `String` or `Map`, a generator result, or an object implementing the iterable protocol.

```
const nonIterable1 = {};
const nonIterable2 = { [Symbol.iterator]: 1 };

[...nonIterable1];
Math.max(...nonIterable1);
for (const x of nonIterable1);
new Set(nonIterable1);
Array.from(nonIterable2);
new Int8Array(nonIterable2);
const [] = nonIterable1;
```

Examples

Array destructuring a non-iterable

```
const myObj = { arrayOrObjProp1: {}, arrayOrObjProp2: [42] };

const {
  arrayOrObjProp1: [value1],
  arrayOrObjProp2: [value2],
} = myObj; // TypeError: object is not iterable

console.log(value1, value2);
```

The non-iterable might turn to be `undefined` in some runtime environments.

Iterating over Object properties

In JavaScript, `Object`s are not iterable unless they implement the iterable protocol. Therefore, you cannot use `for...of` to iterate over the properties of an object.

```
const obj = { France: "Paris", England: "London" };
for (const p of obj) {
  // …
} // TypeError: obj is not iterable
```

Instead you have to use `Object.keys` or `Object.entries`, to iterate over the properties or entries of an object.

```
const obj = { France: "Paris", England: "London" };
// Iterate over the property names:
for (const country of Object.keys(obj)) {
  const capital = obj[country];
  console.log(country, capital);
}

for (const [country, capital] of Object.entries(obj)) {
  console.log(country, capital);
}
```

Another option for this use case might be to use a `Map`:

```
const map = new Map();
map.set("France", "Paris");
map.set("England", "London");
// Iterate over the property names:
for (const country of map.keys()) {
  const capital = map.get(country);
  console.log(country, capital);
}

for (const capital of map.values()) {
  console.log(capital);
}

for (const [country, capital] of map.entries()) {
  console.log(country, capital);
}
```

Iterating over a generator

Generator functions are functions you call to produce an iterable object.

```
function* generate(a, b) {
  yield a;
  yield b;
}

for (const x of generate) {
  console.log(x);
} // TypeError: generate is not iterable
```

When they are not called, the `Function` object corresponding to the generator is callable, but not iterable. Calling a generator produces an iterable object which will iterate over the values yielded during the execution of the generator.

```
function* generate(a, b) {
  yield a;
  yield b;
}

for (const x of generate(1, 2)) {
  console.log(x);
}
```

Iterating over a custom iterable

Custom iterables can be created by implementing the `Symbol.iterator` method. You must be certain that your iterator method returns an object which is an iterator, which is to say it must have a next method.

```
const myEmptyIterable = {
  [Symbol.iterator]() {
    return []; // [] is iterable, but it is not an iterator — it has no next method.
  },
};

Array.from(myEmptyIterable); // TypeError: myEmptyIterable is not iterable
```

Here is a correct implementation:

```
const myEmptyIterable = {
  [Symbol.iterator]() {
    return [][Symbol.iterator]();
  },
};

Array.from(myEmptyIterable); // []
```

SyntaxError: JSON.parse: bad parsing

The JavaScript exceptions thrown by `JSON.parse()` occur when string failed to be parsed as JSON.

Message

```
SyntaxError: JSON.parse: unterminated string literal
SyntaxError: JSON.parse: bad control character in string literal
SyntaxError: JSON.parse: bad character in string literal
SyntaxError: JSON.parse: bad Unicode escape
SyntaxError: JSON.parse: bad escape character
SyntaxError: JSON.parse: unterminated string
SyntaxError: JSON.parse: no number after minus sign
SyntaxError: JSON.parse: unexpected non-digit
SyntaxError: JSON.parse: missing digits after decimal point
SyntaxError: JSON.parse: unterminated fractional number
SyntaxError: JSON.parse: missing digits after exponent indicator
SyntaxError: JSON.parse: missing digits after exponent sign
SyntaxError: JSON.parse: exponent part is missing a number
SyntaxError: JSON.parse: unexpected end of data
SyntaxError: JSON.parse: unexpected keyword
SyntaxError: JSON.parse: unexpected character
SyntaxError: JSON.parse: end of data while reading object contents
SyntaxError: JSON.parse: expected property name or '}'
SyntaxError: JSON.parse: end of data when ',' or ']' was expected
SyntaxError: JSON.parse: expected ',' or ']' after array element
SyntaxError: JSON.parse: end of data when property name was expected
SyntaxError: JSON.parse: expected double-quoted property name
SyntaxError: JSON.parse: end of data after property name when ':' was expected
SyntaxError: JSON.parse: expected ':' after property name in object
SyntaxError: JSON.parse: end of data after property value in object
SyntaxError: JSON.parse: expected ',' or '}' after property value in object
SyntaxError: JSON.parse: expected ',' or '}' after property-value pair in object literal
SyntaxError: JSON.parse: property names must be double-quoted strings
SyntaxError: JSON.parse: expected property name or '}'
SyntaxError: JSON.parse: unexpected character
SyntaxError: JSON.parse: unexpected non-whitespace character after JSON data
```

Error type

`SyntaxError`

What went wrong?

`JSON.parse()` parses a string as JSON. This string has to be valid JSON and will throw this error if incorrect syntax was encountered.

Examples

JSON.parse() does not allow trailing commas

Both lines will throw a SyntaxError:

```
JSON.parse("[1, 2, 3, 4,]");
JSON.parse('{"foo": 1,}');
// SyntaxError JSON.parse: unexpected character
// at line 1 column 14 of the JSON data
```

Omit the trailing commas to parse the JSON correctly:

```
JSON.parse("[1, 2, 3, 4]");
JSON.parse('{"foo": 1}');
```

Property names must be double-quoted strings

You cannot use single-quotes around properties, like 'foo'.

```
JSON.parse("{'foo': 1}");
// SyntaxError: JSON.parse: expected property name or '}'
// at line 1 column 2 of the JSON data
```

Instead write "foo":

```
JSON.parse('{"foo": 1}');
```

Leading zeros and decimal points

You cannot use leading zeros, like 01, and decimal points must be followed by at least one digit.

```
JSON.parse('{"foo": 01}');
// SyntaxError: JSON.parse: expected ',' or '}' after property value
// in object at line 1 column 2 of the JSON data

JSON.parse('{"foo": 1.}');
// SyntaxError: JSON.parse: unterminated fractional number
// at line 1 column 2 of the JSON data
```

Instead write just 1 without a zero and use at least one digit after a decimal point:

```
JSON.parse('{"foo": 1}');
JSON.parse('{"foo": 1.0}');
```

- `JSON`
- `JSON.parse()`
- `JSON.stringify()`

TypeError: WeakSet key/WeakMap value 'x' must be an object or an unregistered symbol

The JavaScript exception "WeakSet key (or WeakMap value) 'x' must be an object or an unregistered symbol" occurs when a value of invalid type is used as a key in a `WeakSet` or as a value in a `WeakMap`.

Message

```
TypeError: Invalid value used as weak map key (V8-based)
TypeError: WeakMap key 1 must be an object or an unregistered symbol (Firefox)
TypeError: WeakMap keys must be objects or non-registered symbols (Safari)

TypeError: Invalid value used in weak set (V8-based)
TypeError: WeakSet value 1 must be an object or an unregistered symbol (Firefox)
TypeError: WeakSet values must be objects or non-registered symbols (Safari)
```

Error type

`TypeError`

What went wrong?

`WeakSet` and `WeakMap` require the keys to be *garbage collectable*. Only objects and non-registered symbols (that is, symbols not returned by `Symbol.for()`) are valid. For more information, see Memory management. If you want to add keys that are strings, numbers, or other primitive values, you should store them in a regular `Set` or `Map` instead.

Examples

Invalid cases

```
new WeakSet().add(1); // TypeError
new WeakMap().set(1, {}); // TypeError
new WeakSet([1]); // TypeError
new WeakMap([[1, {}]]); // TypeError
```

Valid cases

```
new WeakSet().add({}); // OK
new WeakMap().set({}, 1); // OK

new Set([1]); // OK
new Map([[1, {}]]); // OK
```

See also

- Memory management
- `WeakSet`
- `WeakMap`
- `Set`
- `Map`

SyntaxError: label not found

The JavaScript exception "label not found" occurs when a `break` or `continue` statement references a label that does not exist on any statement that contains the `break` or `continue` statement.

Message

```
SyntaxError: Undefined label 'label' (V8-based)
SyntaxError: label not found (Firefox)
SyntaxError: Cannot use the undeclared label 'label'. (Safari)
```

Error type

`SyntaxError`.

What went wrong?

In JavaScript, labels are very limited: you can only use them with `break` and `continue` statements, and you can only jump to them from a statement contained within the labeled statement. You cannot jump to this label from anywhere in the program.

Examples

Unsyntactic jump

You cannot use labels as if they are `goto`.

```
start: console.log("Hello, world!");
console.log("Do it again");
break start;
```

Instead, you can only use labels to enhance the normal semantics of `break` and `continue` statements.

```
start: {
  console.log("Hello, world!");
  if (Math.random() > 0.5) {
    break start;
  }
  console.log("Maybe I'm logged");
}
```

- Labeled statement

URIError: malformed URI sequence

The JavaScript exception "malformed URI sequence" occurs when URI encoding or decoding wasn't successful.

Message

```
URIError: URI malformed (V8-based)
URIError: malformed URI sequence (Firefox)
URIError: String contained an illegal UTF-16 sequence. (Safari)
```

Error type

`URIError`

What went wrong?

URI encoding or decoding wasn't successful. An argument given to either the `decodeURI`, `encodeURI`, `encodeURIComponent`, or `decodeURIComponent` function was not valid, so that the function was unable encode or decode properly.

Examples

Encoding

Encoding replaces each instance of certain characters by one, two, three, or four escape sequences representing the UTF-8 encoding of the character. An `URIError` will be thrown if there is an attempt to encode a surrogate which is not part of a high-low pair, for example:

```
encodeURI("\uD800");
// "URIError: malformed URI sequence"

encodeURI("\uDFFF");
// "URIError: malformed URI sequence"
```

A high-low pair is OK. For example:

```
encodeURI("\uD800\uDFFF");
// "%F0%90%8F%BF"
```

Decoding

Decoding replaces each escape sequence in the encoded URI component with the character that it represents. If there isn't such a character, an error will be thrown:

```
decodeURIComponent("%E0%A4%A");
// "URIError: malformed URI sequence"
```

With proper input, this should usually look like something like this:

```
decodeURIComponent("JavaScript_%D1%88%D0%B5%D0%BB%D0%BB%D1%8B");
// "JavaScript_шеллы"
```

See also

- `URIError`
- `decodeURI`
- `encodeURI`
- `encodeURIComponent`
- `decodeURIComponent`

SyntaxError: missing] after element list

The JavaScript exception "missing] after element list" occurs when there is an error with the array initializer syntax somewhere. Likely there is a closing square bracket (`]`) or a comma (`,`) missing.

Message

```
SyntaxError: missing ] after element list (Firefox)
SyntaxError: Unexpected token ';'. Expected either a closing ']' or a ',' following an array element. (Safari)
```

Error type

`SyntaxError`.

What went wrong?

There is an error with the array initializer syntax somewhere. Likely there is a closing square bracket (`]`) or a comma (`,`) missing.

Examples

Incomplete array initializer

```
const list = [1, 2,

const instruments = [
  "Ukulele",
  "Guitar",
  "Piano",
};

const data = [{ foo: "bar" } { bar: "foo" }];
```

Correct would be:

```
const list = [1, 2];

const instruments = ["Ukulele", "Guitar", "Piano"];

const data = [{ foo: "bar" }, { bar: "foo" }];
```

See also

- `Array`

SyntaxError: missing : after property id

The JavaScript exception "missing : after property id" occurs when objects are created using the object initializer syntax. A colon (`:`) separates keys and values for the object's properties. Somehow, this colon is missing or misplaced.

Message

```
SyntaxError: Invalid shorthand property initializer (V8-based)
SyntaxError: missing : after property id (Firefox)
SyntaxError: Unexpected token '='. Expected a ':' following the property name 'x'. (Safari)
SyntaxError: Unexpected token '+'. Expected an identifier as property name. (Safari)
```

Error type

`SyntaxError`

What went wrong?

When creating objects with the object initializer syntax, a colon (`:`) separates keys and values for the object's properties.

```
const obj = { propertyKey: "value" };
```

Examples

Colons vs. equal signs

This code fails, as the equal sign can't be used this way in this object initializer syntax.

```
const obj = { propertyKey = "value" };
// SyntaxError: missing : after property id
```

Correct would be to use a colon, or to use square brackets to assign a new property after the object has been created already.

```
const obj = { propertyKey: "value" };
```

Or alternatively:

```
const obj = {};
obj.propertyKey = "value";
```

Computed properties

If you create a property key from an expression, you need to use square brackets. Otherwise the property name can't be computed:

```
const obj = { "b"+"ar": "foo" };
// SyntaxError: missing : after property id
```

Put the expression in square brackets `[]`:

```
const obj = { ["b" + "ar"]: "foo" };
```

See also

- Object initializer

SyntaxError: missing } after function body

The JavaScript exception "missing } after function body" occurs when there is a syntax mistake when creating a function somewhere. Check if any closing curly braces or parenthesis are in the correct order.

Message

```
SyntaxError: missing } after function body (Firefox)
```

Error type

`SyntaxError`

What went wrong?

There is a syntax mistake when creating a function somewhere. Also check if any closing curly braces or parenthesis are in the correct order. Indenting or formatting the code a bit nicer might also help you to see through the jungle.

Examples

Forgotten closing curly bracket

Oftentimes, there is a missing curly bracket in your function code:

```
function charge() {
  if (sunny) {
    useSolarCells();
  } else {
```

```
    promptBikeRide();
}
```

Correct would be:

```
function charge() {
  if (sunny) {
    useSolarCells();
  } else {
    promptBikeRide();
  }
}
```

It can be more obscure when using IIFEs or other constructs that use a lot of different parenthesis and curly braces, for example.

```
(function () {
  if (Math.random() < 0.01) {
    doSomething();
  }
)();
```

Oftentimes, indenting differently or double checking indentation helps to spot these errors.

```
(function () {
  if (Math.random() < 0.01) {
    doSomething();
  }
})();
```

See also

- Functions guide

SyntaxError: missing } after property list

The JavaScript exception "missing } after property list" occurs when there is a mistake in the object initializer syntax somewhere. Might be in fact a missing curly bracket, but could also be a missing comma.

Message

```
SyntaxError: missing } after property list (Firefox)
SyntaxError: Unexpected identifier 'c'. Expected '}' to end an object literal. (Safari)
```

Error type

`SyntaxError`

What went wrong?

There is a mistake in the object initializer syntax somewhere. Might be in fact a missing curly bracket, but could also be a missing comma, for example. Also check if any closing curly braces or parenthesis are in the correct order. Indenting or formatting the code a bit nicer might also help you to see through the jungle.

Examples

Forgotten comma

Oftentimes, there is a missing comma in your object initializer code:

```
const obj = {
  a: 1,
  b: { myProp: 2 }
  c: 3
};
```

Correct would be:

```
const obj = {
  a: 1,
  b: { myProp: 2 },
  c: 3,
};
```

See also

- Object initializer

SyntaxError: missing formal parameter

The JavaScript exception "missing formal parameter" occurs when your function declaration is missing valid parameters.

Message

```
SyntaxError: missing formal parameter (Firefox)
SyntaxError: Unexpected number '3'. Expected a parameter pattern or a ')' in parameter list. (Safari)
SyntaxError: Unexpected string literal "x". Expected a parameter pattern or a ')' in parameter list. (Safari)
```

Error type

`SyntaxError`

What went wrong?

"Formal parameter" is a fancy way of saying "function parameter". Your function declaration is missing valid parameters. In the declaration of a function, the parameters must be identifiers, not any value like numbers, strings, or objects. Declaring functions and calling functions are two separate steps. Declarations require identifier as parameters, and only when calling (invoking) the function, you provide the values the function should use.

In JavaScript, identifiers can contain only alphanumeric characters (or "$" or "_"), and may not start with a digit. An identifier differs from a **string** in that a string is data, while an identifier is part of the code.

Examples

Provide proper function parameters

Function parameters must be identifiers when setting up a function. All these function declarations fail, as they are providing values for their parameters:

```
function square(3) {
  return number * number;
}
// SyntaxError: missing formal parameter

function greet("Howdy") {
  return greeting;
}
// SyntaxError: missing formal parameter

function log({ obj: "value"}) {
  console.log(arg)
}
// SyntaxError: missing formal parameter
```

You will need to use identifiers in function declarations:

```
function square(number) {
  return number * number;
}

function greet(greeting) {
  return greeting;
}

function log(arg) {
  console.log(arg);
}
```

You can then call these functions with the arguments you like:

```
square(2); // 4

greet("Howdy"); // "Howdy"

log({ obj: "value" }); // { obj: "value" }
```

See also

- SyntaxError: redeclaration of formal parameter "x"

SyntaxError: missing = in const declaration

The JavaScript exception "missing = in const declaration" occurs when a const declaration was not given a value in the same statement (like `const RED_FLAG;`). You need to provide one (`const RED_FLAG = true`).

Message

```
SyntaxError: Missing initializer in const declaration (V8-based)
SyntaxError: missing = in const declaration (Firefox)
SyntaxError: Unexpected token ';'. const declared variable 'x' must have an initializer. (Safari)
```

Error type

`SyntaxError`

What went wrong?

A constant is a value that cannot be altered by the program during normal execution. It cannot change through re-assignment, and it can't be redeclared. In JavaScript, constants are declared using the `const` keyword. An initializer for a constant is required; that is, you must specify its value in the same statement in which

it's declared (which makes sense, given that it can't be changed later).

Examples

Missing const initializer

Unlike `var` or `let`, you must specify a value for a `const` declaration. This throws:

```
const COLUMNS;
// SyntaxError: missing = in const declaration
```

Fixing the error

There are multiple options to fix this error. Check what was intended to be achieved with the constant in question.

Adding a constant value

Specify the constant value in the same statement in which it's declared:

```
const COLUMNS = 80;
```

`const`, `let` or `var`?

Do not use `const` if you weren't meaning to declare a constant. Maybe you meant to declare a block-scoped variable with `let` or global variable with `var`. Both don't require an initial value.

```
let columns;
```

- `const`
- `let`
- `var`

SyntaxError: missing name after . operator

The JavaScript exception "missing name after . operator" occurs when there is a problem with how the dot operator (`.`) is used for property access.

Message

```
SyntaxError: missing name after . operator (Firefox)
SyntaxError: Unexpected token '['. Expected a property name after '.'. (Safari)
```

Error type

`SyntaxError`

What went wrong?

The dot operator (`.`) is used for property access. You will have to specify the name of the property that you want to access. For computed property access, you might need to change your property access from using a dot to using square brackets. These will allow you to compute an expression. Maybe you intended to do concatenation instead? A plus operator (+) is needed in that case. Please see the examples below.

Examples

Property access

Property accessors in JavaScript use either the dot (.) or square brackets (`[]`), but not both. Square brackets allow computed property access.

```
const obj = { foo: { bar: "baz", bar2: "baz2" } };
const i = 2;

obj.[foo].[bar]
// SyntaxError: missing name after . operator

obj.foo."bar"+i;
// SyntaxError: missing name after . operator
```

To fix this code, you need to access the object like this:

```
obj.foo.bar; // "baz"
// or alternatively
obj["foo"]["bar"]; // "baz"

// computed properties require square brackets
obj.foo["bar" + i]; // "baz2"
// or as template literal
obj.foo[`bar${i}`]; // "baz2"
```

Property access vs. concatenation

If you are coming from another programming language (like PHP), it is also easy to mix up the dot operator (`.`) and the concatenation operator (+).

```
console.log("Hello" . "world");

// SyntaxError: missing name after . operator
```

Instead you need to use a plus sign for concatenation:

```
console.log("Hello" + "World");
```

- Property accessors

SyntaxError: missing) after argument list

The JavaScript exception "missing) after argument list" occurs when there is an error with how a function is called. This might be a typo, a missing operator, or an unescaped string.

Message

```
SyntaxError: missing ) after argument list (V8-based & Firefox)
SyntaxError: Unexpected identifier 'x'. Expected ')' to end an argument list. (Safari)
```

Error type

`SyntaxError`.

What went wrong?

There is an error with how a function is called. This might be a typo, a missing operator, or an unescaped string, for example.

Examples

Because there is no "+" operator to concatenate the string, JavaScript expects the argument for the `log` function to be just `"PI: "`. In that case, it should be terminated by a closing parenthesis.

```
console.log("PI: " Math.PI);
// SyntaxError: missing ) after argument list
```

You can correct the `log` call by adding the `+` operator:

```
console.log("PI: " + Math.PI);
// "PI: 3.141592653589793"
```

Alternatively, you can consider using a template literal, or take advantage of the fact that `console.log` accepts multiple parameters:

```
console.log(`PI: ${Math.PI}`);
console.log("PI:", Math.PI);
```

Unterminated strings

```
console.log('"Java" + "Script" = \"' + "Java" + 'Script\");
// SyntaxError: missing ) after argument list
```

Here JavaScript thinks that you meant to have `);` inside the string and ignores it, and it ends up not knowing that you meant the `);` to end the function `console.log`. To fix this, we could put a `'` after the "Script" string:

```
console.log('"Java" + "Script" = "' + "Java" + 'Script"');
// '"Java" + "Script" = "JavaScript"'
```

SyntaxError: missing) after condition

The JavaScript exception "missing) after condition" occurs when there is an error with how an `if` condition is written. It must appear in parenthesis after the `if` keyword.

Message

```
SyntaxError: missing ) after condition (Firefox)
SyntaxError: Unexpected token '{'. Expected ')' to end an 'if' condition. (Safari)
```

Error type

`SyntaxError`

What went wrong?

There is an error with how an `if` condition is written. In any programming language, code needs to make decisions and carry out actions accordingly depending on different inputs. The if statement executes a statement if a specified condition is truthy. In JavaScript, this condition must appear in parenthesis after the `if` keyword, like this:

```
if (condition) {
  // do something if the condition is true
}
```

Examples

Missing parenthesis

It might just be an oversight, carefully check all you parenthesis in your code.

```
if (Math.PI < 3 {
  console.log("wait what?");
}

// SyntaxError: missing ) after condition
```

To fix this code, you would need to add a parenthesis that closes the condition.

```
if (Math.PI < 3) {
  console.log("wait what?");
}
```

Misused is keyword

If you are coming from another programming language, it is also easy to add keywords that don't mean the same or have no meaning at all in JavaScript.

```
if (done is true) {
 console.log("we are done!");
}

// SyntaxError: missing ) after condition
```

Instead you need to use a correct comparison operator. For example:

```
if (done === true) {
  console.log("we are done!");
}
```

Or even better:

```
if (done) {
  console.log("we are done!");
}
```

TypeError: More arguments needed

The JavaScript exception "more arguments needed" occurs when there is an error with how a function is called. More arguments need to be provided.

Message

```
TypeError: Object prototype may only be an Object or null: undefined (V8-based)
TypeError: Object.create requires at least 1 argument, but only 0 were passed (Firefox)
TypeError: Object.setPrototypeOf requires at least 2 arguments, but only 0 were passed (Firefox)
TypeError: Object.defineProperties requires at least 1 argument, but only 0 were passed (Firefox)
TypeError: Object prototype may only be an Object or null. (Safari)
```

Error type

`TypeError`.

What went wrong?

There is an error with how a function is called. More arguments need to be provided.

Examples

Required arguments not provided

The `Object.create()` method requires at least one argument and the `Object.setPrototypeOf()` method requires at least two arguments:

```
const obj = Object.create();
// TypeError: Object.create requires at least 1 argument, but only 0 were passed

const obj2 = Object.setPrototypeOf({});
// TypeError: Object.setPrototypeOf requires at least 2 arguments, but only 1 were passed
```

You can fix this by setting `null` as the prototype, for example:

```
const obj = Object.create(null);

const obj2 = Object.setPrototypeOf({}, null);
```

See also

- Functions guide

RangeError: repeat count must be non-negative

The JavaScript exception "repeat count must be non-negative" occurs when the `String.prototype.repeat()` method is used with a `count` argument that is a negative number.

Message

```
RangeError: Invalid count value: -1 (V8-based)
RangeError: repeat count must be non-negative (Firefox)
RangeError: String.prototype.repeat argument must be greater than or equal to 0 and not be Infinity (Safari)
```

Error type

`RangeError`

What went wrong?

The `String.prototype.repeat()` method has been used. It has a `count` parameter indicating the number of times to repeat the string. It must be between 0 and less than positive `Infinity` and cannot be a negative number. The range of allowed values can be described like this: [0, +∞).

Examples

Invalid cases

```
"abc".repeat(-1); // RangeError
```

Valid cases

```
"abc".repeat(0); // ''
"abc".repeat(1); // 'abc'
"abc".repeat(2); // 'abcabc'
"abc".repeat(3.5); // 'abcabcabc' (count will be converted to integer)
```

See also

- `String.prototype.repeat()`

TypeError: "x" is not a non-null object

The JavaScript exception "is not a non-null object" occurs when an object is expected somewhere and wasn't provided. `null` is not an object and won't work.

Message

```
TypeError: Property description must be an object: x (V8-based)
TypeError: Property descriptor must be an object, got "x" (Firefox)
TypeError: Property description must be an object. (Safari)
```

Error type

`TypeError`

What went wrong?

An object is expected somewhere and wasn't provided. `null` is not an object and won't work. You must provide a proper object in the given situation.

Examples

Property descriptor expected

When methods like `Object.create()` or `Object.defineProperty()` and `Object.defineProperties()` are used, the optional descriptor parameter expects a property descriptor object. Providing no object (like just a number), will throw an error:

```
Object.defineProperty({}, "key", 1);
// TypeError: 1 is not a non-null object
```

```
Object.defineProperty({}, "key", null);
// TypeError: null is not a non-null object
```

A valid property descriptor object might look like this:

```
Object.defineProperty({}, "key", { value: "foo", writable: false });
```

See also

- `Object.create()`
- `Object.defineProperty()`
- `Object.defineProperties()`

TypeError: null/undefined has no properties

The JavaScript exception "null (or undefined) has no properties" occurs when you attempt to access properties of `null` and `undefined`. They don't have any.

Message

```
TypeError: Cannot read properties of undefined (reading 'x') (V8-based)
TypeError: Cannot destructure 'x' as it is undefined. (V8-based)
TypeError: Cannot destructure property 'x' of 'y' as it is undefined. (V8-based)
TypeError: null has no properties (Firefox)
TypeError: undefined has no properties (Firefox)
TypeError: undefined is not an object (evaluating 'undefined.x') (Safari)
TypeError: Right side of assignment cannot be destructured (Safari)
```

Error type

`TypeError`.

What went wrong?

Both `null` and `undefined` have no properties you could access. Therefore, you cannot use property accessors on them, or destructure them.

Examples

null and undefined have no properties

```
null.foo;
// TypeError: null has no properties

undefined.bar;
// TypeError: undefined has no properties
```

See also

- `null`
- `undefined`

SyntaxError: missing variable name

The JavaScript exception "missing variable name" is a common error. It is usually caused by omitting a variable name or a typographic error.

Message

```
SyntaxError: missing variable name (Firefox)
SyntaxError: Unexpected token '='. Expected a parameter pattern or a ')' in parameter list. (Safari)
```

Error type

`SyntaxError`

What went wrong?

A variable is missing a name. The cause is most likely a typo or a forgotten variable name. Make sure that you've provided the name of the variable before the `=` sign.

When declaring multiple variables at the same time, make sure that the previous lines/declaration does not end with a comma instead of a semicolon.

Examples

Missing a variable name

```
const = "foo";
```

It is easy to forget to assign a name for your variable!

```
const description = "foo";
```

Reserved keywords can't be variable names

There are a few variable names that are reserved keywords. You can't use these. Sorry :(

```
const debugger = "whoop";
// SyntaxError: missing variable name
```

Declaring multiple variables

Pay special attention to commas when declaring multiple variables. Is there an excess comma, or did you use commas instead of semicolons? Did you remember to assign values for all your `const` variables?

```
let x, y = "foo",
const z, = "foo"

const first = document.getElementById("one"),
const second = document.getElementById("two"),

// SyntaxError: missing variable name
```

The fixed version:

```
let x,
  y = "foo";
const z = "foo";

const first = document.getElementById("one");
const second = document.getElementById("two");
```

Arrays

`Array` literals in JavaScript need square brackets around the values. This won't work:

```
const arr = 1,2,3,4,5;
// SyntaxError: missing variable name
```

This would be correct:

```
const arr = [1, 2, 3, 4, 5];
```

TypeError: can't delete non-configurable array element

The JavaScript exception "can't delete non-configurable array element" occurs when it was attempted to shorten the length of an array, but one of the array's elements is non-configurable.

Message

```
TypeError: Cannot delete property '1' of [object Array] (V8-based)
TypeError: can't delete non-configurable array element (Firefox)
TypeError: Unable to delete property. (Safari)
```

Error type

`TypeError`

What went wrong?

It was attempted to shorten the length of an array, but one of the array's elements is non-configurable. When shortening an array, the elements beyond the new array length will be deleted, which failed in this situation.

The `configurable` attribute controls whether the property can be deleted from the object and whether its attributes (other than `writable`) can be changed.

Usually, properties in an object created by an array initializer are configurable. However, for example, when using `Object.defineProperty()`, the property isn't configurable by default.

Examples

Non-configurable properties created by Object.defineProperty

The `Object.defineProperty()` creates non-configurable properties by default if you haven't specified them as configurable.

```
"use strict";
const arr = [];
Object.defineProperty(arr, 0, { value: 0 });
Object.defineProperty(arr, 1, { value: "1" });

arr.length = 1;
// TypeError: can't delete non-configurable array element
```

You will need to set the elements as configurable, if you intend to shorten the array.

```
"use strict";
const arr = [];
Object.defineProperty(arr, 0, { value: 0, configurable: true });
Object.defineProperty(arr, 1, { value: "1", configurable: true });

arr.length = 1;
```

Sealed Arrays

The `Object.seal()` function marks all existing elements as non-configurable.

```
"use strict";
const arr = [1, 2, 3];
Object.seal(arr);

arr.length = 1;
// TypeError: can't delete non-configurable array element
```

You either need to remove the `Object.seal()` call, or make a copy of it. In case of a copy, shortening the copy of the array does not modify the original array length.

```
"use strict";
const arr = [1, 2, 3];
Object.seal(arr);

// Copy the initial array to shorten the copy
const copy = Array.from(arr);
copy.length = 1;
// arr.length === 3
```

See also

- [[Configurable]]
- `length`
- `Object.defineProperty()`
- `Object.seal()`

TypeError: "x" is not a constructor

The JavaScript exception "is not a constructor" occurs when there was an attempt to use an object or a variable as a constructor, but that object or variable is not a constructor.

Message

```
TypeError: x is not a constructor (V8-based & Firefox & Safari)
```

Error type

`TypeError`

What went wrong?

There was an attempt to use an object or a variable as a constructor, but that object or variable is not a constructor. See constructor or the `new` operator for more information on what a constructor is.

There are many global objects, like `String` or `Array`, which are constructable using `new`. However, some global objects are not and their properties and methods are static. The following JavaScript standard built-in objects are not a constructor: `Math`, `JSON`, `Symbol`, `Reflect`, `Intl`, `Atomics`.

Generator functions cannot be used as constructors either.

Examples

Invalid cases

```
const Car = 1;
new Car();
// TypeError: Car is not a constructor

new Math();
// TypeError: Math is not a constructor

new Symbol();
// TypeError: Symbol is not a constructor

function* f() {}
const obj = new f();
// TypeError: f is not a constructor
```

A car constructor

Suppose you want to create an object type for cars. You want this type of object to be called `Car`, and you want it to have properties for make, model, and year. To do this, you would write the following function:

```
function Car(make, model, year) {
  this.make = make;
  this.model = model;
  this.year = year;
}
```

Now you can create an object called `myCar` as follows:

```
const myCar = new Car("Eagle", "Talon TSi", 1993);
```

In Promises

When returning an immediately-resolved or immediately-rejected Promise, you do not need to create a `new Promise(...)` and act on it. Instead, use the `Promise.resolve()` or `Promise.reject()` static methods.

This is not legal (the `Promise` constructor is not being called correctly) and will throw a `TypeError: this is not a constructor` exception:

```
function fn() {
  return new Promise.resolve(true);
}
```

This is legal, but unnecessarily long:

```
function fn() {
  return new Promise((resolve, reject) => {
    resolve(true);
  });
}
```

Instead, return the static method:

```
function resolveAlways() {
  return Promise.resolve(true);
}

function rejectAlways() {
  return Promise.reject(new Error());
}
```

See also

- constructor
- `new`

TypeError: "x" is not a function

The JavaScript exception "is not a function" occurs when there was an attempt to call a value from a function, but the value is not actually a function.

Message

```
TypeError: "x" is not a function. (V8-based & Firefox & Safari)
```

Error type

`TypeError`

What went wrong?

It attempted to call a value from a function, but the value is not actually a function. Some code expects you to provide a function, but that didn't happen.

Maybe there is a typo in the function name? Maybe the object you are calling the method on does not have this function? For example, JavaScript `Objects` have no `map` function, but the JavaScript `Array` object does.

There are many built-in functions in need of a (callback) function. You will have to provide a function in order to have these methods working properly:

- When working with `Array` or `TypedArray` objects:
  - `Array.prototype.every()`, `Array.prototype.some()`, `Array.prototype.forEach()`, `Array.prototype.map()`, `Array.prototype.filter()`, `Array.prototype.reduce()`, `Array.prototype.reduceRight()`, `Array.prototype.find()`
- When working with `Map` and `Set` objects:
  - `Map.prototype.forEach()` and `Set.prototype.forEach()`

Examples

A typo in the function name

In this case, which happens way too often, there is a typo in the method name:

```
const x = document.getElementByID("foo");
// TypeError: document.getElementByID is not a function
```

The correct function name is `getElementById`:

```
const x = document.getElementById("foo");
```

Function called on the wrong object

For certain methods, you have to provide a (callback) function and it will work on specific objects only. In this example, `Array.prototype.map()` is used, which will work with `Array` objects only.

```
const obj = { a: 13, b: 37, c: 42 };

obj.map((num) => num * 2);

// TypeError: obj.map is not a function
```

Use an array instead:

```
const numbers = [1, 4, 9];

numbers.map((num) => num * 2); // [2, 8, 18]
```

Function shares a name with a pre-existing property

Sometimes when making a class, you may have a property and a function with the same name. Upon calling the function, the compiler thinks that the function ceases to exist.

```
function Dog() {
  this.age = 11;
  this.color = "black";
  this.name = "Ralph";
  return this;
}

Dog.prototype.name = function (name) {
  this.name = name;
  return this;
};

const myNewDog = new Dog();
myNewDog.name("Cassidy"); // TypeError: myNewDog.name is not a function
```

Use a different property name instead:

```
function Dog() {
  this.age = 11;
  this.color = "black";
  this.dogName = "Ralph"; // Using this.dogName instead of .name
  return this;
}

Dog.prototype.name = function (name) {
  this.dogName = name;
  return this;
};

const myNewDog = new Dog();
myNewDog.name("Cassidy"); // Dog { age: 11, color: 'black', dogName: 'Cassidy' }
```

Using parentheses for multiplication

In math, you can write 2 × (3 + 5) as 2*(3 + 5) or just 2(3 + 5).

Using the latter will throw an error:

```
const sixteen = 2(3 + 5);
console.log(`2 x (3 + 5) is ${sixteen}`);
// Uncaught TypeError: 2 is not a function
```

You can correct the code by adding a `*` operator:

```
const sixteen = 2 * (3 + 5);
console.log(`2 x (3 + 5) is ${sixteen}`);
// 2 x (3 + 5) is 16
```

Import the exported module correctly

Ensure you are importing the module correctly.

An example helpers library (`helpers.js`)

```
function helpers() {}

helpers.groupBy = function (objectArray, property) {
  return objectArray.reduce((acc, obj) => {
    const key = obj[property];
    acc[key] ??= [];
    acc[key].push(obj);
    return acc;
  }, {});
};

export default helpers;
```

The correct import usage (`App.js`):

```
import helpers from "./helpers";
```

- Functions

RangeError: argument is not a valid code point

The JavaScript exception "Invalid code point" occurs when `NaN` values, negative Integers (-1), non-Integers (5.4), or values larger than 0x10FFFF (1114111) are used with `String.fromCodePoint()`.

Message

```
RangeError: Invalid code point -1 (V8-based)
RangeError: -1 is not a valid code point (Firefox)
RangeError: Arguments contain a value that is out of range of code points (Safari)
```

Error type

`RangeError`

What went wrong?

`String.fromCodePoint()` throws this error when passed `NaN` values, negative Integers (-1), non-Integers (5.4), or values larger than 0x10FFFF (1114111).

A code point is a value in the Unicode codespace; that is, the range of integers from `0` to `0x10FFFF`.

Examples

Invalid cases

```
String.fromCodePoint("_"); // RangeError
String.fromCodePoint(Infinity); // RangeError
String.fromCodePoint(-1); // RangeError
String.fromCodePoint(3.14); // RangeError
String.fromCodePoint(3e-2); // RangeError
String.fromCodePoint(NaN); // RangeError
```

Valid cases

```
String.fromCodePoint(42); // "*"
String.fromCodePoint(65, 90); // "AZ"
String.fromCodePoint(0x404); // 'Є' (U+0404)
String.fromCodePoint(0x2f804); // '你' (U+2F804)
String.fromCodePoint(194564); // '你'
String.fromCodePoint(0x1d306, 0x61, 0x1d307); // '𝌆a𝌇'
```

See also

- `String.fromCodePoint()`

ReferenceError: "x" is not defined

The JavaScript exception "*variable* is not defined" occurs when there is a non-existent variable referenced somewhere.

Message

```
ReferenceError: "x" is not defined (V8-based & Firefox)
ReferenceError: Can't find variable: x (Safari)
```

Error type

`ReferenceError`.

What went wrong?

There is a non-existent variable referenced somewhere. This variable needs to be declared, or you need to make sure it is available in your current script or scope.

> **Note:** When loading a library (such as jQuery), make sure it is loaded before you access library variables, such as "$". Put the `<script>` element that loads the library before your code that uses it.

Examples

Variable not declared

```
foo.substring(1); // ReferenceError: foo is not defined
```

The "foo" variable isn't defined anywhere. It needs to be some string, so that the `String.prototype.substring()` method will work.

```
const foo = "bar";
foo.substring(1); // "ar"
```

Wrong scope

A variable needs to be available in the current context of execution. Variables defined inside a function cannot be accessed from anywhere outside the function, because the variable is defined only in the scope of the function

```
function numbers() {
  const num1 = 2;
  const num2 = 3;
  return num1 + num2;
}

console.log(num1); // ReferenceError num1 is not defined.
```

However, a function can access all variables and functions defined inside the scope in which it is defined. In other words, a function defined in the global scope can access all variables defined in the global scope.

```
const num1 = 2;
const num2 = 3;

function numbers() {
  return num1 + num2;
}

console.log(numbers()); // 5
```

See also

- Scope
- Declaring variables in the JavaScript Guide
- Function scope in the JavaScript Guide

SyntaxError: parameter after rest parameter

The JavaScript exception "parameter after rest parameter" occurs when a rest parameter is followed by anything else in a parameter list, including another rest parameter, a formal parameter, or a trailing comma.

Message

```
SyntaxError: Rest parameter must be last formal parameter (V8-based)
SyntaxError: parameter after rest parameter (Firefox)
SyntaxError: Unexpected token ','. Rest parameter should be the last parameter in a function declaration. (Safari)
```

Error type

`SyntaxError`

What went wrong?

A rest parameter must be the last parameter in a function definition. This is because the rest parameter collects all the remaining arguments passed to the function, so it doesn't make sense to have any parameters after it. The next non-whitespace character must be the closing parenthesis of the parameter list.

Examples

Invalid cases

```
function replacer(match, ...groups, offset, string) {}

function doSomething(
  arg1,
  arg2,
  ...otherArgs, // Accidental trailing comma
) {}
```

Valid cases

```
function replacer(match, ...args) {
  const offset = args.at(-2);
  const string = args.at(-1);
}

function doSomething(arg1, arg2, ...otherArgs) {}
```

RangeError: precision is out of range

The JavaScript exception "precision is out of range" occurs when a number that's outside of the allowed range was passed into `toExponential`, `toFixed`, or `toPrecision`.

Message

```
RangeError: toExponential() argument must be between 0 and 100 (V8-based & Safari)
RangeError: toFixed() digits argument must be between 0 and 100 (V8-based & Safari)
RangeError: toPrecision() argument must be between 1 and 100 (V8-based & Safari)
RangeError: precision -1 out of range (Firefox)
```

Error type

`RangeError`

What went wrong?

There was an out of range precision argument in one of these methods:

- `Number.prototype.toExponential()`, which requires the arguments to be between 0 and 100, inclusive.
- `Number.prototype.toFixed()`, which requires the arguments to be between 0 and 100, inclusive.
- `Number.prototype.toPrecision()`, which requires the arguments to be between 1 and 100, inclusive.

Examples

Invalid cases

```
(77.1234).toExponential(-1); // RangeError
(77.1234).toExponential(101); // RangeError

(2.34).toFixed(-100); // RangeError
(2.34).toFixed(1001); // RangeError

(1234.5).toPrecision(-1); // RangeError
(1234.5).toPrecision(101); // RangeError
```

Valid cases

```
(77.1234).toExponential(4); // 7.7123e+1
(77.1234).toExponential(2); // 7.71e+1

(2.34).toFixed(1); // 2.3
(2.35).toFixed(1); // 2.4 (note that it rounds up in this case)

(5.123456).toPrecision(5); // 5.1235
(5.123456).toPrecision(2); // 5.1
(5.123456).toPrecision(1); // 5
```

TypeError: Initializing an object twice is an error with private fields/methods

The JavaScript exception "Initializing an object twice is an error with private fields/methods" occurs when an object that was created via a class constructor goes through the class construction again, and the class contains a private element. This is usually caused by the return override trick.

Message

```
TypeError: Cannot initialize #x twice on the same object (V8-based)
TypeError: Initializing an object twice is an error with private fields (Firefox)
TypeError: Cannot redefine existing private field (evaluating 'super(o)') (Safari)

TypeError: Cannot initialize private methods of class X twice on the same object (V8-based)
TypeError: Initializing an object twice is an error with private methods (Firefox)
TypeError: Cannot install same private methods on object more than once (evaluating 'super(o)') (Safari)
```

Error type

`TypeError`

What went wrong?

For any object, if it already contains a private field or method, it would be an error to install the same field again. Private elements are installed on the value of `this` when the class constructor is called, so this error could happen if the `this` value is an already-constructed instance of this class.

Usually, `this` in a constructor is a newly created object which doesn't have any preexisting properties. However, it can be overridden by the return value of the base class. If the base class returns another object, that object would replace the current object as the value of `this`:

```
class Base {
  constructor(o) {
    // This object will become the this value of any subclass
    return o;
  }
}

class Derived extends Base {
  #x = 0;
}
```

If you call `new Derived(anyObject)`, where `anyObject` is not an instance of `Derived`, the `Derived` constructor will be called with `anyObject` as the `this` value, and therefore install the `#x` private field on `anyObject`. This is the "return override" trick, which allows you to define arbitrary information on unrelated objects. However, if you call `new Derived(new Derived())`, or call `new Derived(anyObject)` again, the `Derived` constructor will try to install the `#x` private field again on an object which already has the `#x` private field, causing this error.

TypeError: getting private setter-only property

The JavaScript exception "getting private setter-only property" occurs when reading the value of a private element for which only a setter is defined.

Message

```
TypeError: '#x' was defined without a getter (V8-based)
TypeError: getting private setter-only property (Firefox)
TypeError: Trying to access an undefined private getter (Safari)
```

Error type

`TypeError`

What went wrong?

There is an attempt to get the value of a private element for which only a setter is specified. Unlike normal objects, where an undefined getter just means the property would always return undefined, for private elements, this is an error.

Examples

Private element with no getter

Here, `#name` has no getter, so trying to read it using `this.#name` will throw an error.

```
class Person {
  set #name(value) {}

  get name() {
    return this.#name;
  }
}

const person = new Person();
console.log(person.name);
```

It's not usual for a private element to have a setter without a getter. Either add a getter or refactor your program so the setter can be removed too.

- `set`

AggregateError: No Promise in Promise.any was resolved

The JavaScript exception "No Promise in Promise.any was resolved" occurs when all promises passed to `Promise.any()` are rejected. It is the only built-in usage of `AggregateError`.

Message

```
AggregateError: All promises were rejected (V8-based)
AggregateError: No Promise in Promise.any was resolved (Firefox)
```

```
AggregateError (Safari)
```

Error type

`AggregateError`

What went wrong?

`Promise.any()` only rejects when all promises passed to it are rejected. You should access `errors` to get the array of rejection reasons. See Using promises for more information on how to handle asynchronously rejected promises. This error is also raised when `Promise.any()` receives an empty iterable.

Examples

Empty iterable

```
Promise.any([]).catch((error) => {
  console.error(error); // AggregateError: No Promise in Promise.any was resolved
});
```

Handling all rejections

```
const promises = [
  fetch("/data-location1"),
  fetch("/data-location1"),
  fetch("/data-location1"),
];

Promise.any(promises)
  .then((value) => console.log(value))
  .catch((error) => {
    // None of the fetches were successful
    for (const e of error.errors) {
      console.error(e);
    }
  });

// Using await
async function fetchFirstSuccessful() {
  try {
    const value = await Promise.any(promises);
    console.log(value);
  } catch (error) {
    for (const e of error.errors) {
      console.error(e);
    }
  }
}
```

See also

- `AggregateError`
- `Promise.any()`

Error: Permission denied to access property "x"

The JavaScript exception "Permission denied to access property" occurs when there was an attempt to access an object for which you have no permission.

Message

```
DOMException: Blocked a frame with origin "x" from accessing a cross-origin frame. (Chromium-based)
DOMException: Permission denied to access property "x" on cross-origin object (Firefox)
SecurityError: Blocked a frame with origin "x" from accessing a cross-origin frame. Protocols, domains, and ports must match. (Safari)
```

Error type

`DOMException`.

What went wrong?

There was attempt to access an object for which you have no permission. This is likely an `<iframe>` element loaded from a different domain for which you violated the same-origin policy.

Examples

No permission to access document

```
<iframe id="myframe" src="http://www1.w3c-test.org/common/blank.html"></iframe>
```

```
console.log(frames[0].document);
// Error: Permission denied to access property "document"
```

See also

- `<iframe>`
- Same-origin policy

TypeError: "x" is read-only

The JavaScript strict mode-only exception "is read-only" occurs when a global variable or object property that was assigned to is a read-only property.

Message

```
TypeError: Cannot assign to read only property 'x' of #<Object> (V8-based)
TypeError: "x" is read-only (Firefox)
TypeError: Attempted to assign to readonly property. (Safari)
```

Error type

`TypeError` in strict mode only.

What went wrong?

The global variable or object property that was assigned to is a read-only property. (Technically, it is a non-writable data property.)

This error happens only in strict mode code. In non-strict code, the assignment is silently ignored.

Examples

Invalid cases

Read-only properties are not super common, but they can be created using `Object.defineProperty()` or `Object.freeze()`.

```
"use strict";
const obj = Object.freeze({ name: "Elsa", score: 157 });
obj.score = 0; // TypeError

("use strict");
Object.defineProperty(this, "LUNG_COUNT", { value: 2, writable: false });
LUNG_COUNT = 3; // TypeError

("use strict");
const frozenArray = Object.freeze([0, 1, 2]);
frozenArray[0]++; // TypeError
```

There are also a few read-only properties built into JavaScript. Maybe you tried to redefine a mathematical constant.

```
"use strict";
Math.PI = 4; // TypeError
```

Sorry, you can't do that.

The global variable `undefined` is also read-only, so you can't silence the infamous "undefined is not a function" error by doing this:

```
"use strict";
undefined = function () {}; // TypeError: "undefined" is read-only
```

Valid cases

```
"use strict";
let obj = Object.freeze({ name: "Score", points: 157 });
obj = { name: obj.name, points: 0 }; // replacing it with a new object works
```

See also

- `Object.defineProperty()`
- `Object.freeze()`

SyntaxError: redeclaration of formal parameter "x"

The JavaScript exception "redeclaration of formal parameter" occurs when the same variable name occurs as a function parameter and is then redeclared using a `let` assignment in a function body again.

Message

```
SyntaxError: Identifier "x" has already been declared (V8-based)
SyntaxError: redeclaration of formal parameter "x" (Firefox)
SyntaxError: Cannot declare a let variable twice: 'x'. (Safari)
```

Error type

`SyntaxError`

What went wrong?

The same variable name occurs as a function parameter and is then redeclared using a `let` assignment in a function body again. Redeclaring the same variable within the same function or block scope using `let` is not allowed in JavaScript.

Examples

Redeclared argument

In this case, the variable "arg" redeclares the argument.

```
function f(arg) {
  let arg = "foo";
}

// SyntaxError: redeclaration of formal parameter "arg"
```

If you want to change the value of "arg" in the function body, you can do so, but you do not need to declare the same variable again. In other words: you can omit the `let` keyword. If you want to create a new variable, you need to rename it as conflicts with the function parameter already.

```
function f(arg) {
  arg = "foo";
}

function g(arg) {
  let bar = "foo";
}
```

TypeError: Reduce of empty array with no initial value

The JavaScript exception "reduce of empty array with no initial value" occurs when a reduce function is used.

Message

```
TypeError: Reduce of empty array with no initial value (V8-based & Firefox & Safari)
```

Error type

`TypeError`

What went wrong?

In JavaScript, there are several reduce functions:

- `Array.prototype.reduce()`, `Array.prototype.reduceRight()` and
- `TypedArray.prototype.reduce()`, `TypedArray.prototype.reduceRight()`).

These functions optionally take an `initialValue` (which will be used as the first argument to the first call of the `callback`). However, if no initial value is provided, it will use the first element of the `Array` or `TypedArray` as the initial value. This error is raised when an empty array is provided because no initial value can be returned in that case.

Examples

Invalid cases

This problem appears frequently when combined with a filter (`Array.prototype.filter()`, `TypedArray.prototype.filter()`) which will remove all elements of the list. Thus leaving none to be used as the initial value.

```
const ints = [0, -1, -2, -3, -4, -5];
ints
  .filter((x) => x > 0) // removes all elements
  .reduce((x, y) => x + y); // no more elements to use for the initial value.
```

Similarly, the same issue can happen if there is a typo in a selector, or an unexpected number of elements in a list:

```
const names = document.getElementsByClassName("names");
const nameList = Array.prototype.reduce.call(
  names,
  (acc, name) => `${acc}, ${name}`,
);
```

Valid cases

These problems can be solved in two different ways.

One way is to actually provide an `initialValue` as the neutral element of the operator, such as 0 for the addition, 1 for a multiplication, or an empty string for a concatenation.

```
const ints = [0, -1, -2, -3, -4, -5];
ints
  .filter((x) => x > 0) // removes all elements
  .reduce((x, y) => x + y, 0); // the initial value is the neutral element of the addition
```

Another way would be to handle the empty case, either before calling `reduce`, or in the callback after adding an unexpected dummy initial value.

```
const names = document.getElementsByClassName("names");

let nameList1 = "";
if (names.length >= 1) {
  nameList1 = Array.prototype.reduce.call(
    names,
    (acc, name) => `${acc}, ${name}`,
  );
}
// nameList1 === "" when names is empty.

const nameList2 = Array.prototype.reduce.call(
  names,
  (acc, name) => {
    if (acc === "")
      // initial value
      return name;
    return `${acc}, ${name}`;
  },
  "",
);
// nameList2 === "" when names is empty.
```

- `TypedArray.prototype.filter()`

SyntaxError: \ at end of pattern

The JavaScript exception "\ at end of pattern" occurs when a regular expression pattern ends with an unescaped backslash (`\`). In a regex literal, the backslash would cause the closing slash `/` to be a literal character, so this can only appear when using the `RegExp()` constructor.

Message

```
SyntaxError: Invalid regular expression: /\/: \ at end of pattern (V8-based)
SyntaxError: \ at end of pattern (Firefox)
SyntaxError: Invalid regular expression: \ at end of pattern (Safari)
```

Error type

`SyntaxError`

What went wrong?

A backslash cannot appear literally in a regular expression. It either precedes another character to escape it, or is itself escaped by another backslash. A backslash at the end of a regular expression pattern is invalid because it is not escaping anything.

Examples

Double-escaping backslashes

This error can only happen when using the `RegExp()` constructor. Consider the following code, which intends to match a single backslash character:

```
const pattern = new RegExp("\\");
```

In JavaScript strings, backslashes are also escape sequences. Therefore, the two backslashes in the string literal `"\\"` are interpreted as a single backslash. The `RegExp()` constructor then only sees a single backslash character in the regex source. To fix this, you need to double-escape the backslash:

```
const pattern = new RegExp("\\\\");
```

The four backslashes in the string literal represent two backslashes in the regex source, which then becomes a character escape for a single backslash literal character.

- Regular expressions
- Escape sequences

SyntaxError: character class escape cannot be used in class range in regular expression

The JavaScript exception "character class escape cannot be used in class range in regular expression" occurs when a Unicode-aware regular expression pattern contains a character class where a boundary of a character range is another character class, such as a character class escape.

Message

```
SyntaxError: Invalid regular expression: /[\s-1]/u: Invalid character class (V8-based)
SyntaxError: character class escape cannot be used in class range in regular expression (Firefox)
SyntaxError: Invalid regular expression: invalid range in character class for Unicode pattern (Safari)
```

Error type

`SyntaxError`

What went wrong?

A character class can specify a range of characters by using a hyphen (`-`) between two characters. For example, `[a-z]` matches any lowercase letter from `a` to `z`. The two bounds of the range must represent single characters in order for the range to make sense. If one of the bounds actually represents multiple characters, an error is generated. In non-v-mode character classes, only character class escapes are allowed inside character classes; in v-mode character classes, this can also happen if one the bounds is another `[...]` character class.

In Unicode-unaware mode, this syntax causes the `-` to become a literal character instead of generating an error, but this is a deprecated syntax and you should not rely on it.

Examples

Invalid cases

```
/[\s-_]/u; // \s is a character class escape for whitespace
/[A-\D]/u; // \D is a character class escape for non-digits
/[\p{L}-\p{N}]/u; // \p{L} is a character class escape for Unicode letters
/[[A-z]-_]/v; // In unicodeSets mode, character classes can be nested
```

Valid cases

```
// Put the hyphen at the start of the character class,
// so it matches the literal character
/[-\s_]/u;
// Escape the hyphen so it also matches the literal character
/[\s\-_]/u;
// Remove the backslash so the bound is a literal character
/[A-D]/u;
// Remove the hyphen so the two bounds represent two alternatives
/[\p{L}\p{N}]/u;
// Use -- in unicodeSets mode, which represents set subtraction
/[[A-z]--_]/v;
```

SyntaxError: duplicate capture group name in regular expression

The JavaScript exception "duplicate capture group name in regular expression" occurs when a regular expression pattern contains two or more named capturing groups with the same name, and these capture groups could be matched at the same time.

Message

```
SyntaxError: Invalid regular expression: /(?<a>)(?<a>)/: Duplicate capture group name (V8-based)
SyntaxError: duplicate capture group name in regular expression (Firefox)
SyntaxError: Invalid regular expression: duplicate group specifier name (Safari)
```

Error type

`SyntaxError`

What went wrong?

All named capturing groups in a regular expression pattern must have unique names. A more recent feature allows named capturing groups to share names, as long as they belong to different disjunction alternatives and cannot be matched at the same time (see browser compatibility for this). However, it is still an error if the named capturing groups with the same name could be matched at the same time, as that would make other features, such as named backreferences, ambiguous.

Examples

Invalid cases

```
/(?<name>\w+) (?<name>\w+)/;
```

Valid cases

```
/(?<firstName>\w+) (?<lastName>\w+)/;
/(?<year>\d{4})-\d{2}|\d{2}-(?<year>\d{4})/;
```

See also

- Regular expressions
- Named capturing group: `(?<name>...)`

SyntaxError: incomplete quantifier in regular expression

The JavaScript exception "incomplete quantifier in regular expression" occurs when a regular expression pattern contains a `{`, but it does not start a valid quantifier.

Message

```
SyntaxError: Invalid regular expression: /1{/u: Incomplete quantifier (V8-based)
SyntaxError: incomplete quantifier in regular expression (Firefox)
SyntaxError: Invalid regular expression: incomplete {} quantifier for Unicode pattern (Safari)
```

Error type

`SyntaxError`

What went wrong?

A `{` character in a regular expression pattern starts a quantifier. A valid quantifier is in the form `{n}`, `{n,}`, or `{n,m}`, where `n` and `m` are non-negative integers and `m` is not less than `n`. If the `{` character does not start a valid quantifier, a `SyntaxError` occurs.

In Unicode-unaware mode, this syntax causes the `{` to become a literal character instead of generating an error, but this is a deprecated syntax and you should not rely on it.

Examples

Invalid cases

```
/1{/u;
/1{a}/u;
/1{}/u;
/1{1,2,3}/u;
/1{1, 2}/u;
```

Valid cases

```
/1{1}/u;
/1{1,}/u;
/1{1,2}/u;
```

See also

- Regular expressions
- Quantifier: `*`, `+`, `?`, `{n}`, `{n,}`, `{n,m}`

SyntaxError: invalid capture group name in regular expression

The JavaScript exception "invalid capture group name in regular expression" occurs when a named capturing group or named backreference contains an invalid identifier.

Message

```
SyntaxError: Invalid regular expression: /(?<1>)/: Invalid capture group name (V8-based)
SyntaxError: invalid capture group name in regular expression (Firefox)
SyntaxError: Invalid regular expression: invalid group specifier name (Safari)
```

Error type

`SyntaxError`

What went wrong?

Each named capturing group must have a name that is a valid identifier. You cannot use arbitrary strings as the group identifier.

Examples

Invalid cases

```
/(?<1>\d+) (?<2>\d+)/;
```

Or you might be building the regex dynamically:

```
const tokenTypes = {
  "number literal": /\d+/,
  "string literal": /".+?"/,
  identifier: /[a-zA-Z_]\w*/,
```

```
};

const tokenPattern = new RegExp(
  Object.entries(tokenTypes)
    .map(([name, pattern]) => `(?<${name}>${pattern.source})`)
    .join("|"),
);
```

Valid cases

```
/(?<group1>\d+) (?<group2>\d+)/;
```

If the regex is built dynamically, make sure the names are all valid identifiers. For example:

```
const tokenTypes = {
  numberLiteral: /\d+/,
  stringLiteral: /".+?"/,
  identifier: /[a-zA-Z_]\w*/,
};

const tokenPattern = new RegExp(
  Object.entries(tokenTypes)
    .map(([name, pattern]) => `(?<${name}>${pattern.source})`)
    .join("|"),
);
```

See also

- Regular expressions
- Named capturing group: `(?<name>...)`

SyntaxError: invalid character in class in regular expression

The JavaScript exception "invalid character in class in regular expression" occurs when a character appears in a v-mode character class but it's not allowed to appear literally.

Message

```
SyntaxError: Invalid regular expression: /[|]/v: Invalid character in character class (V8-based)
SyntaxError: invalid character in class in regular expression (Firefox)
SyntaxError: Invalid regular expression: invalid class set character (Safari)
```

Error type

`SyntaxError`

What went wrong?

Normally, character classes can contain almost all characters literally. However, the `v` mode made the character class syntax more sophisticated, and in order to leave room for future syntax extensions, some syntax characters are forbidden from appearing literally in a character class. They include: `(`, `)`, `[`, `]`, `{`, `}`, `/`, `-`, `|`. If you want to match these literal characters, escape them; for example: `/[\|]/v`.

Examples

Invalid cases

```
/[(){}]/v;
```

Valid cases

```
/[\(\)\{\}]/v;
```

See also

- Regular expressions
- Character class: `[...]`, `[^...]`

SyntaxError: invalid class set operation in regular expression

The JavaScript exception "invalid class set operation in regular expression" occurs when a double punctuator sequence appears in a v-mode character class but it is not recognized by the syntax.

Message

```
SyntaxError: Invalid regular expression: /[&&]/v: Invalid set operation in character class (V8-based)
SyntaxError: invalid class set operation in regular expression (Firefox)
SyntaxError: Invalid regular expression: invalid operation in class set (Safari)
```

Error type

`SyntaxError`

What went wrong?

There are three possible ways this could happen:

- You are trying to use `&&` or `--`, but the syntax is wrong. Each of these operators must join two characters or character sets.
- You are mixing operators on the same level. For example, `[\w&&[A-z]--_]` is invalid because it uses `&&` and `--` on the same level. You need to use nested character classes to disambiguate, such as `[\w&&[[A-z]--_]]`. Note that the union operation uses an operator that has no text; for example, `[AB&&C]` is invalid because `A` and `B` are implicitly joined by the union operator. You need to use `[A[B&&C]]` instead.
- You are using a double punctuator sequence that's not `&&` or `--`. These sequences are reserved for future syntax extensions. They include: `&&`, `!!`, `##`, `$$`, `%%`, `**`, `++`, `,,`, `..`, `::`, `;;`, `<<`, `==`, `>>`, `??`, `@@`, `^^`, `` `` ``, `~~`. However, these sequences don't make much sense anyway, and can either be replaced with a single character or cause two adjacent ranges to be merged.

See also

- Regular expressions
- Character class: `[...]`, `[^...]`

SyntaxError: invalid decimal escape in regular expression

The JavaScript exception "invalid decimal escape in regular expression" occurs when a legacy octal escape sequence is used in a Unicode-aware regular expression pattern.

Message

```
SyntaxError: Invalid regular expression: /\00/u: Invalid decimal escape (V8-based)
SyntaxError: invalid decimal escape in regular expression (Firefox)
SyntaxError: Invalid regular expression: invalid octal escape for Unicode pattern (Safari)
```

Error type

`SyntaxError`

What went wrong?

In a regular expression, `\0` followed by another digit is a *legacy octal escape sequence*. The same syntax is banned in template strings and strict-mode string literals. In regexes, this feature is disabled by the Unicode-aware modes (`u` and `v`). `\0` *not* followed by another digit is a valid escape sequence that represents the null character (U+0000).

`\` followed by a non-zero digit is a backreference, and is invalid in Unicode-aware mode if it doesn't refer to a capturing group; see invalid identity escape for more information.

Examples

Invalid cases

```
/\00/u;
/\01/u;
```

Valid cases

```
// If you want to match NULL followed by a digit, use a character class
/[\0]0/u;
// If you want to match a character by its character value, use \x
/\x01/u;
```

See also

- Regular expressions
- Escape sequences
- Character escape: `\n`, `\u{...}`

SyntaxError: invalid regexp group

The JavaScript exception "invalid regexp group" occurs when the sequence `(?` does not start a valid group syntax. Recognized group syntaxes that start with `(?` include:

- `(?:` for non-capturing groups
- `(?=` for positive lookahead
- `(?!` for negative lookahead
- `(?<=` for positive lookbehind
- `(?<!` for negative lookbehind
- `(?<` for named capturing groups
- `(?-i:`, `(?i:`, `(?m:`, `(?ims-:`, etc. for modifiers

`(?` followed by any other character would cause this error.

Message

```
SyntaxError: Invalid regular expression: /(?1)/: Invalid group (V8-based)
SyntaxError: invalid regexp group (Firefox)
SyntaxError: Invalid regular expression: unrecognized character after (? (Safari)
```

Error type

`SyntaxError`

What went wrong?

`?` is not an atom, so it does not make sense to appear at the start of a capturing group (`?` is a quantifier and should be placed after an atom). Maybe you want to match the `?` character literally, in which case you should escape it with a backslash (`\?`). Maybe you remembered the regex syntax wrong, and you intend to use one of the recognized group syntaxes listed above. Maybe you are using a feature that is not supported by the current JavaScript engine.

Examples

Invalid cases

```
/Hello(?|!)/;
// This is Perl syntax
/(?[\p{Thai}&\p{Digit}])/;
```

Valid cases

```
/Hello(\?|!)/;
// This is JavaScript syntax for character set operations
/[\p{Script=Thai}&&\p{Nd}]/v;
```

See also

- Non-capturing group: `(?:...)`

SyntaxError: invalid identity escape in regular expression

The JavaScript exception "invalid identity escape in regular expression" occurs when a Unicode-aware regular expression pattern contains an escape sequence that does not represent a recognized escape sequence.

Message

```
SyntaxError: Invalid regular expression: /\q/u: Invalid escape (V8-based)
SyntaxError: invalid identity escape in regular expression (Firefox)
SyntaxError: Invalid regular expression: invalid escaped character for Unicode pattern (Safari)
```

Error type

`SyntaxError`

What went wrong?

In Unicode-unaware mode, `\` could be used to escape any character, including those without a defined meaning. In these cases, the escaped character represents itself. For example, `\q` would match the character `q`. This severely limits the ability to add new escape sequences in the future, so in Unicode-aware mode, only recognized escape sequences are allowed. Do not add `\` redundantly.

This error is also thrown when the `\x` character escape is not followed by two hexadecimal digits.

For an exhaustive list of available escape sequences, see the regular expressions reference. For a table of which characters can appear literally escaped or unescaped in each context, see literal characters.

Examples

Invalid cases

```
/[\f\v\n\t\ ]/u;
```

Valid cases

```
// There's no need to escape the space
/[\f\v\n\t ]/u;
```

- Literal character: `a`, `b`

SyntaxError: invalid named capture reference in regular expression

The JavaScript exception "invalid named capture reference in regular expression" occurs when a regular expression pattern contains a named backreference that does not refer to a named capture group before it. The similar error message "invalid named reference in regular expression" is thrown when the sequence `\k` is encountered but is not followed by `<`.

Message

```
SyntaxError: Invalid regular expression: /\k<x>/u: Invalid named capture referenced (V8-based)
SyntaxError: invalid named capture reference in regular expression (Firefox)
SyntaxError: Invalid regular expression: invalid \k<> named backreference (Safari)

SyntaxError: Invalid regular expression: /\k/u: Invalid named reference (V8-based)
SyntaxError: invalid named reference in regular expression (Firefox)
SyntaxError: Invalid regular expression: invalid escaped character for Unicode pattern (Safari)
```

Error type

`SyntaxError`

What went wrong?

You are using the escape sequence `\k` which is parsed as a named backreference, but the `\k` is either syntactically invalid or does not refer to a named capture group in the pattern.

`\k` only starts a named backreference when the pattern contains a named capturing group or when the pattern is Unicode-aware; otherwise, it is an identity escape for the character `k`.

Examples

Invalid cases

```
/\k<x>/u; // Does not refer to a named capture group
/(?<x>.+)\k<y>/u; // Does not refer to an existing named capture group
/(?<x>.+)\k{x}/u; // Invalid syntax
```

Valid cases

```
/(?<x>.+)\k<x>/u; // Refers to an existing named capture group
```

See also

- Regular expressions
- Named backreference: `\k<name>`
- Named capturing group: `(?<name>...)`

SyntaxError: invalid property name in regular expression

The JavaScript exception "invalid property name in regular expression" or "invalid class property name in regular expression" occurs when the `\p` and `\P` Unicode character class escapes are not followed by a valid Unicode property name and/or value.

Message

```
SyntaxError: Invalid regular expression: /\p{x}/u: Invalid property name (V8-based)
SyntaxError: Invalid regular expression: /[\p{x}]/u: Invalid property name in character class (V8-based)
SyntaxError: invalid property name in regular expression (Firefox)
SyntaxError: invalid class property name in regular expression (Firefox)
SyntaxError: Invalid regular expression: invalid property expression (Safari)
```

Error type

`SyntaxError`

What went wrong?

In Unicode-aware mode, the `\p` and `\P` escape sequences are used to match characters or character sequences based on their Unicode properties. The `\p` escape sequence matches characters with the specified Unicode property, while the `\P` escape sequence matches characters without the specified Unicode property. The syntax is:

```
\p{loneProperty}
\P{loneProperty}

\p{property=value}
\P{property=value}
```

If it's not followed by `{`, then a recognizable property name/value, then `}`, this syntax error is thrown. For more information on what lone properties and property names are allowed, see the Unicode character class escape reference.

Examples

Invalid cases

```
/\p{x}/u; // "x" is not a valid Unicode property name
/\p{Script=x}/u; // "x" is not a valid value for Script
```

```
/\property/u; // "\p" is not followed by the right syntax
/\p{RGI_Emoji_Flag_Sequence}/u;
// "RGI_Emoji_Flag_Sequence" is a property of strings, so the "v" flag must be used
/\P{RGI_Emoji_Flag_Sequence}/v; // \P cannot match properties of strings
```

Valid cases

```
/\p{Script=Latin}/u; // "Script=Latin" is a valid Unicode property
/\p{Letter}/u; // "Letter" is valid value for General_Category
/\p{RGI_Emoji_Flag_Sequence}/v; // Property of strings can only be used in "v" mode
```

- Regular expressions
- Unicode character class escape: `\p{...}`, `\P{...}`

SyntaxError: invalid range in character class

The JavaScript exception "invalid range in character class" occurs when a character class in a regular expression uses a range, but the start of the range is greater than the end.

Message

```
SyntaxError: Invalid regular expression: /[2-1]/: Range out of order in character class (V8-based)
SyntaxError: invalid range in character class (Firefox)
SyntaxError: Invalid regular expression: range out of order in character class (Safari)
```

Error type

`SyntaxError`

What went wrong?

In character classes, you can join two characters with a hyphen `-` to represent an inclusive interval of characters based on their Unicode code points. For example, `[a-z]` matches any lowercase letter. However, if the end of the range is less than the start, the range cannot match anything and is likely a mistake.

Examples

Invalid cases

```
/[9-1]/; // The range is out of order
/[_-=]/; // _ has value 95, = has value 61
```

Valid cases

```
/[1-9]/; // Swap the range
/[_\-=]/; // Escape the hyphen so it matches the literal character
```

See also

- Regular expressions
- Character class: `[...]`, `[^...]`

SyntaxError: invalid unicode escape in regular expression

The JavaScript exception "invalid unicode escape in regular expression" occurs when the `\c` and `\u` character escapes are not followed by valid characters.

Message

```
SyntaxError: Invalid regular expression: /\u{123456}/u: Invalid Unicode escape (V8-based)
SyntaxError: invalid unicode escape in regular expression (Firefox)
SyntaxError: Invalid regular expression: invalid Unicode code point \u{} escape (Safari)
```

Error type

`SyntaxError`

What went wrong?

In Unicode-aware mode, the `\c` escape sequence must be followed by a letter from `A` to `Z` or `a` to `z`, and the `\u` escape sequence must either be followed by 4 hexadecimal digits, or 1 to 6 hexadecimal digits enclosed in curly braces (`{}`). Furthermore, when using the `\u{xxx}` escape sequence, the digits must represent a valid Unicode code point, which means its value cannot exceed `10FFFF`.

Examples

Invalid cases

```
/\u{123456}/u; // Unicode code point is too large
/\u65/u; // Not enough digits
/\c1/u; // Not a letter
```

Valid cases

```
/\u0065/u; // Lowercase "e"
/\u{1f600}/u; // Grinning face emoji
/\cA/u; // U+0001 (Start of Heading)
```

- Regular expressions
- Character escape: `\n`, `\u{...}`

SyntaxError: negated character class with strings in regular expression

The JavaScript exception "negated character class with strings in regular expression" occurs when a v-mode character class is negated and may be able to match a string (more than one character).

Message

```
SyntaxError: Invalid regular expression: /[^\p{RGI_Emoji_Flag_Sequence}]/v: Negated character class may contain strings (V8-based)
SyntaxError: negated character class with strings in regular expression (Firefox)
SyntaxError: Invalid regular expression: negated class set may contain strings (Safari)
```

Error type

`SyntaxError`

What went wrong?

In `v` mode, character classes are able to match more than 1 character. For example, `/[\q{abc}]/v` would match the sequence `"abc"`, and `/[\p{RGI_Emoji_Flag_Sequence}]/v` would match any character sequence that represents an emoji flag. However, negated character classes `[^...]` are not allowed to match strings, so `/[^\p{RGI_Emoji_Flag_Sequence}]/v` is invalid, because it's unclear how many characters it should match. For more information, see the v-mode character class reference.

Examples

Invalid cases

```
/[^\p{RGI_Emoji_Flag_Sequence}]/v;
```

Valid cases

```
// Matches two characters that are not an emoji flag sequence
/(?!\p{RGI_Emoji_Flag_Sequence})../v;
```

See also

- Regular expressions
- Character class: `[...]`, `[^...]`
- Unicode character class escape: `\p{...}`, `\P{...}`

SyntaxError: nothing to repeat

The JavaScript exception "nothing to repeat" or "invalid quantifier in regular expression" occurs when a quantifier in a regular expression is applied to nothing or applied to an assertion.

Message

```
SyntaxError: Invalid regular expression: /\b+/: Nothing to repeat (V8-based)
SyntaxError: Invalid regular expression: /(?=)+/u: Invalid quantifier (V8-based)
SyntaxError: nothing to repeat (Firefox)
SyntaxError: invalid quantifier in regular expression (Firefox)
SyntaxError: Invalid regular expression: nothing to repeat (Safari)
```

Error type

`SyntaxError`

What went wrong?

Quantifiers are used to specify how many times a character or group of characters can appear in a regular expression. For example, `a{3}` matches the character `a` exactly three times. Therefore, if the thing preceding the quantifier is not something that matches characters, the quantifier is invalid. For example: quantifiers at the start of a capturing group, at the start of a disjunction alternative, etc., cannot repeat anything. Assertions don't consume characters, so it also doesn't make sense to repeat them.

In Unicode-unaware mode, there's a deprecated syntax that allows the lookahead assertions to be quantified. This is a deprecated syntax and you should not rely on it.

Examples

Invalid cases

```
/\b+/; // \b is a word boundary assertion, it doesn't consume characters
/(*hello*)/;
```

Valid cases

```
/b+/; // b is a character, it can be repeated
/(\*hello\*)/; // Escape the asterisks to match them literally
```

See also

- Regular expressions
- Quantifier: `*`, `+`, `?`, `{n}`, `{n,}`, `{n,m}`

SyntaxError: numbers out of order in {} quantifier.

The JavaScript exception "numbers out of order in {} quantifier" occurs when a quantifier in a regular expression uses the `{n,m}` syntax but `m` is less than `n`.

Message

```
SyntaxError: Invalid regular expression: /1{2,1}/: numbers out of order in {} quantifier (V8-based)
SyntaxError: numbers out of order in {} quantifier. (Firefox)
SyntaxError: Invalid regular expression: numbers out of order in {} quantifier (Safari)
```

Error type

`SyntaxError`

What went wrong?

The `{n,m}` syntax in a regular expression is used to specify that the preceding item is to be matched at least `n` times, but not more than `m` times. If `m` is less than `n`, the quantifier is nonsensical because, for example, a character cannot appear at least 2 times but not more than 1 time. Therefore, an error is thrown.

Examples

Invalid examples

```
/1{2,1}/;
```

Valid examples

```
/1{1,2}/;
```

See also

- Regular expressions
- Quantifier: `*`, `+`, `?`, `{n}`, `{n,}`, `{n,m}`

SyntaxError: raw bracket is not allowed in regular expression with unicode flag

The JavaScript exception "raw bracket is not allowed in regular expression with unicode flag" occurs when a Unicode-aware regular expression pattern contains a raw bracket (`{`, `}`, `]`) that is not part of a quantifier or character class.

Message

```
SyntaxError: Invalid regular expression: /{/u: Lone quantifier brackets (V8-based)
SyntaxError: raw bracket is not allowed in regular expression with unicode flag (Firefox)
SyntaxError: Invalid regular expression: incomplete {} quantifier for Unicode pattern (Safari)
SyntaxError: Invalid regular expression: unmatched ] or } bracket for Unicode pattern (Safari)
```

Error type

`SyntaxError`

What went wrong?

In Unicode-unaware mode, `{`, `}`, and `]` that are not part of a quantifier or character class are treated as literal characters. This may hide errors in your code and is therefore deprecated and disallowed in Unicode-aware mode. You should either check whether you have invalid syntax or you should escape the characters to match them literally.

If `{` appears in a context that accepts a quantifier, it is treated as the start of a quantifier. If what follows it is not a valid quantifier, another syntax error, incomplete quantifier, is thrown.

Examples

Invalid cases

```
/{{MDN_Macro}}/u;
/\[sic]/u;
```

Valid cases

```
// All { and } need to be escaped
/\{\{MDN_Macro\}\}/u;
```

```
// The ] needs to be escaped
/\[sic\]/u;
```

TypeError: matchAll/replaceAll must be called with a global RegExp

The JavaScript exception "TypeError: matchAll/replaceAll must be called with a global RegExp" occurs when the `String.prototype.matchAll()` or `String.prototype.replaceAll()` method is used with a `RegExp` object that does not have the `global` flag set.

Message

```
TypeError: String.prototype.matchAll called with a non-global RegExp argument (V8-based)
TypeError: String.prototype.replaceAll called with a non-global RegExp argument (V8-based)
TypeError: matchAll must be called with a global RegExp (Firefox)
TypeError: replaceAll must be called with a global RegExp (Firefox)
TypeError: String.prototype.matchAll argument must not be a non-global regular expression (Safari)
TypeError: String.prototype.replaceAll argument must not be a non-global regular expression (Safari)
```

Error type

`TypeError`

What went wrong?

The `String.prototype.matchAll()` and `String.prototype.replaceAll()` methods require a `RegExp` object with the `global` flag set. This flag indicates that the regular expression can match all locations of the input string, instead of stopping at the first match. Although the `g` flag is redundant when using these methods (because these methods always do a global replacement), they are still required to make the intention clear.

It's worth noting that the `g` flag validation is done in the `matchAll` and `replaceAll` methods. If you use the `[Symbol.matchAll]()` method of `RegExp` instead, you won't get this error, but there will only be a single match.

Examples

Invalid cases

```
"abc".matchAll(/./); // TypeError
"abc".replaceAll(/./, "f"); // TypeError
```

Valid cases

If you intend to do global matching/replacement: either add the `g` flag, or construct a new `RegExp` object with the `g` flag, if you want to keep the original regex unchanged.

```
[..."abc".matchAll(/./g)]; // [[ "a" ], [ "b" ], [ "c" ]]
"abc".replaceAll(/./g, "f"); // "fff"

const existingPattern = /./;
const newPattern = new RegExp(
  existingPattern.source,
  `${existingPattern.flags}g`,
);
"abc".replaceAll(newPattern, "f"); // "fff"
```

If you only intend to do a single matching/replacement: use `String.prototype.match()` or `String.prototype.replace()` instead. You can also use the `[Symbol.matchAll]()` method if you want an iterator like `matchAll` returns that only contains one match, but doing so will be very confusing.

```
"abc".match(/./); // [ "a" ]
"abc".replace(/./, "f"); // "fbc"

[..././[Symbol.matchAll]("abc")]; // [[ "a" ]]
```

See also

- `String.prototype.matchAll()`
- `String.prototype.replaceAll()`
- `RegExp.prototype.global`

SyntaxError: "x" is a reserved identifier

The JavaScript exception "*variable* is a reserved identifier" occurs when reserved keywords are used as identifiers.

Message

```
SyntaxError: Unexpected reserved word (V8-based)
SyntaxError: implements is a reserved identifier (Firefox)
```

```
SyntaxError: Cannot use the reserved word 'implements' as a variable name. (Safari)
```

Error type

`SyntaxError`

What went wrong?

Reserved keywords will throw in if they are used as identifiers. These are reserved in strict mode and sloppy mode:

- `enum`

The following are only reserved when they are found in strict mode code:

- `implements`
- `interface`
- `let`
- `package`
- `private`
- `protected`
- `public`
- `static`

Examples

Strict and non-strict reserved keywords

The `enum` identifier is generally reserved.

```
const enum = { RED: 0, GREEN: 1, BLUE: 2 };
// SyntaxError: enum is a reserved identifier
```

In strict mode code, more identifiers are reserved.

```
"use strict";
const package = ["potatoes", "rice", "fries"];
// SyntaxError: package is a reserved identifier
```

You'll need to rename these variables.

```
const colorEnum = { RED: 0, GREEN: 1, BLUE: 2 };
const list = ["potatoes", "rice", "fries"];
```

Update older browsers

If you are using an older browser that does not yet implement `let` or `class`, for example, you should update to a more recent browser version that does support these new language features.

```
"use strict";
class DocArchiver {}

// SyntaxError: class is a reserved identifier
// (throws in older browsers only, e.g. Firefox 44 and older)
```

See also

- Lexical grammar

SyntaxError: rest parameter may not have a default

The JavaScript exception "rest parameter may not have a default" occurs when a rest parameter has a default value. Because the rest parameter always creates an array, the default value would never apply.

Message

```
SyntaxError: Rest parameter may not have a default initializer (V8-based)
SyntaxError: rest parameter may not have a default (Firefox)
SyntaxError: Unexpected token '='. Expected a ')' or a ',' after a parameter declaration. (Safari)
```

Error type

`SyntaxError`

What went wrong?

A default parameter gives a parameter a default value if the argument is not passed or passed as `undefined`. A rest parameter collects all the remaining arguments passed to the function and always creates an array. Therefore, it doesn't make sense to have a default value for a rest parameter.

Examples

Invalid cases

```
function doSomething(...args = []) {}
```

Valid cases

```
function doSomething(...args) {
  // args is always an array
}
```

See also

- Functions
- Default parameters
- Rest parameters

RangeError: repeat count must be less than infinity

The JavaScript exception "repeat count must be less than infinity" occurs when the `String.prototype.repeat()` method is used with a `count` argument that is infinity.

Message

```
RangeError: Invalid string length (V8-based)
RangeError: Invalid count value: Infinity (V8-based)
RangeError: repeat count must be less than infinity and not overflow maximum string size (Firefox)
RangeError: Out of memory (Safari)
RangeError: String.prototype.repeat argument must be greater than or equal to 0 and not be Infinity (Safari)
```

Error type

`RangeError`

What went wrong?

The `String.prototype.repeat()` method has been used. It has a `count` parameter indicating the number of times to repeat the string. It must be between 0 and less than positive `Infinity` and cannot be a negative number. The range of allowed values can be described like this: [0, +∞).

The resulting string can also not be larger than the maximum string size, which can differ in JavaScript engines. In Firefox (SpiderMonkey) the maximum string size is 2^{30} - 2 (~2GiB).

Examples

Invalid cases

```
"abc".repeat(Infinity); // RangeError
"a".repeat(2 ** 30); // RangeError
```

Valid cases

```
"abc".repeat(0); // ''
"abc".repeat(1); // 'abc'
"abc".repeat(2); // 'abcabc'
"abc".repeat(3.5); // 'abcabcabc' (count will be converted to integer)
```

See also

- `String.prototype.repeat()`

SyntaxError: setter functions must have one argument

The JavaScript exception "setter functions must have one argument" occurs when a setter is declared and the parameter list is not consisted of exactly one formal parameter.

Message

```
SyntaxError: Setter must have exactly one formal parameter. (V8-based)
SyntaxError: Setter function argument must not be a rest parameter (V8-based)
SyntaxError: setter functions must have one argument (Firefox)
SyntaxError: Unexpected token ','. setter functions must have one parameter. (Safari)
SyntaxError: Unexpected token '...'. Expected a parameter pattern or a ')' in parameter list. (Safari)
```

Error type

`SyntaxError`

What went wrong?

The `set` property syntax looks like a function, but it is stricter and not all function syntax is allowed. A setter is always invoked with exactly one argument, so defining it with any other number of parameters is likely an error. This parameter can be destructured or have a default value, but it cannot be a rest parameter.

Note that this error only applies to property setters using the `set` syntax. If you define the setter using `Object.defineProperty()`, etc., the setter is defined as a normal function, although it's likely still an error if the setter expects any other number of arguments, as it will be called with exactly one.

Examples

Invalid cases

```
const obj = {
  set value() {
    this._value = Math.random();
  },
};
```

Valid cases

```
// You must declare one parameter, even if you don't use it
const obj = {
  set value(_ignored) {
    this._value = Math.random();
  },
};

// You can also declare a normal method instead
const obj = {
  setValue() {
    this._value = Math.random();
  },
};
```

See also

- Functions
- `set`

Warning: unreachable code after return statement

The JavaScript warning "unreachable code after return statement" occurs when using an expression after a `return` statement, or when using a semicolon-less return statement but including an expression directly after.

Message

```
Warning: unreachable code after return statement (Firefox)
```

Error type

Warning

What went wrong?

Unreachable code after a return statement might occur in these situations:

- When using an expression after a `return` statement, or
- when using a semicolon-less return statement but including an expression directly after.

When an expression exists after a valid `return` statement, a warning is given to indicate that the code after the `return` statement is unreachable, meaning it can never be run.

Why should I have semicolons after `return` statements? In the case of semicolon-less `return` statements, it can be unclear whether the developer intended to return the statement on the following line, or to stop execution and return. The warning indicates that there is ambiguity in the way the `return` statement is written.

Warnings will not be shown for semicolon-less returns if these statements follow it:

- `throw`
- `break`
- `var`
- `function`

Examples

Invalid cases

```
function f() {
  let x = 3;
  x += 4;
  return x;   // return exits the function immediately
  x -= 3;     // so this line will never run; it is unreachable
}

function g() {
  return     // this is treated like `return;`
    3 + 4;   // so the function returns, and this line is never reached
}
```

Valid cases

```
function f() {
  let x = 3;
```

```
  x += 4;
  x -= 3;
  return x; // OK: return after all other statements
}

function g() {
  return 3 + 4 // OK: semicolon-less return with expression on the same line
}
```

See also

- Automatic semicolon insertion

SyntaxError: "use strict" not allowed in function with non-simple parameters

The JavaScript exception "`"use strict"` not allowed in function" occurs when a `"use strict"` directive is used at the top of a function with default parameters, rest parameters, or destructuring parameters.

Message

```
SyntaxError: Illegal 'use strict' directive in function with non-simple parameter list (V8-based)
SyntaxError: "use strict" not allowed in function with default parameter (Firefox)
SyntaxError: "use strict" not allowed in function with rest parameter (Firefox)
SyntaxError: "use strict" not allowed in function with destructuring parameter (Firefox)
SyntaxError: 'use strict' directive not allowed inside a function with a non-simple parameter list. (Safari)
```

Error type

`SyntaxError`.

What went wrong?

A `"use strict"` directive is written at the top of a function that has one of the following parameters:

- Default parameters
- Rest parameters
- Destructuring parameters

A `"use strict"` directive is not allowed at the top of such functions per the ECMAScript specification.

Examples

Function statement

In this case, the function `sum` has default parameters `a=1` and `b=2`:

```
function sum(a = 1, b = 2) {
  // SyntaxError: "use strict" not allowed in function with default parameter
  "use strict";
  return a + b;
}
```

If the function should be in strict mode, and the entire script or enclosing function is also okay to be in strict mode, you can move the `"use strict"` directive outside of the function:

```
"use strict";
function sum(a = 1, b = 2) {
  return a + b;
}
```

Function expression

A function expression can use yet another workaround:

```
const sum = function sum([a, b]) {
  // SyntaxError: "use strict" not allowed in function with destructuring parameter
  "use strict";
  return a + b;
};
```

This can be converted to the following expression:

```
const sum = (function () {
  "use strict";
  return function sum([a, b]) {
    return a + b;
  };
})();
```

Arrow function

If an arrow function needs to access the `this` variable, you can use the arrow function as the enclosing function:

```
const callback = (...args) => {
  // SyntaxError: "use strict" not allowed in function with rest parameter
  "use strict";
  return this.run(args);
};
```

This can be converted to the following expression:

```
const callback = (() => {
  "use strict";
  return (...args) => this.run(args);
})();
```

See also

- Strict mode
- function statement
- function expression
- Default parameters
- Rest parameters
- Destructuring parameters

SyntaxError: string literal contains an unescaped line break

The JavaScript error "string literal contains an unescaped line break" occurs when there is an unterminated string literal somewhere. String literals must be enclosed by single (') or double (") quotes and cannot split across multiple lines.

Message

```
SyntaxError: Invalid or unexpected token (V8-based)
SyntaxError: '' string literal contains an unescaped line break (Firefox)
SyntaxError: Unexpected EOF (Safari)
```

Error type

`SyntaxError`

What went wrong?

There is an unterminated string literal somewhere. String literals must be enclosed by single (') or double (") quotes. JavaScript makes no distinction between single-quoted strings and double-quoted strings. Escape sequences work in strings created with either single or double quotes. To fix this error, check if:

- you have opening and closing quotes (single or double) for your string literal,
- you have escaped your string literal correctly,
- your string literal isn't split across multiple lines.

Examples

Multiple lines

You can't split a string across multiple lines like this in JavaScript:

```
const longString = "This is a very long string which needs
                   to wrap across multiple lines because
                   otherwise my code is unreadable.";
// SyntaxError: unterminated string literal
```

Instead, use the + operator, a backslash, or template literals. The + operator variant looks like this:

```
const longString =
  "This is a very long string which needs " +
  "to wrap across multiple lines because " +
  "otherwise my code is unreadable.";
```

Or you can use the backslash character ("\") at the end of each line to indicate that the string will continue on the next line. Make sure there is no space or any other character after the backslash (except for a line break), or as an indent; otherwise it will not work. That form looks like this:

```
const longString =
  "This is a very long string which needs \
to wrap across multiple lines because \
otherwise my code is unreadable.";
```

Another possibility is to use template literals.

```
const longString = `This is a very long string which needs
to wrap across multiple lines because
otherwise my code is unreadable.`;
```

See also

- string literal

- Template literals

ReferenceError: super() called twice in derived class constructor

The JavaScript exception "super() called twice in derived class constructor" occurs when the `super()` is called a second time for a given derived class constructor.

Message

```
ReferenceError: Super constructor may only be called once (V8-based)
ReferenceError: super() called twice in derived class constructor (Firefox)
ReferenceError: 'super()' can't be called more than once in a constructor. (Safari)
```

Error type

`ReferenceError`

What went wrong?

The `super()` call can only be called at most once for each `new` call to a derived class constructor. This is because `super()` is responsible for initializing the parent class, and calling it more than once would result in the parent constructor being called multiple times.

The best way to prevent this is to ensure that `super()` is placed outside of any control flow structure. Otherwise, make sure that all code paths in the constructor lead to only one `super()` call.

The `super()` call can be "saved" in an arrow function nested within the constructor. Then, when you call the arrow function, you will also call `super()`, and the same rule applies: the arrow function can only be called at most once.

Examples

Invalid cases

```
class Base {}

class Derived extends Base {
  constructor() {
    super();
    super();
  }
}
```

Sometimes the bug may be more subtle.

```
class Base {
  constructor(flavor) {
    // Do something with the flavor
  }
}

class Derived extends Base {
  constructor(flavors) {
    if (flavors.includes("chocolate")) {
      super("chocolate");
    }
    if (flavors.includes("vanilla")) {
      super("vanilla");
    }
  }
}
```

Originally, `flavors` may never simultaneously include both "chocolate" and "vanilla", but if that ever happens, the constructor will call `super()` twice. You need to rethink about how your class should be structured to avoid this issue.

Valid cases

```
class Base {}

class Derived extends Base {
  constructor() {
    super();
    // More initialization logic
  }
}
```

See also

- `super`

ReferenceError: must call super constructor before using 'this' in derived class constructor

The JavaScript exception "must call super constructor before using 'this' in derived class constructor" occurs when the `super()` is not called for a given derived class constructor, and the derived constructor tries to access the value of `this`, or the derived constructor has already returned and the return value is not an object.

Message

```
ReferenceError: Must call super constructor in derived class before accessing 'this' or returning from derived constructor (V8-based)
ReferenceError: must call super constructor before using 'this' in derived class constructor (Firefox)
ReferenceError: 'super()' must be called in derived constructor before accessing |this| or returning non-object. (Safari)
```

Error type

`ReferenceError`

What went wrong?

The `super()` call can only be called at most once for each `new` call to a derived class constructor. Often, you need to call it exactly once, because if you don't call it, the parent constructor cannot initialize the value of `this`, so you cannot access `this` in the derived constructor and the `this` is not considered a valid constructed object (and throws if the derived constructor completes in this state). The way around it is to return an object from the derived class constructor, in which case the object returned will be used as the constructed object instead of `this`, allowing you to not call `super()`. This is rarely done though.

Examples

Invalid cases

```
class Base {
  constructor() {
    this.x = 1;
  }
}

class Derived extends Base {
  constructor() {
    console.log(this.x);
    // The Base constructor is not called yet, so this.x is undefined
    // ReferenceError: must call super constructor before using 'this' in derived class constructor
  }
}
```

Valid cases

```
class Base {
  constructor() {
    this.x = 1;
  }
}

class Derived extends Base {
  constructor() {
    super();
    console.log(this.x); // 1
  }
}
```

InternalError: too much recursion

The JavaScript exception "too much recursion" or "Maximum call stack size exceeded" occurs when there are too many function calls, or a function is missing a base case.

Message

```
RangeError: Maximum call stack size exceeded (Chrome)
InternalError: too much recursion (Firefox)
RangeError: Maximum call stack size exceeded. (Safari)
```

Error type

`InternalError` in Firefox; `RangeError` in Chrome and Safari.

What went wrong?

A function that calls itself is called a *recursive function*. Once a condition is met, the function stops calling itself. This is called a *base case*.

In some ways, recursion is analogous to a loop. Both execute the same code multiple times, and both require a condition (to avoid an infinite loop, or rather, infinite recursion in this case). When there are too many function calls, or a function is missing a base case, JavaScript will throw this error.

Examples

This recursive function runs 10 times, as per the exit condition.

```
function loop(x) {
  if (x >= 10)
```

```
    // "x >= 10" is the exit condition
    return;
  // do stuff
  loop(x + 1); // the recursive call
}
loop(0);
```

Setting this condition to an extremely high value, won't work:

```
function loop(x) {
  if (x >= 1000000000000) return;
  // do stuff
  loop(x + 1);
}
loop(0);

// InternalError: too much recursion
```

This recursive function is missing a base case. As there is no exit condition, the function will call itself infinitely.

```
function loop(x) {
  // The base case is missing
  loop(x + 1); // Recursive call
}

loop(0);

// InternalError: too much recursion
```

Class error: too much recursion

```
class Person {
  constructor() {}
  set name(name) {
    this.name = name; // Recursive call
  }
}

const tony = new Person();
tony.name = "Tonisha"; // InternalError: too much recursion
```

When a value is assigned to the property name (this.name = name;) JavaScript needs to set that property. When this happens, the setter function is triggered.

In this example when the setter is triggered, it is told to do the same thing again: *to set the same property that it is meant to handle.* This causes the function to call itself, again and again, making it infinitely recursive.

This issue also appears if the same variable is used in the getter.

```
class Person {
  get name() {
    return this.name; // Recursive call
  }
}
```

To avoid this problem, make sure that the property being assigned to inside the setter function is different from the one that initially triggered the setter. The same goes for the getter.

```
class Person {
  constructor() {}
  set name(name) {
    this._name = name;
  }
  get name() {
    return this._name;
  }
}
const tony = new Person();
tony.name = "Tonisha";
console.log(tony);
```

SyntaxError: reference to undeclared private field or method #x

The JavaScript exception "reference to undeclared private field or method #x" occurs when a private name is used, but this private name is not declared in the class scope.

Message

```
SyntaxError: Private field '#x' must be declared in an enclosing class (V8-based)
SyntaxError: reference to undeclared private field or method #x (Firefox)
SyntaxError: Cannot reference undeclared private names: "#x" (Safari)
```

Error type

`SyntaxError`

What went wrong?

Unlike normal string or symbol properties, which return `undefined` if the property does not exist, private names are very strict and can only be legally accessed if they actually exist. Accessing an undeclared private name will result in a syntax error, while accessing a private name that is declared but doesn't exist on the object will result in a type error.

Examples

Undeclared private field

You cannot access a private field that is not declared in the class scope.

```
class MyClass {
  doSomething() {
    console.log(this.#x);
  }
}
```

The same error occurs if you use the `in` operator to perform a check on an undeclared private field.

```
class MyClass {
  doSomething() {
    console.log(#x in this);
  }
}
```

These code are probably mistakes because it's impossible for `#x` to exist on `this` if it's not declared in the class scope. Note that you cannot dynamically *add* private elements to unrelated objects. You should either remove this code or declare the private field in the class scope.

```
class MyClass {
  #x = 0;
  doSomething() {
    console.log(this.#x);
  }
}
```

ReferenceError: assignment to undeclared variable "x"

The JavaScript strict mode-only exception "Assignment to undeclared variable" occurs when the value has been assigned to an undeclared variable.

Message

```
ReferenceError: x is not defined (V8-based)
ReferenceError: assignment to undeclared variable x (Firefox)
ReferenceError: Can't find variable: x (Safari)
```

Error type

`ReferenceError` in strict mode only.

What went wrong?

You have an assignment of the form `x = ...`, but `x` has not been previously declared with the `var`, `let`, or `const` keyword. This error occurs in strict mode code only. In non-strict code, assignment to an undeclared variable implicitly creates a property on the global scope.

Examples

Invalid cases

In this case, the variable "bar" is an undeclared variable.

```
function foo() {
  "use strict";
  bar = true;
}
foo(); // ReferenceError: assignment to undeclared variable bar
```

Valid cases

To make "bar" a declared variable, you can add a `let`, `const`, or `var` keyword in front of it.

```
function foo() {
  "use strict";
  const bar = true;
}
foo();
```

SyntaxError: Unexpected token

The JavaScript exceptions "unexpected token" occur when the parser does not see a token it recognizes at the given position, so it cannot make sense of the structure of the program. This might be a simple typo.

Message

```
SyntaxError: Unexpected token ';' (V8-based)
SyntaxError: Unexpected identifier 'x' (V8-based)
SyntaxError: Unexpected number (V8-based)
SyntaxError: Unexpected string (V8-based)
SyntaxError: Unexpected regular expression (V8-based)
SyntaxError: Unexpected template string (V8-based)

SyntaxError: unexpected token: identifier (Firefox)
SyntaxError: expected expression, got "x" (Firefox)
SyntaxError: expected property name, got "x" (Firefox)
SyntaxError: expected target, got "x" (Firefox)
SyntaxError: expected meta, got "x" (Firefox)
SyntaxError: expected rest argument name, got "x" (Firefox)
SyntaxError: expected closing parenthesis, got "x" (Firefox)
```

Error type

`SyntaxError`

What went wrong?

A specific language construct was expected, but something else was provided. This might be a simple typo.

Examples

Expression expected

For example, when chaining expressions, trailing commas are not allowed.

```
for (let i = 0; i < 5,; ++i) {
  console.log(i);
}
// Uncaught SyntaxError: expected expression, got ';'
```

Correct would be omitting the comma or adding another expression:

```
for (let i = 0; i < 5; ++i) {
  console.log(i);
}
```

Not enough parentheses

Sometimes, you leave out parentheses around `if` statements:

```
function round(n, upperBound, lowerBound) {
if (n > upperBound) || (n < lowerBound) { // Missing parentheses here!
    throw new Error(`Number ${n} is more than ${upperBound} or less than ${lowerBound}`);
  } else if (n < (upperBound + lowerBound) / 2) {
    return lowerBound;
  } else {
    return upperBound;
  }
} // SyntaxError: expected expression, got '||'
```

The parentheses may look correct at first, but note how the `||` is outside the parentheses. Correct would be putting parentheses around the `||`:

```
function round(n, upperBound, lowerBound) {
  if ((n > upperBound) || (n < lowerBound)) {
    throw new Error(
      `Number ${n} is more than ${upperBound} or less than ${lowerBound}`,
    );
```

```
  } else if (n < (upperBound + lowerBound) / 2) {
    return lowerBound;
  } else {
    return upperBound;
  }
}
```

A structure error further up confused the meaning

Sometimes, the error is caused by some structure issues not directly next to the error location, so you need to look around for potential errors. For example, you intended to declare a method of an object, but you declared it as a property instead:

```
const MyComponent = {
  mounted: {
    document.getElementById("app").classList.add("loaded");
  }
}
```

The `.` after `document` is unexpected, because JavaScript is parsing the `{}` as an object literal instead of a function body, so it expects a `:`. The problem is solved by declaring `mounted` as a function.

```
const MyComponent = {
  mounted() {
    document.getElementById("app").classList.add("loaded");
  }
}
```

- `SyntaxError`

TypeError: "x" is (not) "y"

The JavaScript exception "*x* is (not) *y*" occurs when there was an unexpected type. Oftentimes, unexpected `undefined` or `null` values.

Message

```
TypeError: Cannot read properties of undefined (reading 'x') (V8-based)
TypeError: "x" is undefined (Firefox)
TypeError: "undefined" is not an object (Firefox)
TypeError: undefined is not an object (evaluating 'obj.x') (Safari)

TypeError: "x" is not a symbol (V8-based & Firefox)
TypeError: Symbol.keyFor requires that the first argument be a symbol (Safari)
```

Error type

`TypeError`.

What went wrong?

There was an unexpected type. This occurs oftentimes with `undefined` or `null` values.

Also, certain methods, such as `Object.create()` or `Symbol.keyFor()`, require a specific type, that must be provided.

Examples

Invalid cases

You cannot invoke a method on an `undefined` or `null` variable.

```
const foo = undefined;
foo.substring(1); // TypeError: foo is undefined

const foo2 = null;
foo2.substring(1); // TypeError: foo2 is null
```

Certain methods might require a specific type.

```
const foo = {};
Symbol.keyFor(foo); // TypeError: foo is not a symbol

const foo2 = "bar";
Object.create(foo2); // TypeError: "foo2" is not an object or null
```

Fixing the issue

To fix null pointer to `undefined` or `null` values, you can test if the value is `undefined` or `null` first.

```
if (foo !== undefined && foo !== null) {
  // Now we know that foo is defined, we are good to go.
}
```

Or, if you are confident that `foo` will not be another falsy value like `""` or `0`, or if filtering those cases out is not an issue, you can simply test for its truthiness.

```
if (foo) {
  // Now we know that foo is truthy, it will necessarily not be null/undefined.
}
```

- `undefined`
- `null`

SyntaxError: function statement requires a name

The JavaScript exception "function statement requires a name" occurs when there is a function statement in the code that requires a name.

Message

```
SyntaxError: Function statements require a function name (V8-based)
SyntaxError: function statement requires a name (Firefox)
SyntaxError: Function statements must have a name. (Safari)
```

Error type

`SyntaxError`

What went wrong?

There is a function statement in the code that requires a name. You'll need to check how functions are defined and if you need to provide a name for it, or if the function in question needs to be a function expression, an IIFE, or if the function code is placed correctly in this context at all.

Examples

Statements vs. expressions

A *function statement* (or *function declaration*) requires a name. This won't work:

```
function () {
  return "Hello world";
}
// SyntaxError: function statement requires a name
```

You can use a function expression (assignment) instead:

```
const greet = function () {
  return "Hello world";
};
```

If your function is intended to be an IIFE (Immediately Invoked Function Expression, which is a function that runs as soon as it is defined) you will need to add a few more braces:

```
(function () {
  // …
})();
```

Labeled functions

Labels are an entirely different feature from function names. You can't use a label as a function name.

```
function Greeter() {
  german: function () {
    return "Moin";
  }
}
// SyntaxError: function statement requires a name
```

In addition, labeled function declarations themselves are a deprecated feature. Use regular function declarations instead.

```
function Greeter() {
  function german() {
    return "Moin";
  }
}
```

Object methods

If you intended to create a method of an object, you will need to create an object. The following syntax without a name after the `function` keyword is valid then.

```
const greeter = {
  german: function () {
    return "Moin";
```

```
  },
};
```

You can also use the method syntax.

```
const greeter = {
  german() {
    return "Moin";
  },
};
```

Callback syntax

Also, check your syntax when using callbacks. Braces and commas can quickly get confusing.

```
promise.then(
  function () {
    console.log("success");
  });
  function () {
    console.log("error");
}
// SyntaxError: function statement requires a name
```

Correct would be:

```
promise.then(
  function () {
    console.log("success");
  },
  function () {
    console.log("error");
  },
);
```

SyntaxError: unparenthesized unary expression can't appear on the left-hand side of '**'

The JavaScript exception "unparenthesized unary expression can't appear on the left-hand side of '**'" occurs when a unary operator (one of `typeof`, `void`, `delete`, `await`, `!`, `~`, `+`, `-`) is used on the left operand of the exponentiation operator without parentheses.

Message

```
SyntaxError: Unary operator used immediately before exponentiation expression. Parenthesis must be used to disambiguate operator precedence (V8-based)
SyntaxError: unparenthesized unary expression can't appear on the left-hand side of '**' (Firefox)
SyntaxError: Unexpected token '**'. Ambiguous unary expression in the left hand side of the exponentiation expression; parentheses must be used to
disambiguate the expression. (Safari)
```

Error type

`SyntaxError`

What went wrong?

You likely wrote something like this:

```
-a ** b
```

Whether it should be evaluated as `(-a) ** b` or `-(a ** b)` is ambiguous. In mathematics, $-x^2$ means `-(x ** 2)` — and that's how many languages, including Python, Haskell, and PHP, handle it. But making the unary minus operator take precedence over `**` breaks symmetry with `a ** -b`, which is unambiguously `a ** (-b)`. Therefore, the language forbids this syntax and requires you to parenthesize either side to resolve the ambiguity.

```
(-a) ** b
-(a ** b)
```

Other unary operators cannot be the left-hand side of exponentiation either.

```
await a ** b
!a ** b
+a ** b
~a ** b
```

Examples

When writing complex math expressions involving exponentiation, you may write something like this:

```
function taylorSin(x) {
  return (n) => (-1 ** n * x ** (2 * n + 1)) / factorial(2 * n + 1);
  // SyntaxError: unparenthesized unary expression can't appear on the left-hand side of '**'
}
```

However, the `-1 ** n` part is illegal in JavaScript. Instead, parenthesize the left operand:

```
function taylorSin(x) {
  return (n) => ((-1) ** n * x ** (2 * n + 1)) / factorial(2 * n + 1);
}
```

This also makes the code's intent much clearer to other readers.

JavaScript execution model

This page introduces the basic infrastructure of the JavaScript runtime environment. The model is largely theoretical and abstract, without any platform-specific or implementation-specific details. Modern JavaScript engines heavily optimize the described semantics.

This page is a reference. It assumes you are already familiar with the execution model of other programming languages, such as C and Java. It makes heavy references to existing concepts in operating systems and programming languages.

The engine and the host

JavaScript execution requires the cooperation of two pieces of software: the **JavaScript engine** and the **host environment**.

The JavaScript engine implements the ECMAScript (JavaScript) language, providing the core functionality. It takes source code, parses it, and executes it. However, in order to interact with the outside world, such as to produce any meaningful output, to interface with external resources, or to implement security- or performance-related mechanisms, we need additional environment-specific mechanisms provided by the host environment. For example, the HTML DOM is the host environment when JavaScript is executed in a web browser. Node.js is another host environment that allows JavaScript to be run on the server side.

While we focus primarily on the mechanisms defined in ECMAScript in this reference, we will occasionally talk about mechanisms defined in the HTML spec, which is often mimicked by other host environments like Node.js or Deno. This way, we can give a coherent picture of the JavaScript execution model as used on the web and beyond.

Agent execution model

In the JavaScript specification, each autonomous executor of JavaScript is called an **agent**, which maintains its facilities for code execution:

- **Heap** (of objects): this is just a name to denote a large (mostly unstructured) region of memory. It gets populated as objects get created in the program. Note that in the case of shared memory, each agent has its own heap with its own version of a `SharedArrayBuffer` object, but the underlying memory represented by the buffer is shared.
- **Queue** (of jobs): this is known in HTML (and also commonly) as the *event loop* which enables asynchronous programming in JavaScript while being single-threaded. It's called a queue because it's generally first-in-first-out: earlier jobs are executed before later ones.
- **Stack** (of execution contexts): this is what's known as a *call stack* and allows transferring control flow by entering and exiting execution contexts like functions. It's called a stack because it's last-in-first-out. Every job enters by pushing a new frame onto the (empty) stack, and exits by emptying the stack.

These are three distinct data structures that keep track of different data. We will introduce the queue and the stack in more detail in the following sections. To read more about how heap memory is allocated and freed, see memory management.

Each agent is analogous to a thread (note that the underlying implementation may or may not be an actual operating system thread). Each agent can own multiple realms (which 1-to-1 correlate with global objects) that can synchronously access each other, and thus needs to run in a single execution thread. An agent also has a single memory model, indicating whether it's little-endian, whether it can be synchronously blocked, whether atomic operations are lock-free, etc.

An agent on the web can be one of the following:

- A *Similar-origin window agent*, which contains various `Window` objects which can potentially reach each other, either directly or by using `document.domain`. If the window is origin-keyed, then only same-origin windows can reach each other.
- A *Dedicated worker agent* containing a single `DedicatedWorkerGlobalScope`.
- A *Shared worker agent* containing a single `SharedWorkerGlobalScope`.
- A *Service worker agent* containing a single `ServiceWorkerGlobalScope`.
- A *Worklet agent* containing a single `WorkletGlobalScope`.

In other words, each worker creates its own agent, while one or more windows may be within the same agent—usually a main document and its similar-origin iframes. In Node.js, a similar concept called worker threads is available.

The diagram below illustrates the execution model of agents:

A diagram consisting of two agents: one HTML page and one worker. Each has its own stack containing execution contexts, heap containing objects, and queue containing jobs.

Realms

Each agent owns one or more **realms**. Each piece of JavaScript code is associated with a realm when it's loaded, which remains the same even when called from another realm. A realm consists of the following information:

- A list of intrinsic objects like `Array`, `Array.prototype`, etc.
- Globally declared variables, the value of `globalThis`, and the global object
- A cache of template literal arrays, because evaluation of the same tagged template literal expression always causes the tag to receive the same array object

On the web, the realm and the global object are 1-to-1 corresponded. The global object is either a `Window`, a `WorkerGlobalScope`, or a `WorkletGlobalScope`. So for example, every `iframe` executes in a different realm, though it may be in the same agent as the parent window.

Realms are usually mentioned when talking about the identities of global objects. For example, we need methods such as `Array.isArray()` or `Error.isError()`, because an array constructed in another realm will have a different prototype object than the `Array.prototype` object in the current realm, so `instanceof Array` will wrongly return `false`.

Stack and execution contexts

We first consider synchronous code execution. Each job enters by calling its associated callback. Code inside this callback may create variables, call functions, or exit. Each function needs to keep track of its own variable environments and where to return to. To handle this, the agent needs a stack to keep track of the execution contexts. An **execution context**, also known generally as a *stack frame*, is the smallest unit of execution. It tracks the following information:

- Code evaluation state
- The module or script, the function (if applicable), and the currently executing generator that contains this code
- The current realm
- Bindings, including:
  - Variables defined with `var`, `let`, `const`, `function`, `class`, etc.
  - Private identifiers like `#foo` which are only valid in the current context
  - `this` reference

Imagine a program consisting of a single job defined by the following code:

```
function foo(b) {
  const a = 10;
  return a + b + 11;
}

function bar(x) {
  const y = 3;
  return foo(x * y);
}

const baz = bar(7); // assigns 42 to baz
```

1. When the job starts, the first frame is created, where the variables `foo`, `bar`, and `baz` are defined. It calls `bar` with the argument `7`.
2. A second frame is created for the `bar` call, containing bindings for the parameter `x` and the local variable `y`. It first performs the multiplication `x * y`, then calls `foo` with the result.
3. A third frame is created for the `foo` call, containing bindings for the parameter `b` and the local variable `a`. It first performs the addition `a + b + 11`, then returns the result.
4. When `foo` returns, the top frame element is popped out of the stack, and the call expression `foo(x * y)` resolves to the return value. It then continues execution, which is just to return this result.
5. When `bar` returns, the top frame element is popped out of the stack, and the call expression `bar(7)` resolves to the return value. This initializes `baz` with the return value.
6. We reach the end of the job's source code, so the stack frame for the entrypoint is popped out of the stack. The stack is empty, so the job is considered completed.

Generators and reentry

When a frame is popped, it's not necessarily gone forever, because sometimes we need to come back to it. For example, consider a generator function:

```
function* gen() {
  console.log(1);
  yield;
  console.log(2);
}

const g = gen();
g.next(); // logs 1
g.next(); // logs 2
```

In this case, calling `gen()` first creates an execution context which is suspended—no code inside `gen` gets executed yet. The generator `g` saves this execution context internally. The current running execution context remains to be the entrypoint. When `g.next()` is called, the execution context for `gen` is pushed onto the stack, and the code inside `gen` is executed until the `yield` expression. Then, the generator execution context gets suspended and removed from the stack, which returns control back to the entrypoint. When `g.next()` is called again, the generator execution context is pushed back onto the stack, and the code inside `gen` resumes from where it left off.

Tail calls

One mechanism defined in the specification is *proper tail call* (PTC). A function call is a tail call if the caller does nothing after the call except return the value:

```
function f() {
  return g();
}
```

In this case, the call to `g` is a tail call. If a function call is in tail position, the engine is required to discard the current execution context and replace it with the context of the tail call, instead of pushing a new frame for the `g()` call. This means that tail recursion is not subject to the stack size limits:

```
function factorial(n, acc = 1) {
  if (n <= 1) return acc;
  return factorial(n - 1, n * acc);
}
```

In reality, discarding the current frame causes debugging problems, because if `g()` throws an error, `f` is no longer on the stack and won't appear in the stack trace. Currently, only Safari (JavaScriptCore) implements PTC, and they have invented some specific infrastructure to address the debuggability issue.

Closures

Another interesting phenomenon related to variable scoping and function calls is closures. Whenever a function is created, it also memorizes internally the variable bindings of the current running execution context. Then, these variable bindings can outlive the execution context.

```
let f;
{
  let x = 10;
  f = () => x;
}
console.log(f()); // logs 10
```

Job queue and event loop

An agent is a thread, which means the interpreter can only process one statement at a time. When the code is all synchronous, this is fine because we can always make progress. But if the code needs to perform asynchronous action, then we cannot progress unless that action is completed. However, it would be detrimental to user experience if that halts the whole program—the nature of JavaScript as a web scripting language requires it to be never blocking. Therefore, the code that handles the completion of that asynchronous action is defined as a callback. This callback defines a **job**, which gets placed into a **job queue**—or, in HTML terminology, an event loop—once the action is completed.

Every time, the agent pulls a job from the queue and executes it. When the job is executed, it may create more jobs, which are added to the end of the queue. Jobs can also be added via the completion of asynchronous platform mechanisms, such as timers, I/O, and events. A job is considered completed when the stack is empty; then, the next job is pulled from the queue. Jobs might not be pulled with uniform priority—for example, HTML event loops split jobs into two categories: *tasks* and *microtasks*. Microtasks have higher priority and the microtask queue is drained first before the task queue is pulled. For more information, check the HTML microtask guide. If the job queue is empty, the agent waits for more jobs to be added.

"Run-to-completion"

Each job is processed completely before any other job is processed. This offers some nice properties when reasoning about your program, including the fact that whenever a function runs, it cannot be preempted and will run entirely before any other code runs (and can modify data the function manipulates). This differs from C, for instance, where if a function runs in a thread, it may be stopped at any point by the runtime system to run some other code in another thread.

For example, consider this example:

```
const promise = Promise.resolve();
let i = 0;
promise.then(() => {
  i += 1;
  console.log(i);
});
promise.then(() => {
  i += 1;
  console.log(i);
});
```

In this example, we create an already-resolved promise, which means any callback attached to it will be immediately scheduled as jobs. The two callbacks seem to cause a race condition, but actually, the output is fully predictable: `1` and `2` will be logged in order. This is because each job runs to completion before the next one is executed, so the overall order is always `i += 1; console.log(i); i += 1; console.log(i);` and never `i += 1; i += 1; console.log(i); console.log(i);`.

A downside of this model is that if a job takes too long to complete, the web application is unable to process user interactions like click or scroll. The browser mitigates this with the "a script is taking too long to run" dialog. A good practice to follow is to make job processing short and, if possible, cut down one job into several jobs.

Never blocking

Another important guarantee offered by the event loop model is that JavaScript execution is never blocking. Handling I/O is typically performed via events and callbacks, so when the application is waiting for an IndexedDB query to return or a `fetch()` request to return, it can still process other things like user input. The code that executes after the completion of an asynchronous action is always provided as a callback function (for example, the promise `then()` handler, the callback function in `setTimeout()`, or the event handler), which defines a job to be added to the job queue once the action completes.

Of course, the guarantee of "never-blocking" requires the platform API to be inherently asynchronous, but some legacy exceptions exist like `alert()` or synchronous XHR. It is considered good practice to avoid them to ensure the responsiveness of the application.

Agent clusters and memory sharing

Multiple agents can communicate via memory sharing, forming an **agent cluster**. Agents are within the same cluster if and only if they can share memory. There is no built-in mechanism for two agent clusters to exchange any information, so they can be regarded as completely isolated execution models.

When creating an agent (such as by spawning a worker), there are some criteria for whether it's in the same cluster as the current agent, or a new cluster is created. For example, the following pairs of global objects are each within the same agent cluster, and thus can share memory with each other:

- A `Window` object and a dedicated worker that it created.
- A worker (of any type) and a dedicated worker it created.
- A `Window` object A and the `Window` object of a same-origin `iframe` element that A created.
- A `Window` object and a same-origin `Window` object that opened it.
- A `Window` object and a worklet that it created.

The following pairs of global objects are not within the same agent cluster, and thus cannot share memory:

- A `Window` object and a shared worker it created.
- A worker (of any type) and a shared worker it created.
- A `Window` object and a service worker it created.
- A `Window` object A and the `Window` object of an `iframe` element that A created that cannot be same origin-domain with A.
- Any two `Window` objects with no opener or ancestor relationship. This holds even if the two `Window` objects are same origin.

For the exact algorithm, check the HTML specification.

Cross-agent communication and memory model

As aforementioned, agents communicate via memory sharing. On the web, memory is shared via the `postMessage()` method. The using web workers guide provides an overview of this. Typically, data is passed by value only (via structured cloning), and therefore does not involve any concurrency complications. To share memory, one must post a `SharedArrayBuffer` object, which can be simultaneously accessed by multiple agents. Once two agents share access to the same memory via a `SharedArrayBuffer`, they can synchronize executions via the `Atomics` object.

There are two ways to access shared memory: via normal memory access (which is not atomic) and via atomic memory access. The latter is sequentially consistent (which means there is a strict total ordering of events agreed upon by all agents in the cluster), while the former is unordered (which means no ordering exists); JavaScript does not provide operations with other ordering guarantees.

The spec provides the following guidelines for programmers working with shared memory:

> We recommend programs be kept data race free, i.e., make it so that it is impossible for there to be concurrent non-atomic operations on the same memory location. Data race free programs have interleaving semantics where each step in the evaluation semantics of each agent are interleaved with each other. For data race free programs, it is not necessary to understand the details of the memory model. The details are unlikely to build intuition that will help one to better write ECMAScript.
>
> More generally, even if a program is not data race free it may have predictable behavior, so long as atomic operations are not involved in any data races and the operations that race all have the same access size. The simplest way to arrange for atomics not to be involved in races is to ensure that different memory cells are used by atomic and non-atomic operations and that atomic accesses of different sizes are not used to access the same cells at the same time. Effectively, the program should treat shared memory as strongly typed as much as possible. One still cannot depend on the ordering and timing of non-atomic accesses that race, but if memory is treated as strongly typed the racing accesses will not "tear" (bits of their values will not be mixed).

Concurrency and ensuring forward progress

When multiple agents cooperate, the never-blocking guarantee does not always hold. An agent can become *blocked*, or paused, while waiting for another agent to perform some action. This is different from waiting on a promise in the same agent, because it halts the entire agent and does not allow any other code to run in the meantime—in other words, it cannot make *forward progress*.

To prevent deadlocks, there are some strong restrictions on when and which agents can become blocked.

- Every unblocked agent with a dedicated executing thread eventually makes forward progress.
- In a set of agents that share an executing thread, one agent eventually makes forward progress.
- An agent does not cause another agent to become blocked except via explicit APIs that provide blocking.
- Only certain agents can be blocked. On the web, this includes dedicated workers and shared workers, but not similar-origin windows or service workers.

The agent cluster ensures some level of integrity over the activeness of its agents, in the case of external pauses or terminations:

- An agent may be paused or resumed without its knowledge or cooperation. For example, navigating away from a window may suspend code execution but preserve its state. However, an agent cluster is not allowed to be partially deactivated, to avoid an agent starving because another agent has been deactivated. For example, shared workers are never in the same agent cluster as the creator window or other dedicated workers. This is because a shared worker's lifetime is independent of documents: if a document is deactivated while its dedicated worker holds a lock, the shared worker is blocked from acquiring the lock until the dedicated worker is reactivated, if ever. Meanwhile other workers trying to access the shared worker from other windows will starve.
- Similarly, an agent may be terminated by factors external to the cluster. For example, operating systems or users killing a browser process, or the browser force-terminating one agent because it's using too many resources. In this case, all the agents in the cluster get terminated. (The spec also allows a second strategy, which is an API that allows at least one remaining member of the cluster to identify the termination and the agent that was terminated, but this is not implemented on the web.)

Functions

Generally speaking, a function is a "subprogram" that can be *called* by code external (or internal, in the case of recursion) to the function. Like the program itself, a function is composed of a sequence of statements called the *function body*. Values can be *passed* to a function as parameters, and the function will *return* a value.

In JavaScript, functions are first-class objects, because they can be passed to other functions, returned from functions, and assigned to variables and properties. They can also have properties and methods just like any other object. What distinguishes them from other objects is that functions can be called.

For more examples and explanations, see the JavaScript guide about functions.

Description

Function values are typically instances of `Function`. See `Function` for information on properties and methods of `Function` objects. Callable values cause `typeof` to return `"function"` instead of `"object"`.

> **Note:** Not all callable values are `instanceof Function`. For example, the `Function.prototype` object is callable but not an instance of `Function`. You can also manually set the prototype chain of your function so it no longer inherits from `Function.prototype`. However, such cases are extremely rare.

Return value

By default, if a function's execution doesn't end at a `return` statement, or if the `return` keyword doesn't have an expression after it, then the return value is `undefined`. The `return` statement allows you to return an arbitrary value from the function. One function call can only return one value, but you can simulate the effect of returning multiple values by returning an object or array and destructuring the result.

> **Note:** Constructors called with `new` have a different set of logic to determine their return values.

Passing arguments

Parameters and arguments have slightly different meanings, but in MDN web docs, we often use them interchangeably. For a quick reference:

```
function formatNumber(num) {
  return num.toFixed(2);
}

formatNumber(2);
```

In this example, the `num` variable is called the function's *parameter*: it's declared in the parenthesis-enclosed list of the function's definition. The function expects the `num` parameter to be a number — although this is not enforceable in JavaScript without writing runtime validation code. In the `formatNumber(2)` call, the number `2` is the function's *argument*: it's the value that is actually passed to the function in the function call. The argument value can be accessed inside the function body through the corresponding parameter name or the `arguments` object.

Arguments are always *passed by value* and never *passed by reference*. This means that if a function reassigns a parameter, the value won't change outside the function. More precisely, object arguments are *passed by sharing*, which means if the object's properties are mutated, the change will impact the outside of the function. For example:

```
function updateBrand(obj) {
  // Mutating the object is visible outside the function
  obj.brand = "Toyota";
  // Try to reassign the parameter, but this won't affect
  // the variable's value outside the function
  obj = null;
}

const car = {
  brand: "Honda",
  model: "Accord",
  year: 1998,
};

console.log(car.brand); // Honda

// Pass object reference to the function
updateBrand(car);

// updateBrand mutates car
console.log(car.brand); // Toyota
```

The `this` keyword refers to the object that the function is accessed on — it does not refer to the currently executing function, so you must refer to the function value by name, even within the function body.

Defining functions

Broadly speaking, JavaScript has four kinds of functions:

- Regular function: can return anything; always runs to completion after invocation
- Generator function: returns a `Generator` object; can be paused and resumed with the `yield` operator
- Async function: returns a `Promise`; can be paused and resumed with the `await` operator
- Async generator function: returns an `AsyncGenerator` object; both the `await` and `yield` operators can be used

For every kind of function, there are multiple ways to define it:

Declaration

`function`, `function*`, `async function`, `async function*`

Expression

`function`, `function*`, `async function`, `async function*`

Constructor

`Function()`, `GeneratorFunction()`, `AsyncFunction()`, `AsyncGeneratorFunction()`

In addition, there are special syntaxes for defining arrow functions and methods, which provide more precise semantics for their usage. Classes are conceptually not functions (because they throw an error when called without `new`), but they also inherit from `Function.prototype` and have `typeof MyClass === "function"`.

```
// Constructor
const multiply = new Function("x", "y", "return x * y");

// Declaration
function multiply(x, y) {
  return x * y;
} // No need for semicolon here

// Expression; the function is anonymous but assigned to a variable
const multiply = function (x, y) {
  return x * y;
};
// Expression; the function has its own name
const multiply = function funcName(x, y) {
  return x * y;
};

// Arrow function
const multiply = (x, y) => x * y;

// Method
const obj = {
  multiply(x, y) {
    return x * y;
  },
};
```

All syntaxes do approximately the same thing, but there are some subtle behavior differences.

- The `Function()` constructor, `function` expression, and `function` declaration syntaxes create full-fledged function objects, which can be constructed with `new`. However, arrow functions and methods cannot be constructed. Async functions, generator functions, and async generator functions are not constructible regardless of syntax.
- The `function` declaration creates functions that are *hoisted*. Other syntaxes do not hoist the function and the function value is only visible after the definition.
- The arrow function and `Function()` constructor always create *anonymous* functions, which means they can't easily call themselves recursively. One way to call an arrow function recursively is by assigning it to a variable.
- The arrow function syntax does not have access to `arguments` or `this`.
- The `Function()` constructor cannot access any local variables — it only has access to the global scope.
- The `Function()` constructor causes runtime compilation and is often slower than other syntaxes.

For `function` expressions, there is a distinction between the function name and the variable the function is assigned to. The function name cannot be changed, while the variable the function is assigned to can be reassigned. The function name can be different from the variable the function is assigned to — they have no relation to each other. The function name can be used only within the function's body. Attempting to use it outside the function's body results in an error (or gets another value, if the same name is declared elsewhere). For example:

```
const y = function x() {};
console.log(x); // ReferenceError: x is not defined
```

On the other hand, the variable the function is assigned to is limited only by its scope, which is guaranteed to include the scope in which the function is declared.

A function declaration also creates a variable with the same name as the function name. Thus, unlike those defined by function expressions, functions defined by function declarations can be accessed by their name in the scope they were defined in, as well as in their own body.

A function defined by `new Function` will dynamically have its source assembled, which is observable when you serialize it. For example, `console.log(new Function().toString())` gives:

```
function anonymous(
) {

}
```

This is the actual source used to compile the function. However, although the `Function()` constructor will create the function with name `anonymous`, this name is not added to the scope of the body. The body only ever has access to global variables. For example, the following would result in an error:

```
new Function("alert(anonymous);")();
```

A function defined by a function expression or by a function declaration inherits the current scope. That is, the function forms a closure. On the other hand, a function defined by a `Function` constructor does not inherit any scope other than the global scope (which all functions inherit).

```
// p is a global variable
globalThis.p = 5;
function myFunc() {
  // p is a local variable
```

```
  const p = 9;

  function decl() {
    console.log(p);
  }
  const expr = function () {
    console.log(p);
  };
  const cons = new Function("\tconsole.log(p);");

  decl();
  expr();
  cons();
}
myFunc();

// Logs:
// 9 (for 'decl' by function declaration (current scope))
// 9 (for 'expr' by function expression (current scope))
// 5 (for 'cons' by Function constructor (global scope))
```

Functions defined by function expressions and function declarations are parsed only once, while a function defined by the `Function` constructor parses the string passed to it each and every time the constructor is called. Although a function expression creates a closure every time, the function body is not reparsed, so function expressions are still faster than `new Function(...)`. Therefore the `Function` constructor should generally be avoided whenever possible.

A function declaration may be unintentionally turned into a function expression when it appears in an expression context.

```
// A function declaration
function foo() {
  console.log("FOO!");
}

doSomething(
  // A function expression passed as an argument
  function foo() {
    console.log("FOO!");
  },
);
```

On the other hand, a function expression may also be turned into a function declaration. An expression statement cannot begin with the `function` or `async function` keywords, which is a common mistake when implementing IIFEs (Immediately Invoked Function Expressions).

```
function () { // SyntaxError: Function statements require a function name
  console.log("FOO!");
}();

function foo() {
  console.log("FOO!");
}(); // SyntaxError: Unexpected token ')'
```

Instead, start the expression statement with something else, so that the `function` keyword unambiguously starts a function expression. Common options include grouping and using `void`.

```
(function () {
  console.log("FOO!");
})();

void function () {
  console.log("FOO!");
}();
```

Function parameters

Each function parameter is a simple identifier that you can access in the local scope.

```
function myFunc(a, b, c) {
  // You can access the values of a, b, and c here
}
```

There are three special parameter syntaxes:

- *Default parameters* allow formal parameters to be initialized with default values if no value or `undefined` is passed.
- The *rest parameter* allows representing an indefinite number of arguments as an array.
- *Destructuring* allows unpacking elements from arrays, or properties from objects, into distinct variables.

```
function myFunc({ a, b }, c = 1, ...rest) {
  // You can access the values of a, b, c, and rest here
}
```

There are some consequences if one of the above non-simple parameter syntaxes is used:

- You cannot apply `"use strict"` to the function body — this causes a syntax error.

- Even if the function is not in strict mode, certain strict mode function features apply, including that the `arguments` object stops syncing with the named parameters, `arguments.callee` throws an error when accessed, and duplicate parameter names are not allowed.

The arguments object

You can refer to a function's arguments within the function by using the `arguments` object.

`arguments`

: An array-like object containing the arguments passed to the currently executing function.

`arguments.callee`

: The currently executing function.

`arguments.length`

: The number of arguments passed to the function.

Getter and setter functions

You can define accessor properties on any standard built-in object or user-defined object that supports the addition of new properties. Within object literals and classes, you can use special syntaxes to define the getter and setter of an accessor property.

get

: Binds an object property to a function that will be called when that property is looked up.

set

: Binds an object property to a function to be called when there is an attempt to set that property.

Note that these syntaxes create an *object property*, not a *method*. The getter and setter functions themselves can only be accessed using reflective APIs such as `Object.getOwnPropertyDescriptor()`.

Block-level functions

In strict mode, functions inside blocks are scoped to that block. Prior to ES2015, block-level functions were forbidden in strict mode.

```
"use strict";

function f() {
  return 1;
}

{
  function f() {
    return 2;
  }
}

f() === 1; // true

// f() === 2 in non-strict mode
```

Block-level functions in non-strict code

In a word: **Don't.**

In non-strict code, function declarations inside blocks behave strangely. For example:

```
if (shouldDefineZero) {
  function zero() {
    // DANGER: compatibility risk
    console.log("This is zero.");
  }
}
```

The semantics of this in strict mode are well-specified — `zero` only ever exists within that scope of the `if` block. If `shouldDefineZero` is false, then `zero` should never be defined, since the block never executes. However, historically, this was left unspecified, so different browsers implemented it differently in non-strict mode. For more information, see the `function` declaration reference.

A safer way to define functions conditionally is to assign a function expression to a variable:

```
// Using a var makes it available as a global variable,
// with closer behavior to a top-level function declaration
var zero;
if (shouldDefineZero) {
  zero = function () {
    console.log("This is zero.");
  };
}
```

Examples

Returning a formatted number

The following function returns a string containing the formatted representation of a number padded with leading zeros.

```
// This function returns a string padded with leading zeros
function padZeros(num, totalLen) {
  let numStr = num.toString(); // Initialize return value as string
  const numZeros = totalLen - numStr.length; // Calculate no. of zeros
  for (let i = 1; i <= numZeros; i++) {
    numStr = `0${numStr}`;
  }
  return numStr;
}
```

The following statements call the `padZeros` function.

```
let result;
result = padZeros(42, 4); // returns "0042"
result = padZeros(42, 2); // returns "42"
result = padZeros(5, 4); // returns "0005"
```

Determining whether a function exists

You can determine whether a function exists by using the `typeof` operator. In the following example, a test is performed to determine if the `window` object has a property called `noFunc` that is a function. If so, it is used; otherwise, some other action is taken.

```
if (typeof window.noFunc === "function") {
  // use noFunc()
} else {
  // do something else
}
```

Note that in the `if` test, a reference to `noFunc` is used — there are no parentheses `()` after the function name so the actual function is not called.

The arguments object

`arguments` is an array-like object accessible inside functions that contains the values of the arguments passed to that function.

Try it

```
function func1(a, b, c) {
  console.log(arguments[0]);
  // Expected output: 1

  console.log(arguments[1]);
  // Expected output: 2

  console.log(arguments[2]);
  // Expected output: 3
}

func1(1, 2, 3);
```

Description

> **Note:** In modern code, rest parameters should be preferred.

The `arguments` object is a local variable available within all non-arrow functions. You can refer to a function's arguments inside that function by using its `arguments` object. It has entries for each argument the function was called with, with the first entry's index at `0`.

For example, if a function is passed 3 arguments, you can access them as follows:

```
arguments[0]; // first argument
arguments[1]; // second argument
arguments[2]; // third argument
```

The `arguments` object is useful for functions called with more arguments than they are formally declared to accept, called *variadic functions*, such as `Math.min()`. This example function accepts any number of string arguments and returns the longest one:

```
function longestString() {
  let longest = "";
  if (arguments.length === 0) {
```

```
    throw new TypeError("At least one string is required");
  }
  for (const arg of arguments) {
    if (arg.length > longest.length) {
      longest = arg;
    }
  }
  return longest;
}
```

You can use `arguments.length` to count how many arguments the function was called with. If you instead want to count how many parameters a function is declared to accept, inspect that function's `length` property.

Assigning to indices

Each argument index can also be set or reassigned:

```
arguments[1] = "new value";
```

Non-strict functions that only have simple parameters (that is, no rest, default, or destructured parameters) will sync the new value of parameters with the `arguments` object, and vice versa:

```
function func(a) {
  arguments[0] = 99; // updating arguments[0] also updates a
  console.log(a);
}
func(10); // 99

function func2(a) {
  a = 99; // updating a also updates arguments[0]
  console.log(arguments[0]);
}
func2(10); // 99
```

Non-strict functions that *are* passed rest, default, or destructured parameters will not sync new values assigned to parameters in the function body with the `arguments` object. Instead, the `arguments` object in non-strict functions with complex parameters will always reflect the values passed to the function when the function was called.

```
function funcWithDefault(a = 55) {
  arguments[0] = 99; // updating arguments[0] does not also update a
  console.log(a);
}
funcWithDefault(10); // 10

function funcWithDefault2(a = 55) {
  a = 99; // updating a does not also update arguments[0]
  console.log(arguments[0]);
}
funcWithDefault2(10); // 10

// An untracked default parameter
function funcWithDefault3(a = 55) {
  console.log(arguments[0]);
  console.log(arguments.length);
}
funcWithDefault3(); // undefined; 0
```

This is the same behavior exhibited by all strict-mode functions, regardless of the type of parameters they are passed. That is, assigning new values to parameters in the body of the function never affects the `arguments` object, nor will assigning new values to the `arguments` indices affect the value of parameters, even when the function only has simple parameters.

> **Note:** You cannot write a `"use strict";` directive in the body of a function definition that accepts rest, default, or destructured parameters. Doing so will throw a syntax error.

arguments is an array-like object

`arguments` is an array-like object, which means that `arguments` has a `length` property and properties indexed from zero, but it doesn't have `Array`'s built-in methods like `forEach()` or `map()`. However, it can be converted to a real `Array`, using one of `slice()`, `Array.from()`, or spread syntax.

```
const args = Array.prototype.slice.call(arguments);
// or
const args = Array.from(arguments);
// or
const args = [...arguments];
```

For common use cases, using it as an array-like object is sufficient, since it both is iterable and has `length` and number indices. For example, `Function.prototype.apply()` accepts array-like objects.

```
function midpoint() {
  return (
    (Math.min.apply(null, arguments) + Math.max.apply(null, arguments)) / 2
```

```
  );
}

console.log(midpoint(3, 1, 4, 1, 5)); // 3
```

Properties

`arguments.callee`

Reference to the currently executing function that the arguments belong to. Forbidden in strict mode.

`arguments.length`

The number of arguments that were passed to the function.

`arguments[Symbol.iterator]()`

Returns a new array iterator object that contains the values for each index in `arguments`.

Examples

Defining a function that concatenates several strings

This example defines a function that concatenates several strings. The function's only formal argument is a string containing the characters that separate the items to concatenate.

```
function myConcat(separator) {
  const args = Array.prototype.slice.call(arguments, 1);
  return args.join(separator);
}
```

You can pass as many arguments as you like to this function. It returns a string list using each argument in the list:

```
myConcat(", ", "red", "orange", "blue");
// "red, orange, blue"

myConcat("; ", "elephant", "giraffe", "lion", "cheetah");
// "elephant; giraffe; lion; cheetah"

myConcat(". ", "sage", "basil", "oregano", "pepper", "parsley");
// "sage. basil. oregano. pepper. parsley"
```

Defining a function that creates HTML lists

This example defines a function that creates a string containing HTML for a list. The only formal argument for the function is a string that is `"u"` if the list is to be unordered (bulleted), or `"o"` if the list is to be ordered (numbered). The function is defined as follows:

```
function list(type) {
  let html = `<${type}l><li>`;
  const args = Array.prototype.slice.call(arguments, 1);
  html += args.join("</li><li>");
  html += `</li></${type}l>`; // end list
  return html;
}
```

You can pass any number of arguments to this function, and it adds each argument as a list item to a list of the type indicated. For example:

```
list("u", "One", "Two", "Three");
// "<ul><li>One</li><li>Two</li><li>Three</li></ul>"
```

Using typeof with arguments

The `typeof` operator returns `'object'` when used with `arguments`

```
console.log(typeof arguments); // 'object'
```

The type of individual arguments can be determined by indexing `arguments`:

```
console.log(typeof arguments[0]); // returns the type of the first argument
```

arguments.callee

> **Note:** Accessing `arguments.callee` in strict mode will throw a `TypeError`. If a function must reference itself, either give the function expression a name or use a function declaration.

The **`arguments.callee`** data property contains the currently executing function that the arguments belong to.

Value

A reference to the currently executing function.

Property attributes of `arguments.callee`	
Writable	yes
Enumerable	no
Configurable	yes

> **Note:** `callee` is a data property only in non-strict functions with simple parameters (in which case the `arguments` object is also auto-syncing). Otherwise, it is an accessor property whose getter and setter both throw a `TypeError`.

Description

`callee` is a property of the `arguments` object. It can be used to refer to the currently executing function inside the function body of that function. This is useful when the name of the function is unknown, such as within a function expression with no name (also called "anonymous functions").

(The text below is largely adapted from a Stack Overflow answer by olliej)

Early versions of JavaScript did not allow named function expressions, and for this reason you could not make a recursive function expression.

For example, this syntax worked:

```
function factorial(n) {
  return n <= 1 ? 1 : factorial(n - 1) * n;
}

[1, 2, 3, 4, 5].map(factorial);
```

but:

```
[1, 2, 3, 4, 5].map(function (n) {
  return n <= 1 ? 1 : /* what goes here? */ (n - 1) * n;
});
```

did not. To get around this `arguments.callee` was added so you could do

```
[1, 2, 3, 4, 5].map(function (n) {
  return n <= 1 ? 1 : arguments.callee(n - 1) * n;
});
```

However, the design of `arguments.callee` has multiple issues. The first problem is that the recursive call will get a different `this` value. For example:

```
function sillyFunction(recursed) {
  if (this !== globalThis) {
    console.log("This is:", this);
  } else {
    console.log("This is the global");
  }

  if (!recursed) {
    return arguments.callee(true);
  }
}

sillyFunction();
// This is the global
// This is: [object Arguments]
```

In addition, references to `arguments.callee` make inlining and tail recursion impossible in the general case. (You can achieve it in select cases through tracing, etc., but even the best code is suboptimal due to checks that would not otherwise be necessary.)

ECMAScript 3 resolved these issues by allowing named function expressions. For example:

```
[1, 2, 3, 4, 5].map(function factorial(n) {
  return n <= 1 ? 1 : factorial(n - 1) * n;
});
```

This has numerous benefits:

- the function can be called like any other from inside your code
- it does not create a variable in the outer scope (except for IE 8 and below)
- it has better performance than accessing the arguments object

Strict mode has banned other properties that leak stack information, like the `caller` property of functions. This is because looking at the call stack has one single major effect: it makes a large number of optimizations impossible, or much more difficult. For example, if you cannot guarantee that a function `f` will not call an unknown

function, it is not possible to inline `f`.

```
function f(a, b, c, d, e) {
  return a ? b * c : d * e;
}
```

If the JavaScript interpreter cannot guarantee that all the provided arguments are numbers at the point that the call is made, it needs to either insert checks for all the arguments before the inlined code, or it cannot inline the function. This means any call site that may have been trivially inlinable accumulates a large number of guards. Now in this particular case a smart interpreter should be able to rearrange the checks to be more optimal and not check any values that would not be used. However in many cases that's just not possible and therefore it becomes impossible to inline.

Examples

Using arguments.callee in an anonymous recursive function

A recursive function must be able to refer to itself. Typically, a function refers to itself by its name. However, an anonymous function (which can be created by a function expression or the `Function` constructor) does not have a name. Therefore if there is no accessible variable referring to it, the only way the function can refer to itself is by `arguments.callee`.

The following example defines a function, which, in turn, defines and returns a factorial function. This example isn't very practical, and there are nearly no cases where the same result cannot be achieved with named function expressions.

```
function create() {
  return function (n) {
    if (n <= 1) {
      return 1;
    }
    return n * arguments.callee(n - 1);
  };
}

const result = create()(5); // returns 120 (5 * 4 * 3 * 2 * 1)
```

Recursion of anonymous functions with a Y-combinator

Although function expressions can now be named, arrow functions always remain anonymous, which means they cannot reference themselves without being assigned to a variable first. Fortunately, in Lambda calculus there's a very good solution which allows a function to both be anonymous and self-referential. The technique is called a Y-combinator. Here we will not explain *how* it works, only *that* it works.

```
// The Y-combinator: a utility function!
const Y = (hof) => ((x) => x(x))((x) => hof((y) => x(x)(y)));

console.log(
  [1, 2, 3, 4, 5].map(
    // Wrap the higher-order function in the Y-combinator
    // "factorial" is not a function's name: it's introduced as a parameter
    Y((factorial) => (n) => (n <= 1 ? 1 : factorial(n - 1) * n)),
  ),
);
// [ 1, 2, 6, 24, 120 ]
```

> **Note:** This method allocates a new closure for every iteration, which may significantly increase memory usage. It's only here to demonstrate the possibility, but should be avoided in production. Use a temporary variable or a named function expression instead.

arguments.length

The **`arguments.length`** data property contains the number of arguments passed to the function.

Value

A non-negative integer.

Property attributes of `arguments.length`	
Writable	yes
Enumerable	no
Configurable	yes

Description

The `arguments.length` property provides the number of arguments actually passed to a function. This can be more or less than the defined parameter's count (see `Function.prototype.length`). For example, for the function below:

```
function func1(a, b, c) {
  console.log(arguments.length);
}
```

`func1.length` returns `3`, because `func1` declares three formal parameters. However, `func1(1, 2, 3, 4, 5)` logs `5`, because `func1` was called with five arguments. Similarly, `func1(1)` logs `1`, because `func1` was called with one argument.

Examples

Using arguments.length

In this example, we define a function that can add two or more numbers together.

```
function adder(base /*, num1, …, numN */) {
  base = Number(base);
  for (let i = 1; i < arguments.length; i++) {
    base += Number(arguments[i]);
  }
  return base;
}
```

arguments[Symbol.iterator]()

The **`[Symbol.iterator]()`** method of `arguments` objects implements the iterable protocol and allows `arguments` objects to be consumed by most syntaxes expecting iterables, such as the spread syntax and `for...of` loops. It returns an array iterator object that yields the value of each index in the `arguments` object.

The initial value of this property is the same function object as the initial value of the `Array.prototype.values` property (and also the same as `Array.prototype[Symbol.iterator]()`).

Syntax

```
arguments[Symbol.iterator]()
```

Parameters

None.

Return value

The same return value as `Array.prototype.values()`: a new iterable iterator object that yields the value of each index in the `arguments` object.

Examples

Iteration using for...of loop

Note that you seldom need to call this method directly. The existence of the `[Symbol.iterator]()` method makes `arguments` objects iterable, and iterating syntaxes like the `for...of` loop automatically call this method to obtain the iterator to loop over.

```
function f() {
  for (const letter of arguments) {
    console.log(letter);
  }
}
f("w", "y", "k", "o", "p");
```

Manually hand-rolling the iterator

You may still manually call the `next()` method of the returned iterator object to achieve maximum control over the iteration process.

```
function f() {
  const argsIter = arguments[Symbol.iterator]();
  console.log(argsIter.next().value); // w
  console.log(argsIter.next().value); // y
  console.log(argsIter.next().value); // k
  console.log(argsIter.next().value); // o
  console.log(argsIter.next().value); // p
}
f("w", "y", "k", "o", "p");
```

Arrow function expressions

An **arrow function expression** is a compact alternative to a traditional function expression, with some semantic differences and deliberate limitations in usage:

- Arrow functions don't have their own bindings to `this`, `arguments`, or `super`, and should not be used as methods.
- Arrow functions cannot be used as constructors. Calling them with `new` throws a `TypeError`. They also don't have access to the `new.target` keyword.
- Arrow functions cannot use `yield` within their body and cannot be created as generator functions.

Try it

```
const materials = ["Hydrogen", "Helium", "Lithium", "Beryllium"];

console.log(materials.map((material) => material.length));
// Expected output: Array [8, 6, 7, 9]
```

Syntax

```
() => expression

param => expression

(param) => expression

(param1, paramN) => expression

() => {
  statements
}

param => {
  statements
}

(param1, paramN) => {
  statements
}
```

Rest parameters, default parameters, and destructuring within params are supported, and always require parentheses:

```
(a, b, ...r) => expression
(a = 400, b = 20, c) => expression
([a, b] = [10, 20]) => expression
({ a, b } = { a: 10, b: 20 }) => expression
```

Arrow functions can be `async` by prefixing the expression with the `async` keyword.

```
async param => expression
async (param1, param2, ...paramN) => {
  statements
}
```

Description

Let's decompose a traditional anonymous function down to the simplest arrow function step-by-step. Each step along the way is a valid arrow function.

> **Note:** Traditional function expressions and arrow functions have more differences than their syntax. We will introduce their behavior differences in more detail in the next few subsections.

```
// Traditional anonymous function
(function (a) {
  return a + 100;
});

// 1. Remove the word "function" and place arrow between the argument and opening body brace
(a) => {
  return a + 100;
};

// 2. Remove the body braces and word "return" — the return is implied.
(a) => a + 100;

// 3. Remove the parameter parentheses
a => a + 100;
```

In the example above, both the parentheses around the parameter and the braces around the function body may be omitted. However, they can only be omitted in certain cases.

The parentheses can only be omitted if the function has a single simple parameter. If it has multiple parameters, no parameters, or default, destructured, or rest parameters, the parentheses around the parameter list are required.

```
// Traditional anonymous function
(function (a, b) {
  return a + b + 100;
});

// Arrow function
(a, b) => a + b + 100;

const a = 4;
const b = 2;

// Traditional anonymous function (no parameters)
(function () {
  return a + b + 100;
});

// Arrow function (no parameters)
() => a + b + 100;
```

The braces can only be omitted if the function directly returns an expression. If the body has statements, the braces are required. In this case, return values must be explicitly specified with the `return` keyword. Arrow functions cannot guess what or when you want to return.

```
// Traditional anonymous function
(function (a, b) {
  const chuck = 42;
  return a + b + chuck;
});

// Arrow function
(a, b) => {
  const chuck = 42;
  return a + b + chuck;
};
```

Arrow functions are not inherently associated with a name. If the arrow function needs to call itself, use a named function expression instead. You can also assign the arrow function to a variable, allowing you to refer to it through that variable.

```
// Traditional Function
function bob(a) {
  return a + 100;
}

// Arrow Function
const bob2 = (a) => a + 100;
```

Function body

Arrow functions can have either an *expression body* or the usual *block body*.

In an expression body, only a single expression is specified, which becomes the implicit return value. The block body is analogous to traditional function bodies, where return values must be explicitly specified with the `return` keyword. Arrow functions are not required to return a value. If execution of the block body reaches the end without encountering a `return` statement, the function returns `undefined` like other functions.

```
// Expression body
const add = (a, b) => a + b; // Implicitly returns a + b

// Block body
const add2 = (a, b) => {
  console.log(a, b);
  return a + b; // Must explicitly return a value
};

// No return value
const add3 = (b) => {
  a += b;
  // No return statement, so returns undefined
};
```

Returning object literals using the expression body syntax `(params) => { object: literal }` does not work as expected.

```
const func = () => { foo: 1 };
// Calling func() returns undefined!

const func2 = () => { foo: function () {} };
// SyntaxError: function statement requires a name

const func3 = () => { foo() {} };
// SyntaxError: Unexpected token '{'
```

This is because JavaScript only sees the arrow function as having an expression body if the token following the arrow is not a left brace, so the code inside braces ({}) is parsed as a sequence of statements, where `foo` is a label, not a key in an object literal.

To fix this, wrap the object literal in parentheses:

```
const func = () => ({ foo: 1 });
```

Cannot be used as methods

Arrow function expressions should only be used for non-method functions because they do not have their own `this`. Let's see what happens when we try to use them as methods:

```
"use strict";

const obj = {
  i: 10,
  b: () => console.log(this.i, this),
  c() {
    console.log(this.i, this);
  },
};

obj.b(); // logs undefined, Window { /* … */ } (or the global object)
obj.c(); // logs 10, Object { /* … */ }
```

Another example involving `Object.defineProperty()`:

```
"use strict";

const obj = {
  a: 10,
};

Object.defineProperty(obj, "b", {
  get: () => {
    console.log(this.a, typeof this.a, this); // undefined 'undefined' Window { /* … */ } (or the global object)
    return this.a + 10; // represents global object 'Window', therefore 'this.a' returns 'undefined'
  },
});
```

Because a class's body has a `this` context, arrow functions as class fields close over the class's `this` context, and the `this` inside the arrow function's body will correctly point to the instance (or the class itself, for static fields). However, because it is a closure, not the function's own binding, the value of `this` will not change based on the execution context.

```
class C {
  a = 1;
  autoBoundMethod = () => {
    console.log(this.a);
  };
}

const c = new C();
c.autoBoundMethod(); // 1
const { autoBoundMethod } = c;
autoBoundMethod(); // 1
// If it were a normal method, it should be undefined in this case
```

Arrow function properties are often said to be "auto-bound methods", because the equivalent with normal methods is:

```
class C {
  a = 1;
  constructor() {
    this.method = this.method.bind(this);
  }
  method() {
    console.log(this.a);
  }
}
```

> **Note:** Class fields are defined on the *instance*, not on the *prototype*, so every instance creation would create a new function reference and allocate a new closure, potentially leading to more memory usage than a normal unbound method.

For similar reasons, the `call()`, `apply()`, and `bind()` methods are not useful when called on arrow functions, because arrow functions establish `this` based on the scope the arrow function is defined within, and the `this` value does not change based on how the function is invoked.

No binding of arguments

Arrow functions do not have their own `arguments` object. Thus, in this example, `arguments` is a reference to the arguments of the enclosing scope:

```
function foo(n) {
  const f = () => arguments[0] + n; // foo's implicit arguments binding. arguments[0] is n
  return f();
}

foo(3); // 3 + 3 = 6
```

In most cases, using rest parameters is a good alternative to using an `arguments` object.

```
function foo(n) {
  const f = (...args) => args[0] + n;
  return f(10);
}

foo(1); // 11
```

Cannot be used as constructors

Arrow functions cannot be used as constructors and will throw an error when called with `new`. They also do not have a `prototype` property.

```
const Foo = () => {};
const foo = new Foo(); // TypeError: Foo is not a constructor
console.log("prototype" in Foo); // false
```

Cannot be used as generators

The `yield` keyword cannot be used in an arrow function's body (except when used within generator functions further nested within the arrow function). As a consequence, arrow functions cannot be used as generators.

Line break before arrow

An arrow function cannot contain a line break between its parameters and its arrow.

```
const func = (a, b, c)
  => 1;
// SyntaxError: Unexpected token '=>'
```

For the purpose of formatting, you may put the line break after the arrow or use parentheses/braces around the function body, as shown below. You can also put line breaks between parameters.

```
const func = (a, b, c) =>
  1;

const func2 = (a, b, c) => (
  1
);

const func3 = (a, b, c) => {
  return 1;
};

const func4 = (
  a,
  b,
  c,
) => 1;
```

Precedence of arrow

Although the arrow in an arrow function is not an operator, arrow functions have special parsing rules that interact differently with operator precedence compared to regular functions.

```
let callback;

callback = callback || () => {};
// SyntaxError: invalid arrow-function arguments
```

Because `=>` has a lower precedence than most operators, parentheses are necessary to avoid `callback || ()` being parsed as the arguments list of the arrow function.

```
callback = callback || (() => {});
```

Examples

Using arrow functions

```
// An empty arrow function returns undefined
const empty = () => {};

(() => "foobar")();
// Returns "foobar"
// (this is an Immediately Invoked Function Expression)
```

```
const simple = (a) => (a > 15 ? 15 : a);
simple(16); // 15
simple(10); // 10

const max = (a, b) => (a > b ? a : b);

// Easy array filtering, mapping, etc.
const arr = [5, 6, 13, 0, 1, 18, 23];

const sum = arr.reduce((a, b) => a + b);
// 66

const even = arr.filter((v) => v % 2 === 0);
// [6, 0, 18]

const double = arr.map((v) => v * 2);
// [10, 12, 26, 0, 2, 36, 46]

// More concise promise chains
promise
  .then((a) => {
    // …
  })
  .then((b) => {
    // …
  });

// Arrow functions without parameters
setTimeout(() => {
  console.log("I happen sooner");
  setTimeout(() => {
    // deeper code
    console.log("I happen later");
  }, 1);
}, 1);
```

Using call, bind, and apply

The `call()`, `apply()`, and `bind()` methods work as expected with traditional functions, because we establish the scope for each of the methods:

```
const obj = {
  num: 100,
};

// Setting "num" on globalThis to show how it is NOT used.
globalThis.num = 42;

// A traditional function to operate on "this"
function add(a, b, c) {
  return this.num + a + b + c;
}

console.log(add.call(obj, 1, 2, 3)); // 106
console.log(add.apply(obj, [1, 2, 3])); // 106
const boundAdd = add.bind(obj);
console.log(boundAdd(1, 2, 3)); // 106
```

With arrow functions, since our `add` function is essentially created on the `globalThis` (global) scope, it will assume `this` is the `globalThis`.

```
const obj = {
  num: 100,
};

// Setting "num" on globalThis to show how it gets picked up.
globalThis.num = 42;

// Arrow function
const add = (a, b, c) => this.num + a + b + c;

console.log(add.call(obj, 1, 2, 3)); // 48
console.log(add.apply(obj, [1, 2, 3])); // 48
const boundAdd = add.bind(obj);
console.log(boundAdd(1, 2, 3)); // 48
```

Perhaps the greatest benefit of using arrow functions is with methods like `setTimeout()` and `EventTarget.prototype.addEventListener()` that usually require some kind of closure, `call()`, `apply()`, or `bind()` to ensure that the function is executed in the proper scope.

With traditional function expressions, code like this does not work as expected:

```
const obj = {
  count: 10,
  doSomethingLater() {
    setTimeout(function () {
      // the function executes on the window scope
```

```
      this.count++;
      console.log(this.count);
    }, 300);
  },
};

obj.doSomethingLater(); // logs "NaN", because the property "count" is not in the window scope.
```

With arrow functions, the `this` scope is more easily preserved:

```
const obj = {
  count: 10,
  doSomethingLater() {
    // The method syntax binds "this" to the "obj" context.
    setTimeout(() => {
      // Since the arrow function doesn't have its own binding and
      // setTimeout (as a function call) doesn't create a binding
      // itself, the "obj" context of the outer method is used.
      this.count++;
      console.log(this.count);
    }, 300);
  },
};

obj.doSomethingLater(); // logs 11
```

Default parameters

Default function parameters allow named parameters to be initialized with default values if no value or `undefined` is passed.

Try it

```
function multiply(a, b = 1) {
  return a * b;
}

console.log(multiply(5, 2));
// Expected output: 10

console.log(multiply(5));
// Expected output: 5
```

Syntax

```
function fnName(param1 = defaultValue1, /* …, */ paramN = defaultValueN) {
  // …
}
```

Description

In JavaScript, function parameters default to `undefined`. However, it's often useful to set a different default value. This is where default parameters can help.

In the following example, if no value is provided for `b` when `multiply` is called, `b`'s value would be `undefined` when evaluating `a * b` and `multiply` would return `NaN`.

```
function multiply(a, b) {
  return a * b;
}

multiply(5, 2); // 10
multiply(5); // NaN !
```

In the past, the general strategy for setting defaults was to test parameter values in the function body and assign a value if they are `undefined`. In the following example, `b` is set to `1` if `multiply` is called with only one argument:

```
function multiply(a, b) {
  b = typeof b !== "undefined" ? b : 1;
  return a * b;
}

multiply(5, 2); // 10
multiply(5); // 5
```

With default parameters, checks in the function body are no longer necessary. Now, you can assign `1` as the default value for `b` in the function head:

```
function multiply(a, b = 1) {
  return a * b;
}

multiply(5, 2); // 10
multiply(5); // 5
multiply(5, undefined); // 5
```

Parameters are still set left-to-right, overwriting default parameters even if there are later parameters without defaults.

```
function f(x = 1, y) {
  return [x, y];
}

f(); // [1, undefined]
f(2); // [2, undefined]
```

> **Note:** The first default parameter and all parameters after it will not contribute to the function's `length`.

The default parameter initializers live in their own scope, which is a parent of the scope created for the function body.

This means that earlier parameters can be referred to in the initializers of later parameters. However, functions and variables declared in the function body cannot be referred to from default value parameter initializers; attempting to do so throws a run-time `ReferenceError`. This also includes `var`-declared variables in the function body.

For example, the following function will throw a `ReferenceError` when invoked, because the default parameter value does not have access to the child scope of the function body:

```
function f(a = go()) {
  function go() {
    return ":P";
  }
}

f(); // ReferenceError: go is not defined
```

This function will print the value of the *parameter* `a`, because the variable `var a` is hoisted only to the top of the scope created for the function body, not the parent scope created for the parameter list, so its value is not visible to `b`.

```
function f(a, b = () => console.log(a)) {
  var a = 1;
  b();
}

f(); // undefined
f(5); // 5
```

The default parameter allows any expression, but you cannot use `await` or `yield` that would pause the evaluation of the default expression. The parameter must be initialized *synchronously*.

```
async function f(a = await Promise.resolve(1)) {
  return a;
}
```

> **Note:** Because the default parameter is evaluated when the function is called, not when the function is defined, the validity of the `await` and `yield` operators depends on the function itself, not its surrounding function. For example, if the current function is not `async`, `await` will be parsed as an identifier and follow normal identifier syntax rules, even when this function is nested in an `async` function.

Examples

Passing undefined vs. other falsy values

In the second call in this example, even if the first argument is set explicitly to `undefined` (though not `null` or other falsy values), the value of the `num` argument is still the default.

```
function test(num = 1) {
  console.log(typeof num);
}

test(); // 'number' (num is set to 1)
test(undefined); // 'number' (num is set to 1 too)

// test with other falsy values:
test(""); // 'string' (num is set to '')
test(null); // 'object' (num is set to null)
```

Evaluated at call time

The default argument is evaluated at *call time*. Unlike with Python (for example), a new object is created each time the function is called.

```
function append(value, array = []) {
  array.push(value);
  return array;
}

append(1); // [1]
append(2); // [2], not [1, 2]
```

This even applies to functions and variables:

```
function callSomething(thing = something()) {
  return thing;
}

let numberOfTimesCalled = 0;
function something() {
  numberOfTimesCalled += 1;
  return numberOfTimesCalled;
}

callSomething(); // 1
callSomething(); // 2
```

Earlier parameters are available to later default parameters

Parameters defined earlier (to the left) are available to later default parameters:

```
function greet(name, greeting, message = `${greeting} ${name}`) {
  return [name, greeting, message];
}

greet("David", "Hi"); // ["David", "Hi", "Hi David"]
greet("David", "Hi", "Happy Birthday!"); // ["David", "Hi", "Happy Birthday!"]
```

This functionality can be approximated like this, which demonstrates how many edge cases are handled:

```
function go() {
  return ":P";
}

function withDefaults(
  a,
  b = 5,
  c = b,
  d = go(),
  e = this,
  f = arguments,
  g = this.value,
) {
  return [a, b, c, d, e, f, g];
}

function withoutDefaults(a, b, c, d, e, f, g) {
  switch (arguments.length) {
    case 0:
    case 1:
      b = 5;
    case 2:
      c = b;
    case 3:
      d = go();
    case 4:
      e = this;
    case 5:
      f = arguments;
    case 6:
      g = this.value;
  }
  return [a, b, c, d, e, f, g];
}

withDefaults.call({ value: "=^_^=" });
// [undefined, 5, 5, ":P", {value:"=^_^="}, arguments, "=^_^="]

withoutDefaults.call({ value: "=^_^=" });
// [undefined, 5, 5, ":P", {value:"=^_^="}, arguments, "=^_^="]
```

Destructured parameter with default value assignment

You can use default value assignment with the destructuring syntax.

A common way of doing that is to set an empty object/array as the default value for the destructured parameter; for example: `[x = 1, y = 2] = []`. This makes it possible to pass nothing to the function and still have those values prefilled:

```
function preFilledArray([x = 1, y = 2] = []) {
  return x + y;
}

preFilledArray(); // 3
preFilledArray([]); // 3
preFilledArray([2]); // 4
preFilledArray([2, 3]); // 5

// Works the same for objects:
function preFilledObject({ z = 3 } = {}) {
  return z;
}

preFilledObject(); // 3
preFilledObject({}); // 3
preFilledObject({ z: 2 }); // 2
```

get

The **`get`** syntax binds an object property to a function that will be called when that property is looked up. It can also be used in classes.

Try it

```
const obj = {
  log: ["a", "b", "c"],
  get latest() {
    return this.log[this.log.length - 1];
  },
};

console.log(obj.latest);
// Expected output: "c"
```

Syntax

```
{ get prop() { /* … */ } }
{ get [expression]() { /* … */ } }
```

There are some additional syntax restrictions:

- A getter must have exactly zero parameters.

Parameters

`prop`

> The name of the property to bind to the given function. In the same way as other properties in object initializers, it can be a string literal, a number literal, or an identifier.

`expression`

> You can also use expressions for a computed property name to bind to the given function.

Description

Sometimes, it is desirable to allow access to a property that returns a dynamically computed value, or you may want to reflect the status of an internal variable without requiring the use of explicit method calls. In JavaScript, this can be accomplished with the use of a *getter*.

An object property is either a data property or an accessor property, but it cannot simultaneously be both. Read `Object.defineProperty()` for more information. The getter syntax allows you to specify the getter function in an object initializer.

```
const obj = {
  get prop() {
    // getter, the code executed when reading obj.prop
    return someValue;
  },
};
```

Properties defined using this syntax are own properties of the created object, and they are configurable and enumerable.

Examples

Defining a getter on new objects in object initializers

This will create a pseudo-property `latest` for object `obj`, which will return the last array item in `log`.

```
const obj = {
  log: ["example", "test"],
  get latest() {
    return this.log.at(-1);
  },
};
console.log(obj.latest); // "test"
```

Note that attempting to assign a value to `latest` will not change it.

Using getters in classes

You can use the exact same syntax to define public instance getters that are available on class instances. In classes, you don't need the comma separator between methods.

```
class ClassWithGetSet {
  #msg = "hello world";
  get msg() {
    return this.#msg;
  }
  set msg(x) {
    this.#msg = `hello ${x}`;
  }
}

const instance = new ClassWithGetSet();
console.log(instance.msg); // "hello world"

instance.msg = "cake";
console.log(instance.msg); // "hello cake"
```

Getter properties are defined on the `prototype` property of the class and are thus shared by all instances of the class. Unlike getter properties in object literals, getter properties in classes are not enumerable.

Static getters and private getters use similar syntaxes, which are described in the `static` and private elements pages.

Deleting a getter using the <code>delete</code> operator

If you want to remove the getter, you can just `delete` it:

```
delete obj.latest;
```

Defining a getter on existing objects using <code>defineProperty</code>

To append a getter to an existing object later at any time, use `Object.defineProperty()`.

```
const o = { a: 0 };

Object.defineProperty(o, "b", {
  get() {
    return this.a + 1;
  },
});

console.log(o.b); // Runs the getter, which yields a + 1 (which is 1)
```

Using a computed property name

```
const expr = "foo";

const obj = {
  get [expr]() {
    return "bar";
  },
};

console.log(obj.foo); // "bar"
```

Defining static getters

```
class MyConstants {
  static get foo() {
    return "foo";
  }
}

console.log(MyConstants.foo); // 'foo'
```

```
MyConstants.foo = "bar";
console.log(MyConstants.foo); // 'foo', a static getter's value cannot be changed
```

Smart / self-overwriting / lazy getters

Getters give you a way to *define* a property of an object, but they do not *calculate* the property's value until it is accessed. A getter defers the cost of calculating the value until the value is needed. If it is never needed, you never pay the cost.

An additional optimization technique to lazify or delay the calculation of a property value and cache it for later access are *smart* (or *memoized*) getters. The value is calculated the first time the getter is called and is then cached so subsequent accesses return the cached value without recalculating it. This is useful in the following situations:

- If the calculation of a property value is expensive (takes much RAM or CPU time, spawns worker threads, retrieves remote file, etc.).
- If the value isn't needed just now. It will be used later, or in some cases, it's not used at all.
- If it's used, it will be accessed several times, and there is no need to re-calculate that value will never be changed or shouldn't be re-calculated.

> **Note:** This means that you shouldn't write a lazy getter for a property whose value you expect to change, because if the getter is lazy, then it will not recalculate the value.
>
> Note that getters are not "lazy" or "memoized" by nature; you must implement this technique if you desire this behavior.

In the following example, the object has a getter as its own property. On getting the property, the property is removed from the object and re-added, but implicitly as a data property this time. Finally, the value gets returned.

```
const obj = {
  get notifier() {
    delete this.notifier;
    this.notifier = document.getElementById("bookmarked-notification-anchor");
    return this.notifier;
  },
};
```

Feature detection

Many functions accept an object and retrieve individual properties from it as separate parameters (this object parameter is known as an *options bag*). You can detect whether a specific option is supported by using a getter to track if the property has been retrieved. This example checks if the `colorType` option is supported by the `HTMLCanvasElement.getContext()` method.

```
function isColorTypeSupported() {
  let supported = false;
  const obj = {
    get colorType() {
      supported = true;
      return undefined;
    },
  };
  document.createElement("canvas").getContext("2d", obj);
  return supported;
}
```

get vs. defineProperty

While using the `get` keyword and `Object.defineProperty()` have similar results, there is a subtle difference between the two when used on classes. The `get` syntax defines the property on the instance's prototype, while `Object.defineProperty()` defines the property on the instance it is applied to.

```
class Example {
  get hello() {
    return "world";
  }
}

const obj = new Example();
console.log(obj.hello);
// "world"

console.log(Object.getOwnPropertyDescriptor(obj, "hello"));
// undefined

console.log(
  Object.getOwnPropertyDescriptor(Object.getPrototypeOf(obj), "hello"),
);
// { configurable: true, enumerable: false, get: function get hello() { return 'world'; }, set: undefined }
```

Method definitions

Method definition is a shorter syntax for defining a function property in an object initializer. It can also be used in classes.

Try it

```
const obj = {
  foo() {
    return "bar";
  },
};

console.log(obj.foo());
// Expected output: "bar"
```

Syntax

```
({
  property(parameters) {},
  *generator(parameters) {},
  async property(parameters) {},
  async *generator(parameters) {},

  // with computed keys
  [expression](parameters) {},
  *[expression](parameters) {},
  async [expression](parameters) {},
  async *[expression](parameters) {},
})
```

Description

The shorthand syntax is similar to the getter and setter syntax.

Given the following code:

```
const obj = {
  foo: function () {
    // …
  },
  bar: function () {
    // …
  },
};
```

You are now able to shorten this to:

```
const obj = {
  foo() {
    // …
  },
  bar() {
    // …
  },
};
```

Properties defined using this syntax are own properties of the created object, and they are configurable, enumerable, and writable, just like normal properties.

`function*`, `async function`, and `async function*` properties all have their respective method syntaxes; see examples below.

However, note that the method syntax is not equivalent to a normal property with a function as its value — there are semantic differences. This makes methods defined in object literals more consistent with methods in classes.

Method definitions are not constructable

Methods cannot be constructors! They will throw a `TypeError` if you try to instantiate them. On the other hand, a property created as a function can be used as a constructor.

```
const obj = {
  method() {},
};
new obj.method(); // TypeError: obj.method is not a constructor
```

Using super in method definitions

Only functions defined as methods have access to the `super` keyword. `super.prop` looks up the property on the prototype of the object that the method was initialized on.

```
const obj = {
  __proto__: {
    prop: "foo",
  },
  notAMethod: function () {
    console.log(super.prop); // SyntaxError: 'super' keyword unexpected here
  },
};
```

Examples

Using method definitions

```
const obj = {
  a: "foo",
  b() {
    return this.a;
  },
};
console.log(obj.b()); // "foo"
```

Method definitions in classes

You can use the exact same syntax to define public instance methods that are available on class instances. In classes, you don't need the comma separator between methods.

```
class ClassWithPublicInstanceMethod {
  publicMethod() {
    return "hello world";
  }
  secondPublicMethod() {
    return "goodbye world";
  }
}

const instance = new ClassWithPublicInstanceMethod();
console.log(instance.publicMethod()); // "hello world"
```

Public instance methods are defined on the `prototype` property of the class and are thus shared by all instances of the class. They are writable, non-enumerable, and configurable.

Inside instance methods, `this` and `super` work like in normal methods. Usually, `this` refers to the instance itself. In subclasses, `super` lets you access the prototype of the object that the method is attached to, allowing you to call methods from the superclass.

```
class BaseClass {
  msg = "hello world";
  basePublicMethod() {
    return this.msg;
  }
}

class SubClass extends BaseClass {
  subPublicMethod() {
    return super.basePublicMethod();
  }
}

const instance = new SubClass();
console.log(instance.subPublicMethod()); // "hello world"
```

Static methods and private methods use similar syntaxes, which are described in the `static` and private elements pages.

Computed property names

The method syntax also supports computed property names.

```
const bar = {
  foo0: function () {
    return 0;
  },
  foo1() {
    return 1;
  },
  ["foo".toUpperCase()]() {
    return 2;
  },
};

console.log(bar.foo0()); // 0
console.log(bar.foo1()); // 1
console.log(bar.FOO()); // 2
```

Generator methods

Note that the asterisk (`*`) in the generator method syntax must be *before* the generator property name. (That is, `* g(){}` will work, but `g *(){}` will not.)

```
// Using a named property
const obj = {
  g: function* () {
    let index = 0;
    while (true) {
      yield index++;
    }
  },
};

// The same object using shorthand syntax
const obj2 = {
  *g() {
    let index = 0;
    while (true) {
      yield index++;
    }
  },
};

const it = obj2.g();
console.log(it.next().value); // 0
console.log(it.next().value); // 1
```

Async methods

```
// Using a named property
const obj = {
  f: async function () {
    await somePromise;
  },
};

// The same object using shorthand syntax
const obj2 = {
  async f() {
    await somePromise;
  },
};
```

Async generator methods

```
// Using a named property
const obj = {
  f: async function* () {
    yield 1;
    yield 2;
    yield 3;
  },
};

// The same object using shorthand syntax
const obj2 = {
  async *f() {
    yield 1;
    yield 2;
    yield 3;
  },
};
```

Rest parameters

The **rest parameter** syntax allows a function to accept an indefinite number of arguments as an array, providing a way to represent variadic functions in JavaScript.

Try it

```
function sum(...theArgs) {
  let total = 0;
  for (const arg of theArgs) {
    total += arg;
  }
  return total;
```

```
}

console.log(sum(1, 2, 3));
// Expected output: 6

console.log(sum(1, 2, 3, 4));
// Expected output: 10
```

Syntax

```
function f(a, b, ...theArgs) {
  // …
}
```

There are some additional syntax restrictions:

- A function definition can only have one rest parameter.
- The rest parameter must be the last parameter in the function definition.
- Trailing commas are not allowed after the rest parameter.
- The rest parameter cannot have a default value.

Description

A function definition's last parameter can be prefixed with `...` (three U+002E FULL STOP characters), which will cause all remaining (user supplied) parameters to be placed within an `Array` object.

```
function myFun(a, b, ...manyMoreArgs) {
  console.log("a", a);
  console.log("b", b);
  console.log("manyMoreArgs", manyMoreArgs);
}

myFun("one", "two", "three", "four", "five", "six");

// Console Output:
// a, one
// b, two
// manyMoreArgs, ["three", "four", "five", "six"]
```

The rest parameter may be destructured, which allows you to ignore certain parameter positions.

```
function ignoreFirst(...[, b, c]) {
  return b + c;
}
```

However, the following are all syntax errors:

```
function wrong1(...one, ...wrong) {}
function wrong2(...wrong, arg2, arg3) {}
function wrong3(...wrong,) {}
function wrong4(...wrong = []) {}
```

The rest parameter is not counted towards the function's `length` property.

The difference between rest parameters and the arguments object

There are four main differences between rest parameters and the `arguments` object:

- The `arguments` object is **not a real array**, while rest parameters are `Array` instances, meaning methods like `sort()`, `map()`, `forEach()` or `pop()` can be applied on it directly.
- The `arguments` object has the additional (deprecated) `callee` property.
- In a non-strict function with simple parameters, the `arguments` object syncs its indices with the values of parameters. The rest parameter array never updates its value when the named parameters are re-assigned.
- The rest parameter bundles all the *extra* parameters into a single array, but does not contain any named argument defined *before* the `...restParam`. The `arguments` object contains all of the parameters — including the parameters in the `...restParam` array — bundled into one array-like object.

Examples

Using rest parameters

In this example, the first argument is mapped to `a` and the second to `b`, so these named arguments are used as normal.

However, the third argument, `manyMoreArgs`, will be an array that contains the third, fourth, fifth, sixth, …, nth — as many arguments as the user specifies.

```
function myFun(a, b, ...manyMoreArgs) {
  console.log("a", a);
  console.log("b", b);
  console.log("manyMoreArgs", manyMoreArgs);
}

myFun("one", "two", "three", "four", "five", "six");
```

```
// a, "one"
// b, "two"
// manyMoreArgs, ["three", "four", "five", "six"] <-- an array
```

Below, even though there is just one value, the last argument still gets put into an array.

```
// Using the same function definition from example above

myFun("one", "two", "three");

// a, "one"
// b, "two"
// manyMoreArgs, ["three"] <-- an array with just one value
```

Below, the third argument isn't provided, but `manyMoreArgs` is still an array (albeit an empty one).

```
// Using the same function definition from example above

myFun("one", "two");

// a, "one"
// b, "two"
// manyMoreArgs, [] <-- still an array
```

Below, only one argument is provided, so `b` gets the default value `undefined`, but `manyMoreArgs` is still an empty array.

```
// Using the same function definition from example above

myFun("one");

// a, "one"
// b, undefined
// manyMoreArgs, [] <-- still an array
```

Argument length

Since `theArgs` is an array, a count of its elements is given by the `length` property. If the function's only parameter is a rest parameter, `restParams.length` will be equal to `arguments.length`.

```
function fun1(...theArgs) {
  console.log(theArgs.length);
}

fun1(); // 0
fun1(5); // 1
fun1(5, 6, 7); // 3
```

Using rest parameters in combination with ordinary parameters

In the next example, a rest parameter is used to collect all parameters after the first parameter into an array. Each one of the parameter values collected into the array is then multiplied by the first parameter, and the array is returned:

```
function multiply(multiplier, ...theArgs) {
  return theArgs.map((element) => multiplier * element);
}

const arr = multiply(2, 15, 25, 42);
console.log(arr); // [30, 50, 84]
```

From arguments to an array

`Array` methods can be used on rest parameters, but not on the `arguments` object:

```
function sortRestArgs(...theArgs) {
  const sortedArgs = theArgs.sort();
  return sortedArgs;
}

console.log(sortRestArgs(5, 3, 7, 1)); // 1, 3, 5, 7

function sortArguments() {
  const sortedArgs = arguments.sort();
  return sortedArgs; // this will never happen
}

console.log(sortArguments(5, 3, 7, 1));
// throws a TypeError (arguments.sort is not a function)
```

Rest parameters were introduced to reduce the boilerplate code that was commonly used for converting a set of arguments to an array.

Before rest parameters, `arguments` need to be converted to a normal array before calling array methods on them:

```
function fn(a, b) {
  const normalArray = Array.prototype.slice.call(arguments);
  // — or —
  const normalArray2 = [].slice.call(arguments);
  // — or —
  const normalArrayFrom = Array.from(arguments);

  const first = normalArray.shift(); // OK, gives the first argument
  const firstBad = arguments.shift(); // ERROR (arguments is not a normal array)
}
```

Now, you can easily gain access to a normal array using a rest parameter:

```
function fn(...args) {
  const normalArray = args;
  const first = normalArray.shift(); // OK, gives the first argument
}
```

- Functions
- Spread syntax (`...`)
- Default parameters
- `arguments`
- `Array`

set

The **`set`** syntax binds an object property to a function to be called when there is an attempt to set that property. It can also be used in classes.

Try it

```
const language = {
  set current(name) {
    this.log.push(name);
  },
  log: [],
};

language.current = "EN";
language.current = "FA";

console.log(language.log);
// Expected output: Array ["EN", "FA"]
```

Syntax

```
{ set prop(val) { /* … */ } }
{ set [expression](val) { /* … */ } }
```

There are some additional syntax restrictions:

- A setter must have exactly one parameter.

Parameters

`prop`

The name of the property to bind to the given function. In the same way as other properties in object initializers, it can be a string literal, a number literal, or an identifier.

`val`

An alias for the variable that holds the value attempted to be assigned to `prop`.

`expression`

You can also use expressions for a computed property name to bind to the given function.

Description

In JavaScript, a setter can be used to execute a function whenever an attempt is made to change a property's value. Setters are most often used in conjunction with getters.

An object property is either a data property or an accessor property, but it cannot simultaneously be both. Read `Object.defineProperty()` for more information. The setter syntax allows you to specify the setter function in an object initializer.

```
const obj = {
  set prop(val) {
    // setter, the code executed when setting obj.prop
```

```
  },
};
```

Properties defined using this syntax are own properties of the created object, and they are configurable and enumerable.

Examples

Defining a setter on new objects in object initializers

The following example defines a pseudo-property `current` of object `language`. When `current` is assigned a value, it updates `log` with that value:

```
const language = {
  set current(name) {
    this.log.push(name);
  },
  log: [],
};

language.current = "EN";
console.log(language.log); // ['EN']

language.current = "FA";
console.log(language.log); // ['EN', 'FA']
```

Note that `current` is not defined, and any attempts to access it will result in `undefined`.

Using setters in classes

You can use the exact same syntax to define public instance setters that are available on class instances. In classes, you don't need the comma separator between methods.

```
class ClassWithGetSet {
  #msg = "hello world";
  get msg() {
    return this.#msg;
  }
  set msg(x) {
    this.#msg = `hello ${x}`;
  }
}

const instance = new ClassWithGetSet();
console.log(instance.msg); // "hello world"

instance.msg = "cake";
console.log(instance.msg); // "hello cake"
```

Setter properties are defined on the `prototype` property of the class and are thus shared by all instances of the class. Unlike setter properties in object literals, setter properties in classes are not enumerable.

Static setters and private setters use similar syntaxes, which are described in the `static` and private elements pages.

Removing a setter with the <code>delete</code> operator

If you want to remove the setter, you can just `delete` it:

```
delete language.current;
```

Defining a setter on existing objects using <code>defineProperty</code>

To append a setter to an *existing* object, use `Object.defineProperty()`.

```
const o = { a: 0 };

Object.defineProperty(o, "b", {
  set(x) {
    this.a = x / 2;
  },
});

o.b = 10;
// Runs the setter, which assigns 10 / 2 (5) to the 'a' property

console.log(o.a); // 5
```

Using a computed property name

```
const expr = "foo";

const obj = {
  baz: "bar",
  set [expr](v) {
    this.baz = v;
```

```
  },
};

console.log(obj.baz); // "bar"

obj.foo = "baz";
// Run the setter

console.log(obj.baz); // "baz"
```

Standard built-in objects

This chapter documents all of JavaScript's standard, built-in objects, including their methods and properties.

The term "global objects" (or standard built-in objects) here is not to be confused with **the global object**. Here, "global objects" refer to **objects in the global scope**.

The **global object** itself can be accessed using the `this` operator in the global scope. In fact, the global scope **consists of** the properties of the global object, including inherited properties, if any.

Other objects in the global scope are either created by the user script or provided by the host application. The host objects available in browser contexts are documented in the API reference.

For more information about the distinction between the DOM and core JavaScript, see JavaScript technologies overview.

Standard objects by category

Value properties

These global properties return a simple value. They have no properties or methods.

- `globalThis`
- `Infinity`
- `NaN`
- `undefined`

Function properties

These global functions—functions which are called globally, rather than on an object—directly return their results to the caller.

- `eval()`
- `isFinite()`
- `isNaN()`
- `parseFloat()`
- `parseInt()`
- `decodeURI()`
- `decodeURIComponent()`
- `encodeURI()`
- `encodeURIComponent()`
- `escape()`
- `unescape()`

Fundamental objects

These objects represent fundamental language constructs.

- `Object`
- `Function`
- `Boolean`
- `Symbol`

Error objects

Error objects are a special type of fundamental object. They include the basic `Error` type, as well as several specialized error types.

- `Error`
- `AggregateError`
- `EvalError`
- `RangeError`

- `ReferenceError`
- `SuppressedError`
- `SyntaxError`
- `TypeError`
- `URIError`
- `InternalError`

Numbers and dates

These are the base objects representing numbers, dates, and mathematical calculations.

- `Number`
- `BigInt`
- `Math`
- `Date`
- `Temporal`

Text processing

These objects represent strings and support manipulating them.

- `String`
- `RegExp`

Indexed collections

These objects represent collections of data which are ordered by an index value. This includes (typed) arrays and array-like constructs.

- `Array`
- `TypedArray`
- `Int8Array`
- `Uint8Array`
- `Uint8ClampedArray`
- `Int16Array`
- `Uint16Array`
- `Int32Array`
- `Uint32Array`
- `BigInt64Array`
- `BigUint64Array`
- `Float16Array`
- `Float32Array`
- `Float64Array`

Keyed collections

These objects represent collections which use keys. The iterable collections (`Map` and `Set`) contain elements which are easily iterated in the order of insertion.

- `Map`
- `Set`
- `WeakMap`
- `WeakSet`

Structured data

These objects represent and interact with structured data buffers and data coded using JavaScript Object Notation (JSON).

- `ArrayBuffer`
- `SharedArrayBuffer`
- `DataView`
- `Atomics`
- `JSON`

Managing memory

These objects interact with the garbage collection mechanism.

- `WeakRef`
- `FinalizationRegistry`

Control abstraction objects

Control abstractions can help to structure code, especially async code (without using deeply nested callbacks, for example).

- `Iterator`
- `AsyncIterator`
- `Promise`
- `GeneratorFunction`
- `AsyncGeneratorFunction`
- `Generator`
- `AsyncGenerator`

- `AsyncFunction`
- `DisposableStack`
- `AsyncDisposableStack`

Reflection

- `AbstractModuleSource`
- `Reflect`
- `Proxy`

Internationalization

Additions to the ECMAScript core for language-sensitive functionalities.

- `Intl`
- `Intl.Collator`
- `Intl.DateTimeFormat`
- `Intl.DisplayNames`
- `Intl.DurationFormat`
- `Intl.ListFormat`
- `Intl.Locale`
- `Intl.NumberFormat`
- `Intl.PluralRules`
- `Intl.RelativeTimeFormat`
- `Intl.Segmenter`

AbstractModuleSource

An ***AbstractModuleSource*** object represents the compiled source of a module obtained with `import source` or `import.source()`. There is no directly visible `AbstractModuleSource` constructor.

Description

The `AbstractModuleSource` constructor (often referred to as `%AbstractModuleSource%` to indicate its "intrinsicness", since it does not correspond to any global exposed to a JavaScript program) serves as the superclass of all module source subclasses, providing a common interface of utility methods. This constructor is not directly exposed: there is no global `AbstractModuleSource` property. It is only accessible through `Object.getPrototypeOf(moduleSourceObject.constructor)` and similar.

AbstractModuleSource objects

- `WebAssembly.Module`

JavaScript module source objects will be added by the ECMAScript Module Phase Imports proposal.

Constructor

This object cannot be instantiated directly — attempting to construct it with `new` throws a `TypeError`.

```
import source modSource from "./module.wasm";

new (Object.getPrototypeOf(modSource.constructor))();
// TypeError: Abstract class AbstractModuleSource not directly constructable
```

Instead, obtain a module source object using `import source`, `import.source()`, or a concrete module type's API, such as `WebAssembly.Module()`. These mechanisms do not call the abstract constructor.

Instance properties

These properties are defined on `AbstractModuleSource.prototype` and shared by all `AbstractModuleSource` subclass instances.

`AbstractModuleSource.prototype.constructor`

> The constructor function that created the instance object. `AbstractModuleSource.prototype.constructor` is the hidden `AbstractModuleSource` constructor function, but each module source subclass also defines its own `constructor` property.

`AbstractModuleSource.prototype[Symbol.toStringTag]`

> The initial value of the `AbstractModuleSource.prototype[Symbol.toStringTag]` property is a getter that returns a string based on the constructor's identity, such as `"WebAssembly.Module"` or `"ModuleSource"`. It returns `undefined` if the `this` value is not an instance of one of the module source subclasses. This property is used in `Object.prototype.toString()`.

- `import source`

AggregateError

The **`AggregateError`** object represents an error when several errors need to be wrapped in a single error. It is thrown when multiple errors need to be reported by an operation, for example by `Promise.any()`, when all promises passed to it reject.

Compared to `SuppressedError`, `AggregateError` represents a list of unrelated errors, while `SuppressedError` represents an error that happened during the handling of another error.

`AggregateError` is a subclass of `Error`.

Constructor

`AggregateError()`

Creates a new `AggregateError` object.

Instance properties

Also inherits instance properties from its parent `Error`.

These properties are defined on `AggregateError.prototype` and shared by all `AggregateError` instances.

`AggregateError.prototype.constructor`

The constructor function that created the instance object. For `AggregateError` instances, the initial value is the `AggregateError` constructor.

`AggregateError.prototype.name`

Represents the name for the type of error. For `AggregateError.prototype.name`, the initial value is `"AggregateError"`.

These properties are own properties of each `AggregateError` instance.

`errors`

An array representing the errors that were aggregated.

Instance methods

Inherits instance methods from its parent `Error`.

Examples

Catching an AggregateError

```
Promise.any([Promise.reject(new Error("some error"))]).catch((e) => {
  console.log(e instanceof AggregateError); // true
  console.log(e.message); // "All Promises rejected"
  console.log(e.name); // "AggregateError"
  console.log(e.errors); // [ Error: "some error" ]
});
```

Creating an AggregateError

```
try {
  throw new AggregateError([new Error("some error")], "Hello");
} catch (e) {
  console.log(e instanceof AggregateError); // true
  console.log(e.message); // "Hello"
  console.log(e.name); // "AggregateError"
  console.log(e.errors); // [ Error: "some error" ]
}
```

- `Error`
- `Promise.any`

AggregateError() constructor

The **`AggregateError()`** constructor creates `AggregateError` objects.

Syntax

```
new AggregateError(errors)
new AggregateError(errors, message)
new AggregateError(errors, message, options)

AggregateError(errors)
AggregateError(errors, message)
AggregateError(errors, message, options)
```

> **Note:** `AggregateError()` can be called with or without `new`. Both create a new `AggregateError` instance.

Parameters

`errors`

An iterable of errors, may not actually be `Error` instances.

`message` Optional

An optional human-readable description of the aggregate error.

`options` Optional

An object that has the following properties:

`cause` Optional

A property indicating the specific cause of the error. When catching and re-throwing an error with a more-specific or useful error message, this property can be used to pass the original error.

Examples

Creating an AggregateError

```
try {
  throw new AggregateError([new Error("some error")], "Hello");
} catch (e) {
  console.log(e instanceof AggregateError); // true
  console.log(e.message); // "Hello"
  console.log(e.name); // "AggregateError"
  console.log(e.errors); // [ Error: "some error" ]
}
```

- `Promise.any`

AggregateError: errors

The **`errors`** data property of an `AggregateError` instance contains an array representing the errors that were aggregated.

Value

An `Array` containing values in the same order as the iterable passed as the first argument of the `AggregateError()` constructor.

Property attributes of `AggregateError: errors`	
Writable	yes
Enumerable	no
Configurable	yes

Examples

Using errors

```
try {
  throw new AggregateError(
    // An iterable of errors
    new Set([new Error("some error"), new Error("another error")]),
    "Multiple errors thrown",
  );
} catch (err) {
  console.log(err.errors);
  // [
  //   Error: some error,
  //   Error: another error
  // ]
}
```

Array

The **`Array`** object, as with arrays in other programming languages, enables storing a collection of multiple items under a single variable name, and has members for performing common array operations.

Description

In JavaScript, arrays aren't primitives but are instead `Array` objects with the following core characteristics:

- **JavaScript arrays are resizable** and **can contain a mix of different data types**. (When those characteristics are undesirable, use typed arrays instead.)
- **JavaScript arrays are not associative arrays** and so, array elements cannot be accessed using arbitrary strings as indexes, but must be accessed using nonnegative integers (or their respective string form) as indexes.
- **JavaScript arrays are zero-indexed**: the first element of an array is at index `0`, the second is at index `1`, and so on — and the last element is at the value of the array's `length` property minus `1`.
- **JavaScript array-copy operations create shallow copies**. (All standard built-in copy operations with *any* JavaScript objects create shallow copies, rather than deep copies).

Array indices

`Array` objects cannot use arbitrary strings as element indexes (as in an associative array) but must use nonnegative integers (or their respective string form). Setting or accessing via non-integers will not set or retrieve an element from the array list itself, but will set or access a variable associated with that array's object property collection. The array's object properties and list of array elements are separate, and the array's traversal and mutation operations cannot be applied to these named properties.

Array elements are object properties in the same way that `toString` is a property (to be specific, however, `toString()` is a method). Nevertheless, trying to access an element of an array as follows throws a syntax error because the property name is not valid:

```
arr.0; // a syntax error
```

JavaScript syntax requires properties beginning with a digit to be accessed using bracket notation instead of dot notation. It's also possible to quote the array indices (e.g., `years['2']` instead of `years[2]`), although usually not necessary.

The `2` in `years[2]` is coerced into a string by the JavaScript engine through an implicit `toString` conversion. As a result, `'2'` and `'02'` would refer to two different slots on the `years` object, and the following example could be `true`:

```
console.log(years["2"] !== years["02"]);
```

Only `years['2']` is an actual array index. `years['02']` is an arbitrary string property that will not be visited in array iteration.

Relationship between length and numerical properties

A JavaScript array's `length` property and numerical properties are connected.

Several of the built-in array methods (e.g., `join()`, `slice()`, `indexOf()`, etc.) take into account the value of an array's `length` property when they're called.

Other methods (e.g., `push()`, `splice()`, etc.) also result in updates to an array's `length` property.

```
const fruits = [];
fruits.push("banana", "apple", "peach");
console.log(fruits.length); // 3
```

When setting a property on a JavaScript array when the property is a valid array index and that index is outside the current bounds of the array, the engine will update the array's `length` property accordingly:

```
fruits[5] = "mango";
console.log(fruits[5]); // 'mango'
console.log(Object.keys(fruits)); // ['0', '1', '2', '5']
console.log(fruits.length); // 6
```

Increasing the `length` extends the array by adding empty slots without creating any new elements — not even `undefined`.

```
fruits.length = 10;
console.log(fruits); // ['banana', 'apple', 'peach', empty x 2, 'mango', empty x 4]
console.log(Object.keys(fruits)); // ['0', '1', '2', '5']
console.log(fruits.length); // 10
console.log(fruits[8]); // undefined
```

Decreasing the `length` property does, however, delete elements.

```
fruits.length = 2;
console.log(Object.keys(fruits)); // ['0', '1']
console.log(fruits.length); // 2
```

This is explained further on the `length` page.

Array methods and empty slots

Array methods have different behaviors when encountering empty slots in sparse arrays. In general, older methods (e.g., `forEach`) treat empty slots differently from indices that contain `undefined`.

Methods that have special treatment for empty slots include the following: `concat()`, `copyWithin()`, `every()`, `filter()`, `flat()`, `flatMap()`, `forEach()`, `indexOf()`, `lastIndexOf()`, `map()`, `reduce()`, `reduceRight()`, `reverse()`, `slice()`, `some()`, `sort()`, and `splice()`. Iteration methods such as `forEach` don't visit empty slots at all. Other methods, such as `concat`, `copyWithin`, etc., preserve empty slots when doing the copying, so in the end the array is still sparse.

```
const colors = ["red", "yellow", "blue"];
colors[5] = "purple";
colors.forEach((item, index) => {
  console.log(`${index}: ${item}`);
});
```

```
// Output:
// 0: red
// 1: yellow
// 2: blue
// 5: purple

colors.reverse(); // ['purple', empty × 2, 'blue', 'yellow', 'red']
```

Newer methods (e.g., `keys`) do not treat empty slots specially and treat them as if they contain `undefined`. Methods that conflate empty slots with `undefined` elements include the following: `entries()`, `fill()`, `find()`, `findIndex()`, `findLast()`, `findLastIndex()`, `includes()`, `join()`, `keys()`, `toLocaleString()`, `toReversed()`, `toSorted()`, `toSpliced()`, `values()`, and `with()`.

```
const colors = ["red", "yellow", "blue"];
colors[5] = "purple";
const iterator = colors.keys();
for (const key of iterator) {
  console.log(`${key}: ${colors[key]}`);
}
// Output
// 0: red
// 1: yellow
// 2: blue
// 3: undefined
// 4: undefined
// 5: purple

const newColors = colors.toReversed(); // ['purple', undefined, undefined, 'blue', 'yellow', 'red']
```

Copying methods and mutating methods

Some methods do not mutate the existing array that the method was called on, but instead return a new array. They do so by first constructing a new array and then populating it with elements. The copy always happens *shallowly* — the method never copies anything beyond the initially created array. Elements of the original array(s) are copied into the new array as follows:

- Objects: the object reference is copied into the new array. Both the original and new array refer to the same object. That is, if a referenced object is modified, the changes are visible to both the new and original arrays.
- Primitive types such as strings, numbers and booleans (not `String`, `Number`, and `Boolean` objects): their values are copied into the new array.

Other methods mutate the array that the method was called on, in which case their return value differs depending on the method: sometimes a reference to the same array, sometimes the length of the new array.

The following methods create new arrays by accessing `this.constructor[Symbol.species]` to determine the constructor to use: `concat()`, `filter()`, `flat()`, `flatMap()`, `map()`, `slice()`, and `splice()` (to construct the array of removed elements that's returned).

The following methods always create new arrays with the `Array` base constructor: `toReversed()`, `toSorted()`, `toSpliced()`, and `with()`.

The following table lists the methods that mutate the original array, and the corresponding non-mutating alternative:

Mutating method	Non-mutating alternative
`copyWithin()`	No one-method alternative
`fill()`	No one-method alternative
`pop()`	`slice(0, -1)`
`push(v1, v2)`	`concat([v1, v2])`
`reverse()`	`toReversed()`
`shift()`	`slice(1)`
`sort()`	`toSorted()`
`splice()`	`toSpliced()`
`unshift(v1, v2)`	`toSpliced(0, 0, v1, v2)`

An easy way to change a mutating method into a non-mutating alternative is to use the spread syntax or `slice()` to create a copy first:

```
arr.copyWithin(0, 1, 2); // mutates arr
const arr2 = arr.slice().copyWithin(0, 1, 2); // does not mutate arr
const arr3 = [...arr].copyWithin(0, 1, 2); // does not mutate arr
```

Iterative methods

Many array methods take a callback function as an argument. The callback function is called sequentially and at most once for each element in the array, and the return value of the callback function is used to determine the return value of the method. They all share the same signature:

```
method(callbackFn, thisArg)
```

Where `callbackFn` takes three arguments:

`element`

The current element being processed in the array.

`index`

: The index of the current element being processed in the array.

`array`

: The array that the method was called upon.

What `callbackFn` is expected to return depends on the array method that was called.

The `thisArg` argument (defaults to `undefined`) will be used as the `this` value when calling `callbackFn`. The `this` value ultimately observable by `callbackFn` is determined according to the usual rules: if `callbackFn` is non-strict, primitive `this` values are wrapped into objects, and `undefined`/`null` is substituted with `globalThis`. The `thisArg` argument is irrelevant for any `callbackFn` defined with an arrow function, as arrow functions don't have their own `this` binding.

The `array` argument passed to `callbackFn` is most useful if you want to read another index during iteration, because you may not always have an existing variable that refers to the current array. You should generally not mutate the array during iteration (see mutating initial array in iterative methods), but you can also use this argument to do so. The `array` argument is *not* the array that is being built, in the case of methods like `map()`, `filter()`, and `flatMap()` — there is no way to access the array being built from the callback function.

All iterative methods are copying and generic, although they behave differently with empty slots.

The following methods are iterative: `every()`, `filter()`, `find()`, `findIndex()`, `findLast()`, `findLastIndex()`, `flatMap()`, `forEach()`, `map()`, and `some()`.

In particular, `every()`, `find()`, `findIndex()`, `findLast()`, `findLastIndex()`, and `some()` do not always invoke `callbackFn` on every element — they stop iteration as soon as the return value is determined.

The `reduce()` and `reduceRight()` methods also take a callback function and run it at most once for each element in the array, but they have slightly different signatures from typical iterative methods (for example, they don't accept `thisArg`).

The `sort()` method also takes a callback function, but it is not an iterative method. It mutates the array in-place, doesn't accept `thisArg`, and may invoke the callback multiple times on an index.

Iterative methods iterate the array like the following (with a lot of technical details omitted):

```
function method(callbackFn, thisArg) {
  const length = this.length;
  for (let i = 0; i < length; i++) {
    if (i in this) {
      const result = callbackFn.call(thisArg, this[i], i, this);
      // Do something with result; maybe return early
    }
  }
}
```

Note the following:

1. Not all methods do the `i in this` test. The `find`, `findIndex`, `findLast`, and `findLastIndex` methods do not, but other methods do.
2. The `length` is memorized before the loop starts. This affects how insertions and deletions during iteration are handled (see mutating initial array in iterative methods).
3. The method doesn't memorize the array contents, so if any index is modified during iteration, the new value might be observed.
4. The code above iterates the array in ascending order of index. Some methods iterate in descending order of index (`for (let i = length - 1; i >= 0; i--)`): `reduceRight()`, `findLast()`, and `findLastIndex()`.
5. `reduce` and `reduceRight` have slightly different signatures and do not always start at the first/last element.

Generic array methods

Array methods are always generic — they don't access any internal data of the array object. They only access the array elements through the `length` property and the indexed elements. This means that they can be called on array-like objects as well.

```
const arrayLike = {
  0: "a",
  1: "b",
  length: 2,
};
console.log(Array.prototype.join.call(arrayLike, "+")); // 'a+b'
```

Normalization of the length property

The `length` property is converted to an integer and then clamped to the range between 0 and 2^{53} - 1. `NaN` becomes `0`, so even when `length` is not present or is `undefined`, it behaves as if it has value `0`.

The language avoids setting `length` to an unsafe integer. All built-in methods will throw a `TypeError` if `length` will be set to a number greater than 2^{53} - 1. However, because the `length` property of arrays throws an error if it's set to greater than 2^{32} - 1, the safe integer threshold is usually not reached unless the method is called on a non-array object.

```
Array.prototype.flat.call({}); // []
```

Some array methods set the `length` property of the array object. They always set the value after normalization, so `length` always ends as an integer.

```
const a = { length: 0.7 };
Array.prototype.push.call(a);
```

```
console.log(a.length); // 0
```

Array-like objects

The term *array-like object* refers to any object that doesn't throw during the `length` conversion process described above. In practice, such object is expected to actually have a `length` property and to have indexed elements in the range `0` to `length - 1`. (If it doesn't have all indices, it will be functionally equivalent to a sparse array.) Any integer index less than zero or greater than `length - 1` is ignored when an array method operates on an array-like object.

Many DOM objects are array-like — for example, `NodeList` and `HTMLCollection`. The `arguments` object is also array-like. You can call array methods on them even if they don't have these methods themselves.

```
function f() {
  console.log(Array.prototype.join.call(arguments, "+"));
}

f("a", "b"); // 'a+b'
```

Constructor

`Array()`

Creates a new `Array` object.

Static properties

`Array[Symbol.species]`

Returns the `Array` constructor.

Static methods

`Array.from()`

Creates a new `Array` instance from an iterable or array-like object.

`Array.fromAsync()`

Creates a new `Array` instance from an async iterable, iterable, or array-like object.

`Array.isArray()`

Returns `true` if the argument is an array, or `false` otherwise.

`Array.of()`

Creates a new `Array` instance with a variable number of arguments, regardless of number or type of the arguments.

Instance properties

These properties are defined on `Array.prototype` and shared by all `Array` instances.

`Array.prototype.constructor`

The constructor function that created the instance object. For `Array` instances, the initial value is the `Array` constructor.

`Array.prototype[Symbol.unscopables]`

Contains property names that were not included in the ECMAScript standard prior to the ES2015 version and that are ignored for `with` statement-binding purposes.

These properties are own properties of each `Array` instance.

`length`

Reflects the number of elements in an array.

Instance methods

`Array.prototype.at()`

Returns the array item at the given index. Accepts negative integers, which count back from the last item.

`Array.prototype.concat()`

Returns a new array that is the calling array joined with other array(s) and/or value(s).

`Array.prototype.copyWithin()`

Copies a sequence of array elements within an array.

`Array.prototype.entries()`

Returns a new *array iterator* object that contains the key/value pairs for each index in an array.

`Array.prototype.every()`

Returns `false` if it finds an element in the array that does not satisfy the provided testing function. Otherwise, it returns `true`.

`Array.prototype.fill()`

Fills all the elements of an array from a start index to an end index with a static value.

`Array.prototype.filter()`

Returns a new array containing all elements of the calling array for which the provided filtering function returns `true`.

`Array.prototype.find()`

Returns the value of the first element in the array that satisfies the provided testing function, or `undefined` if no appropriate element is found.

`Array.prototype.findIndex()`

Returns the index of the first element in the array that satisfies the provided testing function, or `-1` if no appropriate element was found.

`Array.prototype.findLast()`

Returns the value of the last element in the array that satisfies the provided testing function, or `undefined` if no appropriate element is found.

`Array.prototype.findLastIndex()`

Returns the index of the last element in the array that satisfies the provided testing function, or `-1` if no appropriate element was found.

`Array.prototype.flat()`

Returns a new array with all sub-array elements concatenated into it recursively up to the specified depth.

`Array.prototype.flatMap()`

Returns a new array formed by applying a given callback function to each element of the calling array, and then flattening the result by one level.

`Array.prototype.forEach()`

Calls a function for each element in the calling array.

`Array.prototype.includes()`

Determines whether the calling array contains a value, returning `true` or `false` as appropriate.

`Array.prototype.indexOf()`

Returns the first (least) index at which a given element can be found in the calling array.

`Array.prototype.join()`

Returns a new string that is the concatenation of all elements in this array, separated by commas or a specified separator string.

`Array.prototype.keys()`

Returns a new *array iterator* that contains the keys for each index in the calling array.

`Array.prototype.lastIndexOf()`

Returns the last (greatest) index at which a given element can be found in the calling array, or `-1` if none is found.

`Array.prototype.map()`

Returns a new array containing the results of invoking a function on every element in the calling array.

`Array.prototype.pop()`

Removes the last element from an array and returns that element.

`Array.prototype.push()`

Adds one or more elements to the end of an array, and returns the new `length` of the array.

`Array.prototype.reduce()`

Executes a user-supplied "reducer" callback function on each element of the array (from left to right), to reduce it to a single value.

`Array.prototype.reduceRight()`

Executes a user-supplied "reducer" callback function on each element of the array (from right to left), to reduce it to a single value.

`Array.prototype.reverse()`

Reverses the order of the elements of an array *in place*. (First becomes the last, last becomes first.)

`Array.prototype.shift()`

Removes the first element from an array and returns that element.

`Array.prototype.slice()`

Extracts a section of the calling array and returns a new array.

`Array.prototype.some()`

Returns `true` if it finds an element in the array that satisfies the provided testing function. Otherwise, it returns `false`.

`Array.prototype.sort()`

Sorts the elements of an array in place and returns the array.

`Array.prototype.splice()`

Adds and/or removes elements from an array.

`Array.prototype.toLocaleString()`

Returns a localized string representing the calling array and its elements. Overrides the `Object.prototype.toLocaleString()` method.

`Array.prototype.toReversed()`

Returns a new array with the elements in reversed order, without modifying the original array.

`Array.prototype.toSorted()`

Returns a new array with the elements sorted in ascending order, without modifying the original array.

`Array.prototype.toSpliced()`

Returns a new array with some elements removed and/or replaced at a given index, without modifying the original array.

`Array.prototype.toString()`

Returns a string representing the calling array and its elements. Overrides the `Object.prototype.toString()` method.

`Array.prototype.unshift()`

Adds one or more elements to the front of an array, and returns the new `length` of the array.

`Array.prototype.values()`

Returns a new *array iterator* object that contains the values for each index in the array.

`Array.prototype.with()`

Returns a new array with the element at the given index replaced with the given value, without modifying the original array.

`Array.prototype[Symbol.iterator]()`

An alias for the `values()` method by default.

Examples

This section provides some examples of common array operations in JavaScript.

> **Note:** If you're not yet familiar with array basics, consider first reading JavaScript First Steps: Arrays, which explains what arrays are, and includes other examples of common array operations.

Create an array

This example shows three ways to create new array: first using array literal notation, then using the `Array()` constructor, and finally using `String.prototype.split()` to build the array from a string.

```
// 'fruits' array created using array literal notation.
const fruits = ["Apple", "Banana"];
console.log(fruits.length);
// 2

// 'fruits2' array created using the Array() constructor.
const fruits2 = new Array("Apple", "Banana");
console.log(fruits2.length);
// 2

// 'fruits3' array created using String.prototype.split().
const fruits3 = "Apple, Banana".split(", ");
console.log(fruits3.length);
// 2
```

Create a string from an array

This example uses the `join()` method to create a string from the `fruits` array.

```
const fruits = ["Apple", "Banana"];
const fruitsString = fruits.join(", ");
```

```
console.log(fruitsString);
// "Apple, Banana"
```

Access an array item by its index

This example shows how to access items in the `fruits` array by specifying the index number of their position in the array.

```
const fruits = ["Apple", "Banana"];

// The index of an array's first element is always 0.
fruits[0]; // Apple

// The index of an array's second element is always 1.
fruits[1]; // Banana

// The index of an array's last element is always one
// less than the length of the array.
fruits[fruits.length - 1]; // Banana

// Using an index number larger than the array's length
// returns 'undefined'.
fruits[99]; // undefined
```

Find the index of an item in an array

This example uses the `indexOf()` method to find the position (index) of the string `"Banana"` in the `fruits` array.

```
const fruits = ["Apple", "Banana"];
console.log(fruits.indexOf("Banana"));
// 1
```

Check if an array contains a certain item

This example shows two ways to check if the `fruits` array contains `"Banana"` and `"Cherry"`: first with the `includes()` method, and then with the `indexOf()` method to test for an index value that's not `-1`.

```
const fruits = ["Apple", "Banana"];

fruits.includes("Banana"); // true
fruits.includes("Cherry"); // false

// If indexOf() doesn't return -1, the array contains the given item.
fruits.indexOf("Banana") !== -1; // true
fruits.indexOf("Cherry") !== -1; // false
```

Append an item to an array

This example uses the `push()` method to append a new string to the `fruits` array.

```
const fruits = ["Apple", "Banana"];
const newLength = fruits.push("Orange");
console.log(fruits);
// ["Apple", "Banana", "Orange"]
console.log(newLength);
// 3
```

Remove the last item from an array

This example uses the `pop()` method to remove the last item from the `fruits` array.

```
const fruits = ["Apple", "Banana", "Orange"];
const removedItem = fruits.pop();
console.log(fruits);
// ["Apple", "Banana"]
console.log(removedItem);
// Orange
```

> **Note:** `pop()` can only be used to remove the last item from an array. To remove multiple items from the end of an array, see the next example.

Remove multiple items from the end of an array

This example uses the `splice()` method to remove the last 3 items from the `fruits` array.

```
const fruits = ["Apple", "Banana", "Strawberry", "Mango", "Cherry"];
const start = -3;
const removedItems = fruits.splice(start);
console.log(fruits);
// ["Apple", "Banana"]
console.log(removedItems);
// ["Strawberry", "Mango", "Cherry"]
```

Truncate an array down to just its first N items

This example uses the `splice()` method to truncate the `fruits` array down to just its first 2 items.

```
const fruits = ["Apple", "Banana", "Strawberry", "Mango", "Cherry"];
const start = 2;
const removedItems = fruits.splice(start);
console.log(fruits);
// ["Apple", "Banana"]
console.log(removedItems);
// ["Strawberry", "Mango", "Cherry"]
```

Remove the first item from an array

This example uses the `shift()` method to remove the first item from the `fruits` array.

```
const fruits = ["Apple", "Banana"];
const removedItem = fruits.shift();
console.log(fruits);
// ["Banana"]
console.log(removedItem);
// Apple
```

> **Note:** `shift()` can only be used to remove the first item from an array. To remove multiple items from the beginning of an array, see the next example.

Remove multiple items from the beginning of an array

This example uses the `splice()` method to remove the first 3 items from the `fruits` array.

```
const fruits = ["Apple", "Strawberry", "Cherry", "Banana", "Mango"];
const start = 0;
const deleteCount = 3;
const removedItems = fruits.splice(start, deleteCount);
console.log(fruits);
// ["Banana", "Mango"]
console.log(removedItems);
// ["Apple", "Strawberry", "Cherry"]
```

Add a new first item to an array

This example uses the `unshift()` method to add, at index `0`, a new item to the `fruits` array — making it the new first item in the array.

```
const fruits = ["Banana", "Mango"];
const newLength = fruits.unshift("Strawberry");
console.log(fruits);
// ["Strawberry", "Banana", "Mango"]
console.log(newLength);
// 3
```

Remove a single item by index

This example uses the `splice()` method to remove the string `"Banana"` from the `fruits` array — by specifying the index position of `"Banana"`.

```
const fruits = ["Strawberry", "Banana", "Mango"];
const start = fruits.indexOf("Banana");
const deleteCount = 1;
const removedItems = fruits.splice(start, deleteCount);
console.log(fruits);
// ["Strawberry", "Mango"]
console.log(removedItems);
// ["Banana"]
```

Remove multiple items by index

This example uses the `splice()` method to remove the strings `"Banana"` and `"Strawberry"` from the `fruits` array — by specifying the index position of `"Banana"`, along with a count of the number of total items to remove.

```
const fruits = ["Apple", "Banana", "Strawberry", "Mango"];
const start = 1;
const deleteCount = 2;
const removedItems = fruits.splice(start, deleteCount);
console.log(fruits);
// ["Apple", "Mango"]
console.log(removedItems);
// ["Banana", "Strawberry"]
```

Replace multiple items in an array

This example uses the `splice()` method to replace the last 2 items in the `fruits` array with new items.

```
const fruits = ["Apple", "Banana", "Strawberry"];
const start = -2;
const deleteCount = 2;
const removedItems = fruits.splice(start, deleteCount, "Mango", "Cherry");
console.log(fruits);
// ["Apple", "Mango", "Cherry"]
console.log(removedItems);
// ["Banana", "Strawberry"]
```

Iterate over an array

This example uses a `for...of` loop to iterate over the `fruits` array, logging each item to the console.

```
const fruits = ["Apple", "Mango", "Cherry"];
for (const fruit of fruits) {
  console.log(fruit);
}
// Apple
// Mango
// Cherry
```

But `for...of` is just one of many ways to iterate over any array; for more ways, see Loops and iteration, and see the documentation for the `every()`, `filter()`, `flatMap()`, `map()`, `reduce()`, and `reduceRight()` methods — and see the next example, which uses the `forEach()` method.

Call a function on each element in an array

This example uses the `forEach()` method to call a function on each element in the `fruits` array; the function causes each item to be logged to the console, along with the item's index number.

```
const fruits = ["Apple", "Mango", "Cherry"];
fruits.forEach((item, index, array) => {
  console.log(item, index);
});
// Apple 0
// Mango 1
// Cherry 2
```

Merge multiple arrays together

This example uses the `concat()` method to merge the `fruits` array with a `moreFruits` array, to produce a new `combinedFruits` array. Notice that `fruits` and `moreFruits` remain unchanged.

```
const fruits = ["Apple", "Banana", "Strawberry"];
const moreFruits = ["Mango", "Cherry"];
const combinedFruits = fruits.concat(moreFruits);
console.log(combinedFruits);
// ["Apple", "Banana", "Strawberry", "Mango", "Cherry"]

// The 'fruits' array remains unchanged.
console.log(fruits);
// ["Apple", "Banana", "Strawberry"]

// The 'moreFruits' array also remains unchanged.
console.log(moreFruits);
// ["Mango", "Cherry"]
```

Copy an array

This example shows three ways to create a new array from the existing `fruits` array: first by using spread syntax, then by using the `from()` method, and then by using the `slice()` method.

```
const fruits = ["Strawberry", "Mango"];

// Create a copy using spread syntax.
const fruitsCopy = [...fruits];
// ["Strawberry", "Mango"]

// Create a copy using the from() method.
const fruitsCopy2 = Array.from(fruits);
// ["Strawberry", "Mango"]

// Create a copy using the slice() method.
const fruitsCopy3 = fruits.slice();
// ["Strawberry", "Mango"]
```

All built-in array-copy operations (spread syntax, `Array.from()`, `Array.prototype.slice()`, and `Array.prototype.concat()`) create shallow copies. If you instead want a deep copy of an array, you can use `JSON.stringify()` to convert the array to a JSON string, and then `JSON.parse()` to convert the string back into a new array that's completely independent from the original array.

```
const fruitsDeepCopy = JSON.parse(JSON.stringify(fruits));
```

You can also create deep copies using the `structuredClone()` method, which has the advantage of allowing transferable objects in the source to be *transferred* to the new copy, rather than just cloned.

Finally, it's important to understand that assigning an existing array to a new variable doesn't create a copy of either the array or its elements. Instead the new variable is just a reference, or alias, to the original array; that is, the original array's name and the new variable name are just two names for the exact same object (and so will always evaluate as strictly equivalent). Therefore, if you make any changes at all either to the value of the original array or to the value of the new variable, the other will change, too:

```
const fruits = ["Strawberry", "Mango"];
const fruitsAlias = fruits;
// 'fruits' and 'fruitsAlias' are the same object, strictly equivalent.
fruits === fruitsAlias; // true
// Any changes to the 'fruits' array change 'fruitsAlias' too.
fruits.unshift("Apple", "Banana");
console.log(fruits);
// ['Apple', 'Banana', 'Strawberry', 'Mango']
console.log(fruitsAlias);
// ['Apple', 'Banana', 'Strawberry', 'Mango']
```

Creating a two-dimensional array

The following creates a chessboard as a two-dimensional array of strings. The first move is made by copying the `'p'` in `board[6][4]` to `board[4][4]`. The old position at `[6][4]` is made blank.

```
const board = [
  ["R", "N", "B", "Q", "K", "B", "N", "R"],
  ["P", "P", "P", "P", "P", "P", "P", "P"],
  [" ", " ", " ", " ", " ", " ", " ", " "],
  [" ", " ", " ", " ", " ", " ", " ", " "],
  [" ", " ", " ", " ", " ", " ", " ", " "],
  [" ", " ", " ", " ", " ", " ", " ", " "],
  ["p", "p", "p", "p", "p", "p", "p", "p"],
  ["r", "n", "b", "q", "k", "b", "n", "r"],
];

console.log(`${board.join("\n")}\n\n`);

// Move King's Pawn forward 2
board[4][4] = board[6][4];
board[6][4] = " ";
console.log(board.join("\n"));
```

Here is the output:

```
R,N,B,Q,K,B,N,R
P,P,P,P,P,P,P,P
 , , , , , , ,
 , , , , , , ,
 , , , , , , ,
 , , , , , , ,
p,p,p,p,p,p,p,p
r,n,b,q,k,b,n,r

R,N,B,Q,K,B,N,R
P,P,P,P,P,P,P,P
 , , , , , , ,
 , , , , , , ,
 , , , ,p, , ,
 , , , , , , ,
p,p,p,p, ,p,p,p
r,n,b,q,k,b,n,r
```

Using an array to tabulate a set of values

```
const values = [];
for (let x = 0; x < 10; x++) {
  values.push([2 ** x, 2 * x ** 2]);
}
console.table(values);
```

Results in

```
// The first column is the index
0  1    0
1  2    2
2  4    8
3  8    18
4  16   32
5  32   50
6  64   72
7  128  98
8  256  128
9  512  162
```

Creating an array using the result of a match

The result of a match between a `RegExp` and a string can create a JavaScript array that has properties and elements which provide information about the match. Such an array is returned by `RegExp.prototype.exec()` and `String.prototype.match()`.

For example:

```
// Match one d followed by one or more b's followed by one d
// Remember matched b's and the following d
// Ignore case

const myRe = /d(b+)(d)/i;
const execResult = myRe.exec("cdbBdbsbz");

console.log(execResult.input); // 'cdbBdbsbz'
console.log(execResult.index); // 1
console.log(execResult); // [ "dbBd", "bB", "d" ]
```

For more information about the result of a match, see the `RegExp.prototype.exec()` and `String.prototype.match()` pages.

Mutating initial array in iterative methods

Iterative methods do not mutate the array on which it is called, but the function provided as `callbackFn` can. The key principle to remember is that only indexes between 0 and `arrayLength - 1` are visited, where `arrayLength` is the length of the array at the time the array method was first called, but the element passed to the callback is the value at the time the index is visited. Therefore:

- `callbackFn` will not visit any elements added beyond the array's initial length when the call to the iterative method began.
- Changes to already-visited indexes do not cause `callbackFn` to be invoked on them again.
- If an existing, yet-unvisited element of the array is changed by `callbackFn`, its value passed to the `callbackFn` will be the value at the time that element gets visited. Removed elements are not visited.

> **Warning:** Concurrent modifications of the kind described above frequently lead to hard-to-understand code and are generally to be avoided (except in special cases).

The following examples use the `forEach` method as an example, but other methods that visit indexes in ascending order work in the same way. We will first define a helper function:

```
function testSideEffect(effect) {
  const arr = ["e1", "e2", "e3", "e4"];
  arr.forEach((elem, index, arr) => {
    console.log(`array: [${arr.join(", ")}], index: ${index}, elem: ${elem}`);
    effect(arr, index);
  });
  console.log(`Final array: [${arr.join(", ")}]`);
}
```

Modification to indexes not visited yet will be visible once the index is reached:

```
testSideEffect((arr, index) => {
  if (index + 1 < arr.length) arr[index + 1] += "*";
});
// array: [e1, e2, e3, e4], index: 0, elem: e1
// array: [e1, e2*, e3, e4], index: 1, elem: e2*
// array: [e1, e2*, e3*, e4], index: 2, elem: e3*
// array: [e1, e2*, e3*, e4*], index: 3, elem: e4*
// Final array: [e1, e2*, e3*, e4*]
```

Modification to already visited indexes does not change iteration behavior, although the array will be different afterwards:

```
testSideEffect((arr, index) => {
  if (index > 0) arr[index - 1] += "*";
});
// array: [e1, e2, e3, e4], index: 0, elem: e1
// array: [e1, e2, e3, e4], index: 1, elem: e2
// array: [e1*, e2, e3, e4], index: 2, elem: e3
// array: [e1*, e2*, e3, e4], index: 3, elem: e4
// Final array: [e1*, e2*, e3*, e4]
```

Inserting *n* elements at unvisited indexes that are less than the initial array length will make them be visited. The last *n* elements in the original array that now have index greater than the initial array length will not be visited:

```
testSideEffect((arr, index) => {
  if (index === 1) arr.splice(2, 0, "new");
});
// array: [e1, e2, e3, e4], index: 0, elem: e1
// array: [e1, e2, e3, e4], index: 1, elem: e2
// array: [e1, e2, new, e3, e4], index: 2, elem: new
// array: [e1, e2, new, e3, e4], index: 3, elem: e3
// Final array: [e1, e2, new, e3, e4]
// e4 is not visited because it now has index 4
```

Inserting *n* elements with index greater than the initial array length will not make them be visited:

```
testSideEffect((arr) => arr.push("new"));
// array: [e1, e2, e3, e4], index: 0, elem: e1
// array: [e1, e2, e3, e4, new], index: 1, elem: e2
// array: [e1, e2, e3, e4, new, new], index: 2, elem: e3
// array: [e1, e2, e3, e4, new, new, new], index: 3, elem: e4
// Final array: [e1, e2, e3, e4, new, new, new, new]
```

Inserting *n* elements at already visited indexes will not make them be visited, but it shifts remaining elements back by *n*, so the current index and the *n* - *1* elements before it are visited again:

```
testSideEffect((arr, index) => arr.splice(index, 0, "new"));
// array: [e1, e2, e3, e4], index: 0, elem: e1
// array: [new, e1, e2, e3, e4], index: 1, elem: e1
// array: [new, new, e1, e2, e3, e4], index: 2, elem: e1
// array: [new, new, new, e1, e2, e3, e4], index: 3, elem: e1
// Final array: [new, new, new, new, e1, e2, e3, e4]
// e1 keeps getting visited because it keeps getting shifted back
```

Deleting *n* elements at unvisited indexes will make them not be visited anymore. Because the array has shrunk, the last *n* iterations will visit out-of-bounds indexes. If the method ignores non-existent indexes (see array methods and empty slots), the last *n* iterations will be skipped; otherwise, they will receive `undefined`:

```
testSideEffect((arr, index) => {
  if (index === 1) arr.splice(2, 1);
});
// array: [e1, e2, e3, e4], index: 0, elem: e1
// array: [e1, e2, e3, e4], index: 1, elem: e2
// array: [e1, e2, e4], index: 2, elem: e4
// Final array: [e1, e2, e4]
// Does not visit index 3 because it's out-of-bounds

// Compare this with find(), which treats nonexistent indexes as undefined:
const arr2 = ["e1", "e2", "e3", "e4"];
arr2.find((elem, index, arr) => {
  console.log(`array: [${arr.join(", ")}], index: ${index}, elem: ${elem}`);
  if (index === 1) arr.splice(2, 1);
  return false;
});
// array: [e1, e2, e3, e4], index: 0, elem: e1
// array: [e1, e2, e3, e4], index: 1, elem: e2
// array: [e1, e2, e4], index: 2, elem: e4
// array: [e1, e2, e4], index: 3, elem: undefined
```

Deleting *n* elements at already visited indexes does not change the fact that they were visited before they get deleted. Because the array has shrunk, the next *n* elements after the current index are skipped. If the method ignores non-existent indexes, the last *n* iterations will be skipped; otherwise, they will receive `undefined`:

```
testSideEffect((arr, index) => arr.splice(index, 1));
// array: [e1, e2, e3, e4], index: 0, elem: e1
// Does not visit e2 because e2 now has index 0, which has already been visited
// array: [e2, e3, e4], index: 1, elem: e3
// Does not visit e4 because e4 now has index 1, which has already been visited
// Final array: [e2, e4]
// Index 2 is out-of-bounds, so it's not visited

// Compare this with find(), which treats nonexistent indexes as undefined:
const arr2 = ["e1", "e2", "e3", "e4"];
arr2.find((elem, index, arr) => {
  console.log(`array: [${arr.join(", ")}], index: ${index}, elem: ${elem}`);
  arr.splice(index, 1);
  return false;
});
// array: [e1, e2, e3, e4], index: 0, elem: e1
// array: [e2, e3, e4], index: 1, elem: e3
// array: [e2, e4], index: 2, elem: undefined
// array: [e2, e4], index: 3, elem: undefined
```

For methods that iterate in descending order of index, insertion causes elements to be skipped, and deletion causes elements to be visited multiple times. Adjust the code above yourself to see the effects.

Array() constructor

The **`Array()`** constructor creates `Array` objects.

Syntax

```
new Array()
new Array(element1)
new Array(element1, element2)
new Array(element1, element2, /* …, */ elementN)
new Array(arrayLength)

Array()
Array(element1)
Array(element1, element2)
Array(element1, element2, /* …, */ elementN)
Array(arrayLength)
```

> **Note:** `Array()` can be called with or without `new`. Both create a new `Array` instance.

Parameters

`element1, ..., elementN`

A JavaScript array is initialized with the given elements, except in the case where a single argument is passed to the `Array` constructor and that argument is a number (see the `arrayLength` parameter below). Note that this special case only applies to JavaScript arrays created with the `Array` constructor, not array literals created with the square bracket syntax.

`arrayLength`

If the only argument passed to the `Array` constructor is an integer between 0 and 2^{32} - 1 (inclusive), this returns a new JavaScript array with its `length` property set to that number.

> **Note:** This implies an array of `arrayLength` empty slots, not slots with actual `undefined` values — see sparse arrays.

Exceptions

`RangeError`

Thrown if there's only one argument (`arrayLength`) that is a number, but its value is not an integer or not between 0 and 2^{32} - 1 (inclusive).

Examples

Array literal notation

Arrays can be created using the literal notation:

```
const fruits = ["Apple", "Banana"];

console.log(fruits.length); // 2
console.log(fruits[0]); // "Apple"
```

Array constructor with a single parameter

Arrays can be created using a constructor with a single number parameter. An array is created with its `length` property set to that number, and the array elements are empty slots.

```
const arrayEmpty = new Array(2);

console.log(arrayEmpty.length); // 2
console.log(arrayEmpty[0]); // undefined; actually, it is an empty slot
console.log(0 in arrayEmpty); // false
console.log(1 in arrayEmpty); // false
```

```
const arrayOfOne = new Array("2"); // Not the number 2 but the string "2"

console.log(arrayOfOne.length); // 1
console.log(arrayOfOne[0]); // "2"
```

Array constructor with multiple parameters

If more than one argument is passed to the constructor, a new `Array` with the given elements is created.

```
const fruits = new Array("Apple", "Banana");

console.log(fruits.length); // 2
console.log(fruits[0]); // "Apple"
```

Array.prototype.at()

The **`at()`** method of `Array` instances takes an integer value and returns the item at that index, allowing for positive and negative integers. Negative integers count back from the last item in the array.

Try it

```
const array = [5, 12, 8, 130, 44];

let index = 2;

console.log(`An index of ${index} returns ${array.at(index)}`);
// Expected output: "An index of 2 returns 8"

index = -2;

console.log(`An index of ${index} returns ${array.at(index)}`);
// Expected output: "An index of -2 returns 130"
```

Syntax

```
at(index)
```

Parameters

`index`

> Zero-based index of the array element to be returned, converted to an integer. Negative index counts back from the end of the array — if `index < 0`, `index + array.length` is accessed.

Return value

The element in the array matching the given index. Always returns `undefined` if `index < -array.length` or `index >= array.length` without attempting to access the corresponding property.

Description

The `at()` method is equivalent to the bracket notation when `index` is a non-negative integer. For example, `array[0]` and `array.at(0)` both return the first item. However, when counting elements from the end of the array, you cannot use `array[-1]` like you may in Python or R, because all values inside the square brackets are treated literally as string properties, so you will end up reading `array["-1"]`, which is just a normal string property instead of an array index.

The usual practice is to access `length` and calculate the index from that — for example, `array[array.length - 1]`. The `at()` method allows relative indexing, so this can be shortened to `array.at(-1)`.

By combining `at()` with `with()`, you can both read and write (respectively) an array using negative indices.

The `at()` method is generic. It only expects the `this` value to have a `length` property and integer-keyed properties.

Examples

Return the last value of an array

The following example provides a function which returns the last element found in a specified array.

```
// Our array with items
const cart = ["apple", "banana", "pear"];

// A function which returns the last item of a given array
function returnLast(arr) {
  return arr.at(-1);
}

// Get the last item of our array 'cart'
const item1 = returnLast(cart);
console.log(item1); // 'pear'

// Add an item to our 'cart' array
cart.push("orange");
const item2 = returnLast(cart);
console.log(item2); // 'orange'
```

Comparing methods

This example compares different ways to select the penultimate (last but one) item of an `Array`. While all the methods shown below are valid, this example highlights the succinctness and readability of the `at()` method.

```
// Our array with items
const colors = ["red", "green", "blue"];

// Using length property
const lengthWay = colors[colors.length - 2];
console.log(lengthWay); // 'green'

// Using slice() method. Note an array is returned
const sliceWay = colors.slice(-2, -1);
```

```
console.log(sliceWay[0]); // 'green'

// Using at() method
const atWay = colors.at(-2);
console.log(atWay); // 'green'
```

Calling at() on non-array objects

The `at()` method reads the `length` property of `this` and calculates the index to access.

```
const arrayLike = {
  length: 2,
  0: "a",
  1: "b",
  2: "c", // ignored by at() since length is 2
};
console.log(Array.prototype.at.call(arrayLike, 0)); // "a"
console.log(Array.prototype.at.call(arrayLike, 2)); // undefined
```

Array.prototype.concat()

The **`concat()`** method of `Array` instances is used to merge two or more arrays. This method does not change the existing arrays, but instead returns a new array.

Try it

```
const array1 = ["a", "b", "c"];
const array2 = ["d", "e", "f"];
const array3 = array1.concat(array2);

console.log(array3);
// Expected output: Array ["a", "b", "c", "d", "e", "f"]
```

Syntax

```
concat()
concat(value1)
concat(value1, value2)
concat(value1, value2, /* … */ valueN)
```

Parameters

`value1, ..., valueN` Optional

> Arrays and/or values to concatenate into a new array. If all `valueN` parameters are omitted, `concat` returns a shallow copy of the existing array on which it is called. See the description below for more details.

Return value

A new `Array` instance.

Description

The `concat` method creates a new array. The array will first be populated by the elements in the object on which it is called. Then, for each argument, its value will be concatenated into the array — for normal objects or primitives, the argument itself will become an element of the final array; for arrays or array-like objects with the property `Symbol.isConcatSpreadable` set to a truthy value, each element of the argument will be independently added to the final array. The `concat` method does not recurse into nested array arguments.

The `concat()` method is a copying method. It does not alter `this` or any of the arrays provided as arguments but instead returns a shallow copy that contains the same elements as the ones from the original arrays.

The `concat()` method preserves empty slots if any of the source arrays is sparse.

The `concat()` method is generic. The `this` value is treated in the same way as the other arguments (except it will be converted to an object first), which means plain objects will be directly prepended to the resulting array, while array-like objects with truthy `[Symbol.isConcatSpreadable]` will be spread into the resulting array.

Examples

Concatenating two arrays

The following code concatenates two arrays:

```
const letters = ["a", "b", "c"];
const numbers = [1, 2, 3];

const alphaNumeric = letters.concat(numbers);
console.log(alphaNumeric);
// results in ['a', 'b', 'c', 1, 2, 3]
```

Concatenating three arrays

The following code concatenates three arrays:

```
const num1 = [1, 2, 3];
const num2 = [4, 5, 6];
const num3 = [7, 8, 9];

const numbers = num1.concat(num2, num3);

console.log(numbers);
// results in [1, 2, 3, 4, 5, 6, 7, 8, 9]
```

Concatenating values to an array

The following code concatenates three values to an array:

```
const letters = ["a", "b", "c"];

const alphaNumeric = letters.concat(1, [2, 3]);

console.log(alphaNumeric);
// results in ['a', 'b', 'c', 1, 2, 3]
```

Concatenating nested arrays

The following code concatenates nested arrays and demonstrates retention of references:

```
const num1 = [[1]];
const num2 = [2, [3]];

const numbers = num1.concat(num2);

console.log(numbers);
// results in [[1], 2, [3]]

// modify the first element of num1
num1[0].push(4);

console.log(numbers);
// results in [[1, 4], 2, [3]]
```

Concatenating array-like objects with Symbol.isConcatSpreadable

`concat` does not treat all array-like objects as arrays by default — only if `Symbol.isConcatSpreadable` is set to a truthy value (e.g., `true`).

```
const obj1 = { 0: 1, 1: 2, 2: 3, length: 3 };
const obj2 = { 0: 1, 1: 2, 2: 3, length: 3, [Symbol.isConcatSpreadable]: true };
console.log([0].concat(obj1, obj2));
// [ 0, { '0': 1, '1': 2, '2': 3, length: 3 }, 1, 2, 3 ]
```

Using concat() on sparse arrays

If any of the source arrays is sparse, the resulting array will also be sparse:

```
console.log([1, , 3].concat([4, 5])); // [1, empty, 3, 4, 5]
console.log([1, 2].concat([3, , 5])); // [1, 2, 3, empty, 5]
```

Calling concat() on non-array objects

If the `this` value is not an array, it is converted to an object and then treated in the same way as the arguments for `concat()`. In this case the return value is always a plain new array.

```
console.log(Array.prototype.concat.call({}, 1, 2, 3)); // [{}, 1, 2, 3]
console.log(Array.prototype.concat.call(1, 2, 3)); // [ [Number: 1], 2, 3 ]
const arrayLike = {
  [Symbol.isConcatSpreadable]: true,
  length: 2,
  0: 1,
  1: 2,
  2: 99, // ignored by concat() since length is 2
};
console.log(Array.prototype.concat.call(arrayLike, 3, 4)); // [1, 2, 3, 4]
```

Array.prototype.copyWithin()

The **`copyWithin()`** method of `Array` instances shallow copies part of this array to another location in the same array and returns this array without modifying its length.

Try it

```
const array = ["a", "b", "c", "d", "e"];

// Copy to index 0 the element at index 3
console.log(array.copyWithin(0, 3, 4));
// Expected output: Array ["d", "b", "c", "d", "e"]

// Copy to index 1 all elements from index 3 to the end
console.log(array.copyWithin(1, 3));
// Expected output: Array ["d", "d", "e", "d", "e"]
```

Syntax

```
copyWithin(target, start)
copyWithin(target, start, end)
```

Parameters

`target`

Zero-based index at which to copy the sequence to, converted to an integer. This corresponds to where the element at `start` will be copied to, and all elements between `start` and `end` are copied to succeeding indices.

- Negative index counts back from the end of the array — if `-array.length <= target < 0`, `target + array.length` is used.
- If `target < -array.length`, `0` is used.
- If `target >= array.length`, nothing is copied.
- If `target` is positioned after `start` after normalization, copying only happens until the end of `array.length` (in other words, `copyWithin()` never extends the array).

`start`

Zero-based index at which to start copying elements from, converted to an integer.

- Negative index counts back from the end of the array — if `-array.length <= start < 0`, `start + array.length` is used.
- If `start < -array.length`, `0` is used.
- If `start >= array.length`, nothing is copied.

`end` Optional

Zero-based index at which to end copying elements from, converted to an integer. `copyWithin()` copies up to but not including `end`.

- Negative index counts back from the end of the array — if `-array.length <= end < 0`, `end + array.length` is used.
- If `end < -array.length`, `0` is used.
- If `end >= array.length` or `end` is omitted or `undefined`, `array.length` is used, causing all elements until the end to be copied.
- If `end` implies a position before or at the position that `start` implies, nothing is copied.

Return value

The modified array.

Description

The `copyWithin()` method works like C and C++'s `memmove`, and is a high-performance method to shift the data of an `Array`. This especially applies to the `TypedArray` method of the same name. The sequence is copied and pasted as one operation; the pasted sequence will have the copied values even when the copy and paste region overlap.

Because `undefined` becomes `0` when converted to an integer, omitting the `start` parameter has the same effect as passing `0`, which copies the entire array to the target position, equivalent to a right shift where the right boundary is clipped off and the left boundary is duplicated. This behavior may confuse readers of your code, so you should explicitly pass `0` as `start` instead.

```
console.log([1, 2, 3, 4, 5].copyWithin(2));
// [1, 2, 1, 2, 3]; move all elements to the right by 2 positions
```

The `copyWithin()` method is a mutating method. It does not alter the length of `this`, but it will change the content of `this` and create new properties or delete existing properties, if necessary.

The `copyWithin()` method preserves empty slots. If the region to be copied from is sparse, the empty slots' corresponding new indices are deleted and also become empty slots.

The `copyWithin()` method is generic. It only expects the `this` value to have a `length` property and integer-keyed properties. Although strings are also array-like, this method is not suitable to be applied on them, as strings are immutable.

Examples

Using copyWithin()

```
console.log([1, 2, 3, 4, 5].copyWithin(0, 3));
// [4, 5, 3, 4, 5]

console.log([1, 2, 3, 4, 5].copyWithin(0, 3, 4));
// [4, 2, 3, 4, 5]

console.log([1, 2, 3, 4, 5].copyWithin(-2, -3, -1));
// [1, 2, 3, 3, 4]
```

Using copyWithin() on sparse arrays

`copyWithin()` will propagate empty slots.

```
console.log([1, , 3].copyWithin(2, 1, 2)); // [1, empty, empty]
```

Calling copyWithin() on non-array objects

The `copyWithin()` method reads the `length` property of `this` and then manipulates the integer indices involved.

```
const arrayLike = {
  length: 5,
  3: 1,
};
console.log(Array.prototype.copyWithin.call(arrayLike, 0, 3));
// { '0': 1, '3': 1, length: 5 }
console.log(Array.prototype.copyWithin.call(arrayLike, 3, 1));
// { '0': 1, length: 5 }
// The '3' property is deleted because the copied source is an empty slot
```

- Indexed collections guide
- `Array`
- `TypedArray.prototype.copyWithin()`

Array.prototype.entries()

The **`entries()`** method of `Array` instances returns a new *array iterator* object that contains the key/value pairs for each index in the array.

Try it

```
const array = ["a", "b", "c"];

const iterator = array.entries();

console.log(iterator.next().value);
// Expected output: Array [0, "a"]

console.log(iterator.next().value);
// Expected output: Array [1, "b"]
```

Syntax

```
entries()
```

Parameters

None.

Return value

A new iterable iterator object.

Description

When used on sparse arrays, the `entries()` method iterates empty slots as if they have the value `undefined`.

The `entries()` method is generic. It only expects the `this` value to have a `length` property and integer-keyed properties.

Examples

Iterating with index and element

```
const a = ["a", "b", "c"];

for (const [index, element] of a.entries()) {
  console.log(index, element);
}

// 0 'a'
// 1 'b'
// 2 'c'
```

Using a for...of loop

```
const array = ["a", "b", "c"];
const arrayEntries = array.entries();

for (const element of arrayEntries) {
  console.log(element);
}

// [0, 'a']
// [1, 'b']
// [2, 'c']
```

Iterating sparse arrays

`entries()` will visit empty slots as if they are `undefined`.

```
for (const element of [, "a"].entries()) {
  console.log(element);
}
// [0, undefined]
// [1, 'a']
```

Calling entries() on non-array objects

The `entries()` method reads the `length` property of `this` and then accesses each property whose key is a nonnegative integer less than `length`.

```
const arrayLike = {
  length: 3,
  0: "a",
  1: "b",
  2: "c",
  3: "d", // ignored by entries() since length is 3
};
for (const entry of Array.prototype.entries.call(arrayLike)) {
  console.log(entry);
}
// [ 0, 'a' ]
// [ 1, 'b' ]
// [ 2, 'c' ]
```

Array.prototype.every()

The **`every()`** method of `Array` instances returns `false` if it finds an element in the array that does not satisfy the provided testing function. Otherwise, it returns `true`.

Try it

```
const isBelowThreshold = (currentValue) => currentValue < 40;

const array1 = [1, 30, 39, 29, 10, 13];

console.log(array1.every(isBelowThreshold));
// Expected output: true
```

Syntax

```
every(callbackFn)
```

```
every(callbackFn, thisArg)
```

Parameters

`callbackFn`

A function to execute for each element in the array. It should return a truthy value to indicate the element passes the test, and a falsy value otherwise. The function is called with the following arguments:

`element`

The current element being processed in the array.

`index`

The index of the current element being processed in the array.

`array`

The array `every()` was called upon.

`thisArg` Optional

A value to use as `this` when executing `callbackFn`. See iterative methods.

Return value

`true` unless `callbackFn` returns a falsy value for an array element, in which case `false` is immediately returned.

Description

The `every()` method is an iterative method. It calls a provided `callbackFn` function once for each element in an array, until the `callbackFn` returns a falsy value. If such an element is found, `every()` immediately returns `false` and stops iterating through the array. Otherwise, if `callbackFn` returns a truthy value for all elements, `every()` returns `true`. Read the iterative methods section for more information about how these methods work in general.

`every` acts like the "for all" quantifier in mathematics. In particular, for an empty array, it returns `true`. (It is vacuously true that all elements of the empty set satisfy any given condition.)

`callbackFn` is invoked only for array indexes which have assigned values. It is not invoked for empty slots in sparse arrays.

The `every()` method is generic. It only expects the `this` value to have a `length` property and integer-keyed properties.

Examples

Testing size of all array elements

The following example tests whether all elements in the array are 10 or bigger.

```
function isBigEnough(element, index, array) {
  return element >= 10;
}
[12, 5, 8, 130, 44].every(isBigEnough); // false
[12, 54, 18, 130, 44].every(isBigEnough); // true
```

Check if one array is a subset of another array

The following example tests if all the elements of an array are present in another array.

```
const isSubset = (array1, array2) =>
  array2.every((element) => array1.includes(element));

console.log(isSubset([1, 2, 3, 4, 5, 6, 7], [5, 7, 6])); // true
console.log(isSubset([1, 2, 3, 4, 5, 6, 7], [5, 8, 7])); // false
```

Using the third argument of callbackFn

The `array` argument is useful if you want to access another element in the array. The following example first uses `filter()` to extract the positive values and then uses `every()` to check whether the array is strictly increasing.

```
const numbers = [-2, 4, -8, 16, -32];
const isIncreasing = numbers
  .filter((num) => num > 0)
  .every((num, idx, arr) => {
    // Without the arr argument, there's no way to easily access the
    // intermediate array without saving it to a variable.
    if (idx === 0) return true;
    return num > arr[idx - 1];
  });
console.log(isIncreasing); // true
```

Using every() on sparse arrays

`every()` will not run its predicate on empty slots.

```
console.log([1, , 3].every((x) => x !== undefined)); // true
console.log([2, , 2].every((x) => x === 2)); // true
```

Calling every() on non-array objects

The `every()` method reads the `length` property of `this` and then accesses each property with a nonnegative integer key less than `length` until they all have been accessed or `callbackFn` returns `false`.

```
const arrayLike = {
  length: 3,
  0: "a",
  1: "b",
  2: "c",
  3: 345, // ignored by every() since length is 3
};
console.log(
  Array.prototype.every.call(arrayLike, (x) => typeof x === "string"),
); // true
```

- `Array.prototype.find()`
- `TypedArray.prototype.every()`

Array.prototype.fill()

The **`fill()`** method of `Array` instances changes all elements within a range of indices in an array to a static value. It returns the modified array.

Try it

```
const array = [1, 2, 3, 4];

// Fill with 0 from position 2 until position 4
console.log(array.fill(0, 2, 4));
// Expected output: Array [1, 2, 0, 0]

// Fill with 5 from position 1
console.log(array.fill(5, 1));
// Expected output: Array [1, 5, 5, 5]

console.log(array.fill(6));
// Expected output: Array [6, 6, 6, 6]
```

Syntax

```
fill(value)
fill(value, start)
fill(value, start, end)
```

Parameters

`value`

Value to fill the array with. Note all elements in the array will be this exact value: if `value` is an object, each slot in the array will reference that object.

`start` Optional

Zero-based index at which to start filling, converted to an integer.

- Negative index counts back from the end of the array — if `-array.length <= start < 0`, `start + array.length` is used.
- If `start < -array.length` or `start` is omitted, `0` is used.
- If `start >= array.length`, no index is filled.

`end` Optional

Zero-based index at which to end filling, converted to an integer. `fill()` fills up to but not including `end`.

- Negative index counts back from the end of the array — if `-array.length <= end < 0`, `end + array.length` is used.
- If `end < -array.length`, `0` is used.
- If `end >= array.length` or `end` is omitted or `undefined`, `array.length` is used, causing all indices until the end to be filled.
- If `end` implies a position before or at the position that `start` implies, nothing is filled.

Return value

The modified array, filled with `value`.

Description

The `fill()` method is a mutating method. It does not alter the length of `this`, but it will change the content of `this`.

The `fill()` method fills empty slots in sparse arrays with `value` as well.

The `fill()` method is generic. It only expects the `this` value to have a `length` property. Although strings are also array-like, this method is not suitable to be applied on them, as strings are immutable.

> **Note:** Using `Array.prototype.fill()` on an empty array (`length = 0`) would not modify it as the array has nothing to be modified. To use `Array.prototype.fill()` when declaring an array, make sure the array has non-zero `length`. See example.

Examples

Using fill()

```
console.log([1, 2, 3].fill(4)); // [4, 4, 4]
console.log([1, 2, 3].fill(4, 1)); // [1, 4, 4]
console.log([1, 2, 3].fill(4, 1, 2)); // [1, 4, 3]
console.log([1, 2, 3].fill(4, 1, 1)); // [1, 2, 3]
console.log([1, 2, 3].fill(4, 3, 3)); // [1, 2, 3]
console.log([1, 2, 3].fill(4, -3, -2)); // [4, 2, 3]
console.log([1, 2, 3].fill(4, NaN, NaN)); // [1, 2, 3]
console.log([1, 2, 3].fill(4, 3, 5)); // [1, 2, 3]
console.log(Array(3).fill(4)); // [4, 4, 4]

// A single object, referenced by each slot of the array:
const arr = Array(3).fill({}); // [{}, {}, {}]
arr[0].hi = "hi"; // [{ hi: "hi" }, { hi: "hi" }, { hi: "hi" }]
```

Using fill() to create a matrix of all 1

This example shows how to create a matrix of all 1, like the `ones()` function of Octave or MATLAB.

```
const arr = new Array(3);
for (let i = 0; i < arr.length; i++) {
  arr[i] = new Array(4).fill(1); // Creating an array of size 4 and filled of 1
}
arr[0][0] = 10;
console.log(arr[0][0]); // 10
console.log(arr[1][0]); // 1
console.log(arr[2][0]); // 1
```

Using fill() to populate an empty array

This example shows how to populate an array, setting all elements to a specific value. The `end` parameter does not have to be specified.

```
const tempGirls = Array(5).fill("girl", 0);
```

Note that the array was initially a sparse array with no assigned indices. `fill()` is still able to fill this array.

Calling fill() on non-array objects

The `fill()` method reads the `length` property of `this` and sets the value of each integer-keyed property from `start` to `end`.

```
const arrayLike = { length: 2 };
console.log(Array.prototype.fill.call(arrayLike, 1));
// { '0': 1, '1': 1, length: 2 }
```

See also

- Polyfill of `Array.prototype.fill` in `core-js`
- Indexed collections guide
- `Array`
- `TypedArray.prototype.fill()`

Array.prototype.filter()

The **`filter()`** method of `Array` instances creates a shallow copy of a portion of a given array, filtered down to just the elements from the given array that pass the test implemented by the provided function.

Try it

```
const words = ["spray", "elite", "exuberant", "destruction", "present"];

const result = words.filter((word) => word.length > 6);

console.log(result);
// Expected output: Array ["exuberant", "destruction", "present"]
```

Syntax

```
filter(callbackFn)
filter(callbackFn, thisArg)
```

Parameters

`callbackFn`

A function to execute for each element in the array. It should return a truthy value to keep the element in the resulting array, and a falsy value otherwise. The function is called with the following arguments:

`element`

The current element being processed in the array.

`index`

The index of the current element being processed in the array.

`array`

The array `filter()` was called upon.

`thisArg` Optional

A value to use as `this` when executing `callbackFn`. See iterative methods.

Return value

A shallow copy of the given array containing just the elements that pass the test. If no elements pass the test, an empty array is returned.

Description

The `filter()` method is an iterative method. It calls a provided `callbackFn` function once for each element in an array, and constructs a new array of all the values for which `callbackFn` returns a truthy value. Array elements which do not pass the `callbackFn` test are not included in the new array. Read the iterative methods section for more information about how these methods work in general.

`callbackFn` is invoked only for array indexes which have assigned values. It is not invoked for empty slots in sparse arrays.

The `filter()` method is generic. It only expects the `this` value to have a `length` property and integer-keyed properties.

Examples

Filtering out all small values

The following example uses `filter()` to create a filtered array that has all elements with values less than 10 removed.

```
function isBigEnough(value) {
  return value >= 10;
}

const filtered = [12, 5, 8, 130, 44].filter(isBigEnough);
// filtered is [12, 130, 44]
```

Find all prime numbers in an array

The following example returns all prime numbers in the array:

```
const array = [-3, -2, -1, 0, 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13];

function isPrime(n) {
  if (n < 2) {
    return false;
  }
  if (n % 2 === 0) {
    return n === 2;
  }
  for (let factor = 3; factor * factor <= n; factor += 2) {
    if (n % factor === 0) {
      return false;
    }
  }
  return true;
}

console.log(array.filter(isPrime)); // [2, 3, 5, 7, 11, 13]
```

> **Note:** The `isPrime()` implementation is for demonstration only. For a real-world application, you would want to use a heavily memoized algorithm such as the Sieve of Eratosthenes to avoid repeated calculations.

Filtering invalid objects from an array of objects

The following example uses `filter()` to create a filtered array of all objects with non-zero, numeric `id`.

```
const arr = [
  { id: 15 },
  { id: -1 },
  { id: 0 },
  { id: 3 },
  { id: 12.2 },
  {},
  { id: null },
  { id: NaN },
  { id: "undefined" },
];

let invalidEntries = 0;

function filterByID(item) {
  if (Number.isFinite(item.id) && item.id !== 0) {
    return true;
  }
  invalidEntries++;
  return false;
}

const arrByID = arr.filter(filterByID);

console.log("Filtered Array\n", arrByID);
// Filtered Array
// [{ id: 15 }, { id: -1 }, { id: 3 }, { id: 12.2 }]

console.log("Number of Invalid Entries =", invalidEntries);
// Number of Invalid Entries = 5
```

Searching in array

The following example uses `filter()` to filter array content based on search criteria.

```
const fruits = ["apple", "banana", "grapes", "mango", "orange"];

/**
 * Filter array items based on search criteria (query)
 */
function filterItems(arr, query) {
  return arr.filter((el) => el.toLowerCase().includes(query.toLowerCase()));
}

console.log(filterItems(fruits, "ap")); // ['apple', 'grapes']
console.log(filterItems(fruits, "an")); // ['banana', 'mango', 'orange']
```

Using the third argument of callbackFn

The `array` argument is useful if you want to access another element in the array, especially when you don't have an existing variable that refers to the array. The following example first uses `map()` to extract the numerical ID from each name and then uses `filter()` to select the ones that are greater than its neighbors.

```
const names = ["JC63", "Bob132", "Ursula89", "Ben96"];
const greatIDs = names
  .map((name) => parseInt(name.match(/\d+/)[0], 10))
  .filter((id, idx, arr) => {
    // Without the arr argument, there's no way to easily access the
    // intermediate array without saving it to a variable.
    if (idx > 0 && id <= arr[idx - 1]) return false;
    if (idx < arr.length - 1 && id <= arr[idx + 1]) return false;
    return true;
  });
console.log(greatIDs); // [132, 96]
```

The `array` argument is *not* the array that is being built — there is no way to access the array being built from the callback function.

Using filter() on sparse arrays

`filter()` will skip empty slots.

```
console.log([1, , undefined].filter((x) => x === undefined)); // [undefined]
console.log([1, , undefined].filter((x) => x !== 2)); // [1, undefined]
```

Calling filter() on non-array objects

The `filter()` method reads the `length` property of `this` and then accesses each property whose key is a nonnegative integer less than `length`.

```
const arrayLike = {
  length: 3,
  0: "a",
  1: "b",
```

```
  2: "c",
  3: "a", // ignored by filter() since length is 3
};
console.log(Array.prototype.filter.call(arrayLike, (x) => x <= "b"));
// [ 'a', 'b' ]
```

Array.prototype.find()

The **`find()`** method of `Array` instances returns the first element in the provided array that satisfies the provided testing function. If no values satisfy the testing function, `undefined` is returned.

- If you need the **index** of the found element in the array, use `findIndex()`.
- If you need to find the **index of a value**, use `indexOf()`. (It's similar to `findIndex()`, but checks each element for equality with the value instead of using a testing function.)
- If you need to find if a value **exists** in an array, use `includes()`. Again, it checks each element for equality with the value instead of using a testing function.
- If you need to find if any element satisfies the provided testing function, use `some()`.
- If you need to find all elements that satisfy the provided testing function, use `filter()`.

Try it

```
const array = [5, 12, 8, 130, 44];

const found = array.find((element) => element > 10);

console.log(found);
// Expected output: 12
```

Syntax

```
find(callbackFn)
find(callbackFn, thisArg)
```

Parameters

`callbackFn`

A function to execute for each element in the array. It should return a truthy value to indicate a matching element has been found, and a falsy value otherwise. The function is called with the following arguments:

`element`

The current element being processed in the array.

`index`

The index of the current element being processed in the array.

`array`

The array `find()` was called upon.

`thisArg` Optional

A value to use as `this` when executing `callbackFn`. See iterative methods.

Return value

The first element in the array that satisfies the provided testing function. Otherwise, `undefined` is returned.

Description

The `find()` method is an iterative method. It calls a provided `callbackFn` function once for each element in an array in ascending-index order, until `callbackFn` returns a truthy value. `find()` then returns that element and stops iterating through the array. If `callbackFn` never returns a truthy value, `find()` returns `undefined`. Read the iterative methods section for more information about how these methods work in general.

`callbackFn` is invoked for *every* index of the array, not just those with assigned values. Empty slots in sparse arrays behave the same as `undefined`.

The `find()` method is generic. It only expects the `this` value to have a `length` property and integer-keyed properties.

Examples

Find an object in an array by one of its properties

```
const inventory = [
  { name: "apples", quantity: 2 },
  { name: "bananas", quantity: 0 },
  { name: "cherries", quantity: 5 },
];

function isCherries(fruit) {
  return fruit.name === "cherries";
}

console.log(inventory.find(isCherries));
// { name: 'cherries', quantity: 5 }
```

Using arrow function and destructuring

```
const inventory = [
  { name: "apples", quantity: 2 },
  { name: "bananas", quantity: 0 },
  { name: "cherries", quantity: 5 },
];

const result = inventory.find(({ name }) => name === "cherries");

console.log(result); // { name: 'cherries', quantity: 5 }
```

Find the first prime number in an array

The following example returns the first element in the array that is a prime number, or `undefined` if there is no prime number.

```
function isPrime(n) {
  if (n < 2) {
    return false;
  }
  if (n % 2 === 0) {
    return n === 2;
  }
  for (let factor = 3; factor * factor <= n; factor += 2) {
    if (n % factor === 0) {
      return false;
    }
  }
  return true;
}

console.log([4, 6, 8, 12].find(isPrime)); // undefined, not found
console.log([4, 5, 8, 12].find(isPrime)); // 5
```

> **Note:** The `isPrime()` implementation is for demonstration only. For a real-world application, you would want to use a heavily memoized algorithm such as the Sieve of Eratosthenes to avoid repeated calculations.

Using the third argument of callbackFn

The `array` argument is useful if you want to access another element in the array, especially when you don't have an existing variable that refers to the array. The following example first uses `filter()` to extract the positive values and then uses `find()` to find the first element that is less than its neighbors.

```
const numbers = [3, -1, 1, 4, 1, 5, 9, 2, 6];
const firstTrough = numbers
  .filter((num) => num > 0)
  .find((num, idx, arr) => {
    // Without the arr argument, there's no way to easily access the
    // intermediate array without saving it to a variable.
    if (idx > 0 && num >= arr[idx - 1]) return false;
    if (idx < arr.length - 1 && num >= arr[idx + 1]) return false;
    return true;
  });
console.log(firstTrough); // 1
```

Using find() on sparse arrays

Empty slots in sparse arrays *are* visited, and are treated the same as `undefined`.

```
// Declare array with no elements at indexes 2, 3, and 4
const array = [0, 1, , , , 5, 6];

// Shows all indexes, not just those with assigned values
array.find((value, index) => {
  console.log("Visited index", index, "with value", value);
```

```
  return false;
});
// Visited index 0 with value 0
// Visited index 1 with value 1
// Visited index 2 with value undefined
// Visited index 3 with value undefined
// Visited index 4 with value undefined
// Visited index 5 with value 5
// Visited index 6 with value 6

// Shows all indexes, including deleted
array.find((value, index) => {
  // Delete element 5 on first iteration
  if (index === 0) {
    console.log("Deleting array[5] with value", array[5]);
    delete array[5];
  }
  // Element 5 is still visited even though deleted
  console.log("Visited index", index, "with value", value);
  return false;
});
// Deleting array[5] with value 5
// Visited index 0 with value 0
// Visited index 1 with value 1
// Visited index 2 with value undefined
// Visited index 3 with value undefined
// Visited index 4 with value undefined
// Visited index 5 with value undefined
// Visited index 6 with value 6
```

Calling find() on non-array objects

The `find()` method reads the `length` property of `this` and then accesses each property whose key is a nonnegative integer less than `length`.

```
const arrayLike = {
  length: 3,
  "-1": 0.1, // ignored by find() since -1 < 0
  0: 2,
  1: 7.3,
  2: 4,
};
console.log(Array.prototype.find.call(arrayLike, (x) => !Number.isInteger(x)));
// 7.3
```

Array.prototype.findIndex()

The **`findIndex()`** method of `Array` instances returns the index of the first element in an array that satisfies the provided testing function. If no elements satisfy the testing function, -1 is returned.

See also the `find()` method, which returns the first element that satisfies the testing function (rather than its index).

Try it

```
const array = [5, 12, 8, 130, 44];

const isLargeNumber = (element) => element > 13;

console.log(array.findIndex(isLargeNumber));
// Expected output: 3
```

Syntax

```
findIndex(callbackFn)
findIndex(callbackFn, thisArg)
```

Parameters

`callbackFn`

A function to execute for each element in the array. It should return a truthy value to indicate a matching element has been found, and a falsy value otherwise. The function is called with the following arguments:

`element`

The current element being processed in the array.

`index`

The index of the current element being processed in the array.

`array`

The array `findIndex()` was called upon.

`thisArg` Optional

A value to use as `this` when executing `callbackFn`. See iterative methods.

Return value

The index of the first element in the array that passes the test. Otherwise, `-1`.

Description

The `findIndex()` method is an iterative method. It calls a provided `callbackFn` function once for each element in an array in ascending-index order, until `callbackFn` returns a truthy value. `findIndex()` then returns the index of that element and stops iterating through the array. If `callbackFn` never returns a truthy value, `findIndex()` returns `-1`. Read the iterative methods section for more information about how these methods work in general.

`callbackFn` is invoked for *every* index of the array, not just those with assigned values. Empty slots in sparse arrays behave the same as `undefined`.

The `findIndex()` method is generic. It only expects the `this` value to have a `length` property and integer-keyed properties.

Examples

Find the index of the first prime number in an array

The following example returns the index of the first element in the array that is a prime number, or `-1` if there is no prime number.

```
function isPrime(n) {
  if (n < 2) {
    return false;
  }
  if (n % 2 === 0) {
    return n === 2;
  }
  for (let factor = 3; factor * factor <= n; factor += 2) {
    if (n % factor === 0) {
      return false;
    }
  }
  return true;
}

console.log([4, 6, 8, 9, 12].findIndex(isPrime)); // -1, not found
console.log([4, 6, 7, 9, 12].findIndex(isPrime)); // 2 (array[2] is 7)
```

> **Note:** The `isPrime()` implementation is for demonstration only. For a real-world application, you would want to use a heavily memoized algorithm such as the Sieve of Eratosthenes to avoid repeated calculations.

Using the third argument of callbackFn

The `array` argument is useful if you want to access another element in the array, especially when you don't have an existing variable that refers to the array. The following example first uses `filter()` to extract the positive values and then uses `findIndex()` to find the first element that is less than its neighbors.

```
const numbers = [3, -1, 1, 4, 1, 5, 9, 2, 6];
const firstTrough = numbers
  .filter((num) => num > 0)
  .findIndex((num, idx, arr) => {
    // Without the arr argument, there's no way to easily access the
    // intermediate array without saving it to a variable.
    if (idx > 0 && num >= arr[idx - 1]) return false;
    if (idx < arr.length - 1 && num >= arr[idx + 1]) return false;
    return true;
  });
console.log(firstTrough); // 1
```

Using findIndex() on sparse arrays

You can search for `undefined` in a sparse array and get the index of an empty slot.

```
console.log([1, , 3].findIndex((x) => x === undefined)); // 1
```

Calling findIndex() on non-array objects

The `findIndex()` method reads the `length` property of `this` and then accesses each property whose key is a nonnegative integer less than `length`.

```
const arrayLike = {
  length: 3,
  "-1": 0.1, // ignored by findIndex() since -1 < 0
  0: 2,
  1: 7.3,
  2: 4,
};
console.log(
  Array.prototype.findIndex.call(arrayLike, (x) => !Number.isInteger(x)),
); // 1
```

- `Array.prototype.findLastIndex()`
- `Array.prototype.indexOf()`
- `Array.prototype.lastIndexOf()`
- `TypedArray.prototype.findIndex()`

Array.prototype.findLast()

The **`findLast()`** method of `Array` instances iterates the array in reverse order and returns the value of the first element that satisfies the provided testing function. If no elements satisfy the testing function, `undefined` is returned.

If you need to find:

- the *first* element that matches, use `find()`.
- the *index* of the last matching element in the array, use `findLastIndex()`.
- the *index of a value*, use `indexOf()`. (It's similar to `findIndex()`, but checks each element for equality with the value instead of using a testing function.)
- whether a value *exists* in an array, use `includes()`. Again, it checks each element for equality with the value instead of using a testing function.
- if any element satisfies the provided testing function, use `some()`.

Try it

```
const array = [5, 12, 50, 130, 44];

const found = array.findLast((element) => element > 45);

console.log(found);
// Expected output: 130
```

Syntax

```
findLast(callbackFn)
findLast(callbackFn, thisArg)
```

Parameters

`callbackFn`

A function to execute for each element in the array. It should return a truthy value to indicate a matching element has been found, and a falsy value otherwise. The function is called with the following arguments:

`element`

The current element being processed in the array.

`index`

The index of the current element being processed in the array.

`array`

The array `findLast()` was called upon.

`thisArg` Optional

A value to use as `this` when executing `callbackFn`. See iterative methods.

Return value

The last (highest-index) element in the array that satisfies the provided testing function; `undefined` if no matching element is found.

Description

The `findLast()` method is an iterative method. It calls a provided `callbackFn` function once for each element in an array in descending-index order, until `callbackFn` returns a truthy value. `findLast()` then returns that element and stops iterating through the array. If `callbackFn` never returns a truthy value, `findLast()` returns `undefined`. Read the iterative methods section for more information about how these methods work in general.

`callbackFn` is invoked for *every* index of the array, not just those with assigned values. Empty slots in sparse arrays behave the same as `undefined`.

The `findLast()` method is generic. It only expects the `this` value to have a `length` property and integer-keyed properties.

Examples

Find last object in an array matching on element properties

This example shows how you might create a test based on the properties of array elements.

```
const inventory = [
  { name: "apples", quantity: 2 },
  { name: "bananas", quantity: 0 },
  { name: "fish", quantity: 1 },
  { name: "cherries", quantity: 5 },
];

// return true inventory stock is low
function isNotEnough(item) {
  return item.quantity < 2;
}

console.log(inventory.findLast(isNotEnough));
// { name: "fish", quantity: 1 }
```

Using arrow function and destructuring

The previous example might be written using an arrow function and object destructuring:

```
const inventory = [
  { name: "apples", quantity: 2 },
  { name: "bananas", quantity: 0 },
  { name: "fish", quantity: 1 },
  { name: "cherries", quantity: 5 },
];

const result = inventory.findLast(({ quantity }) => quantity < 2);

console.log(result);
// { name: "fish", quantity: 1 }
```

Find the last prime number in an array

The following example returns the last element in the array that is a prime number, or `undefined` if there is no prime number.

```
function isPrime(n) {
  if (n < 2) {
    return false;
  }
  if (n % 2 === 0) {
    return n === 2;
  }
  for (let factor = 3; factor * factor <= n; factor += 2) {
    if (n % factor === 0) {
      return false;
    }
  }
  return true;
}

console.log([4, 6, 8, 12].findLast(isPrime)); // undefined, not found
console.log([4, 5, 7, 8, 9, 11, 12].findLast(isPrime)); // 11
```

> **Note:** The `isPrime()` implementation is for demonstration only. For a real-world application, you would want to use a heavily memoized algorithm such as the Sieve of Eratosthenes to avoid repeated calculations.

Find the most recent completed task

This example demonstrates a practical use case for `findLast()` when working with time-ordered data. It finds the most recent completed task from a list already sorted by `timestamp`.

```
const tasks = [
  { name: "Setup project", completed: true, timestamp: 1609459200000 },
```

```
  { name: "Write tests", completed: false, timestamp: 1609545600000 },
  { name: "Fix bug #42", completed: true, timestamp: 1609632000000 },
  { name: "Deploy to staging", completed: true, timestamp: 1609718400000 },
  { name: "Review PR", completed: false, timestamp: 1609804800000 },
];

const lastCompletedTask = tasks.findLast((task) => task.completed);

console.log(lastCompletedTask.name); // Deploy to staging
```

This is more efficient than using `find()` with a reversed array, because it avoids creating a new array.

Using the third argument of callbackFn

The `array` argument is useful if you want to access another element in the array, especially when you don't have an existing variable that refers to the array. The following example first uses `filter()` to extract the positive values and then uses `findLast()` to find the last element that is less than its neighbors.

```
const numbers = [3, -1, 1, 4, 1, 5, 9, 2, 6];
const lastTrough = numbers
  .filter((num) => num > 0)
  .findLast((num, idx, arr) => {
    // Without the arr argument, there's no way to easily access the
    // intermediate array without saving it to a variable.
    if (idx > 0 && num >= arr[idx - 1]) return false;
    if (idx < arr.length - 1 && num >= arr[idx + 1]) return false;
    return true;
  });
console.log(lastTrough); // 2
```

Using findLast() on sparse arrays

Empty slots in sparse arrays *are* visited, and are treated the same as `undefined`.

```
// Declare array with no elements at indexes 2, 3, and 4
const array = [0, 1, , , , 5, 6];

// Shows all indexes, not just those with assigned values
array.findLast((value, index) => {
  console.log(`Visited index ${index} with value ${value}`);
  return false;
});
// Visited index 6 with value 6
// Visited index 5 with value 5
// Visited index 4 with value undefined
// Visited index 3 with value undefined
// Visited index 2 with value undefined
// Visited index 1 with value 1
// Visited index 0 with value 0

// Shows all indexes, including deleted
array.findLast((value, index) => {
  // Delete element 5 on first iteration
  if (index === 6) {
    console.log(`Deleting array[5] with value ${array[5]}`);
    delete array[5];
  }
  // Element 5 is still visited even though deleted
  console.log(`Visited index ${index} with value ${value}`);
  return false;
});
// Deleting array[5] with value 5
// Visited index 6 with value 6
// Visited index 5 with value undefined
// Visited index 4 with value undefined
// Visited index 3 with value undefined
// Visited index 2 with value undefined
// Visited index 1 with value 1
// Visited index 0 with value 0
```

Calling findLast() on non-array objects

The `findLast()` method reads the `length` property of `this` and then accesses each property whose key is a nonnegative integer less than `length`.

```
const arrayLike = {
  length: 3,
  0: 2,
  1: 7.3,
  2: 4,
  3: 3, // ignored by findLast() since length is 3
};
console.log(
  Array.prototype.findLast.call(arrayLike, (x) => Number.isInteger(x)),
); // 4
```

Array.prototype.findLastIndex()

The **`findLastIndex()`** method of `Array` instances iterates the array in reverse order and returns the index of the first element that satisfies the provided testing function. If no elements satisfy the testing function, -1 is returned.

See also the `findLast()` method, which returns the value of last element that satisfies the testing function (rather than its index).

Try it

```
const array = [5, 12, 50, 130, 44];

const isLargeNumber = (element) => element > 45;

console.log(array.findLastIndex(isLargeNumber));
// Expected output: 3
// Index of element with value: 130
```

Syntax

```
findLastIndex(callbackFn)
findLastIndex(callbackFn, thisArg)
```

Parameters

`callbackFn`

A function to execute for each element in the array. It should return a truthy value to indicate a matching element has been found, and a falsy value otherwise. The function is called with the following arguments:

`element`

The current element being processed in the array.

`index`

The index of the current element being processed in the array.

`array`

The array `findLastIndex()` was called upon.

`thisArg` Optional

A value to use as `this` when executing `callbackFn`. See iterative methods.

Return value

The index of the last (highest-index) element in the array that passes the test. Otherwise `-1` if no matching element is found.

Description

The `findLastIndex()` method is an iterative method. It calls a provided `callbackFn` function once for each element in an array in descending-index order, until `callbackFn` returns a truthy value. `findLastIndex()` then returns the index of that element and stops iterating through the array. If `callbackFn` never returns a truthy value, `findLastIndex()` returns `-1`. Read the iterative methods section for more information about how these methods work in general.

`callbackFn` is invoked for *every* index of the array, not just those with assigned values. Empty slots in sparse arrays behave the same as `undefined`.

The `findLastIndex()` method is generic. It only expects the `this` value to have a `length` property and integer-keyed properties.

Examples

Find the index of the last prime number in an array

The following example returns the index of the last element in the array that is a prime number, or `-1` if there is no prime number.

```
function isPrime(n) {
  if (n < 2) {
```

```
    return false;
  }
  if (n % 2 === 0) {
    return n === 2;
  }
  for (let factor = 3; factor * factor <= n; factor += 2) {
    if (n % factor === 0) {
      return false;
    }
  }
  return true;
}

console.log([4, 6, 8, 12].findLastIndex(isPrime)); // -1, not found
console.log([4, 5, 7, 8, 9, 11, 12].findLastIndex(isPrime)); // 5
```

> **Note:** The `isPrime()` implementation is for demonstration only. For a real-world application, you would want to use a heavily memoized algorithm such as the Sieve of Eratosthenes to avoid repeated calculations.

Using the third argument of callbackFn

The `array` argument is useful if you want to access another element in the array, especially when you don't have an existing variable that refers to the array. The following example first uses `filter()` to extract the positive values and then uses `findLastIndex()` to find the last element that is less than its neighbors.

```
const numbers = [3, -1, 1, 4, 1, 5, 9, 2, 6];
const lastTrough = numbers
  .filter((num) => num > 0)
  .findLastIndex((num, idx, arr) => {
    // Without the arr argument, there's no way to easily access the
    // intermediate array without saving it to a variable.
    if (idx > 0 && num >= arr[idx - 1]) return false;
    if (idx < arr.length - 1 && num >= arr[idx + 1]) return false;
    return true;
  });
console.log(lastTrough); // 6
```

Using findLastIndex() on sparse arrays

You can search for `undefined` in a sparse array and get the index of an empty slot.

```
console.log([1, , 3].findLastIndex((x) => x === undefined)); // 1
```

Calling findLastIndex() on non-array objects

The `findLastIndex()` method reads the `length` property of `this` and then accesses each property whose key is a nonnegative integer less than `length`.

```
const arrayLike = {
  length: 3,
  0: 2,
  1: 7.3,
  2: 4,
  3: 3, // ignored by findLastIndex() since length is 3
};
console.log(
  Array.prototype.findLastIndex.call(arrayLike, (x) => Number.isInteger(x)),
); // 2
```

- `TypedArray.prototype.findLastIndex()`

Array.prototype.flat()

The **`flat()`** method of `Array` instances creates a new array with all sub-array elements concatenated into it recursively up to the specified depth.

Try it

```
const arr1 = [0, 1, 2, [3, 4]];

console.log(arr1.flat());
// expected output: Array [0, 1, 2, 3, 4]
```

```
const arr2 = [0, 1, [2, [3, [4, 5]]]];

console.log(arr2.flat());
// expected output: Array [0, 1, 2, Array [3, Array [4, 5]]]

console.log(arr2.flat(2));
// expected output: Array [0, 1, 2, 3, Array [4, 5]]

console.log(arr2.flat(Infinity));
// expected output: Array [0, 1, 2, 3, 4, 5]
```

Syntax

```
flat()
flat(depth)
```

Parameters

`depth` Optional

The depth level specifying how deep a nested array structure should be flattened. Defaults to 1.

Return value

A new array with the sub-array elements concatenated into it.

Description

The `flat()` method is a copying method. It does not alter `this` but instead returns a shallow copy that contains the same elements as the ones from the original array.

The `flat()` method removes empty slots if the array being flattened is sparse. For example, if `depth` is 1, both empty slots in the root array and in the first level of nested arrays are ignored, but empty slots in further nested arrays are preserved with the arrays themselves.

The `flat()` method is generic. It only expects the `this` value to have a `length` property and integer-keyed properties. However, its elements must be arrays if they are to be flattened.

Examples

Flattening nested arrays

```
const arr1 = [1, 2, [3, 4]];
arr1.flat();
// [1, 2, 3, 4]

const arr2 = [1, 2, [3, 4, [5, 6]]];
arr2.flat();
// [1, 2, 3, 4, [5, 6]]

const arr3 = [1, 2, [3, 4, [5, 6]]];
arr3.flat(2);
// [1, 2, 3, 4, 5, 6]

const arr4 = [1, 2, [3, 4, [5, 6, [7, 8, [9, 10]]]]];
arr4.flat(Infinity);
// [1, 2, 3, 4, 5, 6, 7, 8, 9, 10]
```

Using flat() on sparse arrays

The `flat()` method removes empty slots in arrays:

```
const arr5 = [1, 2, , 4, 5];
console.log(arr5.flat()); // [1, 2, 4, 5]

const array = [1, , 3, ["a", , "c"]];
console.log(array.flat()); // [ 1, 3, "a", "c" ]

const array2 = [1, , 3, undefined, ["a", , ["d", , "e"]], null];
console.log(array2.flat()); // [ 1, 3, undefined, "a", ["d", empty, "e"], null ]
console.log(array2.flat(2)); // [ 1, 3, undefined, "a", "d", "e", null ]
```

Calling flat() on non-array objects

The `flat()` method reads the `length` property of `this` and then accesses each property whose key is a nonnegative integer less than `length`. If the element is not an array, it's directly appended to the result. If the element is an array, it's flattened according to the `depth` parameter.

```
const arrayLike = {
  length: 3,
  0: [1, 2],
  // Array-like objects aren't flattened
  1: { length: 2, 0: 3, 1: 4 },
  2: 5,
  3: 3, // ignored by flat() since length is 3
```

```
};
console.log(Array.prototype.flat.call(arrayLike));
// [ 1, 2, { '0': 3, '1': 4, length: 2 }, 5 ]
```

Array.prototype.flatMap()

The **`flatMap()`** method of `Array` instances returns a new array formed by applying a given callback function to each element of the array, and then flattening the result by one level. It is identical to a `map()` followed by a `flat()` of depth 1 (`arr.map(...args).flat()`), but slightly more efficient than calling those two methods separately.

Try it

```
const arr = [1, 2, 1];

const result = arr.flatMap((num) => (num === 2 ? [2, 2] : 1));

console.log(result);
// Expected output: Array [1, 2, 2, 1]
```

Syntax

```
flatMap(callbackFn)
flatMap(callbackFn, thisArg)
```

Parameters

`callbackFn`

A function to execute for each element in the array. It should return an array containing new elements of the new array, or a single non-array value to be added to the new array. The function is called with the following arguments:

`element`

The current element being processed in the array.

`index`

The index of the current element being processed in the array.

`array`

The array `flatMap()` was called upon.

`thisArg` Optional

A value to use as `this` when executing `callbackFn`. See iterative methods.

Return value

A new array with each element being the result of the callback function and flattened by a depth of 1.

Description

The `flatMap()` method is an iterative method. See `Array.prototype.map()` for a detailed description of the callback function. The `flatMap()` method is identical to `map(callbackFn, thisArg)` followed by `flat(1)` — for each element, it produces an array of new elements, and concatenates the resulting arrays together to form a new array. Read the iterative methods section for more information about how these methods work in general.

The `flatMap()` method is generic. It only expects the `this` value to have a `length` property and integer-keyed properties. However, the value returned from `callbackFn` must be an array if it is to be flattened.

Alternative

Pre-allocate and explicitly iterate

```
const arr = [1, 2, 3, 4];

arr.flatMap((x) => [x, x * 2]);
// is equivalent to
const n = arr.length;
const acc = new Array(n * 2);
for (let i = 0; i < n; i++) {
  const x = arr[i];
  acc[i * 2] = x;
```

```
  acc[i * 2 + 1] = x * 2;
}
// [1, 2, 2, 4, 3, 6, 4, 8]
```

Note that in this particular case the `flatMap` approach is slower than the for-loop approach — due to the creation of temporary arrays that must be garbage collected, as well as the return array not needing to be frequently resized. However, `flatMap` may still be the correct solution in cases where its flexibility and readability are desired.

Examples

map() and flatMap()

```
const arr = [1, 2, 3, 4];

arr.map((x) => [x * 2]);
// [[2], [4], [6], [8]]

arr.flatMap((x) => [x * 2]);
// [2, 4, 6, 8]

// only one level is flattened
arr.flatMap((x) => [[x * 2]]);
// [[2], [4], [6], [8]]
```

While the above could have been achieved by using map itself, here is an example that better showcases the use of `flatMap()`.

Let's generate a list of words from a list of sentences.

```
const arr = ["it's Sunny in", "", "California"];

arr.map((x) => x.split(" "));
// [["it's","Sunny","in"],[""],["California"]]

arr.flatMap((x) => x.split(" "));
// ["it's","Sunny","in", "", "California"]
```

Notice, the output list length can be different from the input list length.

For adding and removing items during a map()

`flatMap` can be used as a way to add and remove items (modify the number of items) during a `map`. In other words, it allows you to map *many items to many items* (by handling each input item separately), rather than always *one-to-one*. In this sense, it works like the opposite of filter. Return a 1-element array to keep the item, a multiple-element array to add items, or a 0-element array to remove the item.

```
// Let's say we want to remove all the negative numbers
// and split the odd numbers into an even number and a 1
const a = [5, 4, -3, 20, 17, -33, -4, 18];
//         |\  \  x   |  | \   x   x   |
//        [4,1, 4,   20, 16, 1,       18]

const result = a.flatMap((n) => {
  if (n < 0) {
    return [];
  }
  return n % 2 === 0 ? [n] : [n - 1, 1];
});
console.log(result); // [4, 1, 4, 20, 16, 1, 18]
```

Using the third argument of callbackFn

The `array` argument is useful if you want to access another element in the array, especially when you don't have an existing variable that refers to the array. The following example first uses `filter()` to extract operational stations and then uses `flatMap()` to create a new array where each element contains a station and its next station. On the last station, it returns an empty array to exclude it from the final array.

```
const stations = ["New Haven", "West Haven", "Milford (closed)", "Stratford"];
const line = stations
  .filter((name) => !name.endsWith("(closed)"))
  .flatMap((name, idx, arr) => {
    // Without the arr argument, there's no way to easily access the
    // intermediate array without saving it to a variable.
    if (idx === arr.length - 1) return []; // last station has no next station
    return [`${name} - ${arr[idx + 1]}`];
  });
console.log(line); // ['New Haven - West Haven', 'West Haven - Stratford']
```

The `array` argument is *not* the array that is being built — there is no way to access the array being built from the callback function.

Using flatMap() on sparse arrays

The `callbackFn` won't be called for empty slots in the source array because `map()` doesn't, while `flat()` ignores empty slots in the returned arrays.

```
console.log([1, 2, , 4, 5].flatMap((x) => [x, x * 2])); // [1, 2, 2, 4, 4, 8, 5, 10]
console.log([1, 2, 3, 4].flatMap((x) => [, x * 2])); // [2, 4, 6, 8]
```

Calling flatMap() on non-array objects

The `flatMap()` method reads the `length` property of `this` and then accesses each property whose key is a nonnegative integer less than `length`. If the return value of the callback function is not an array, it is always directly appended to the result array.

```
const arrayLike = {
  length: 3,
  0: 1,
  1: 2,
  2: 3,
  3: 4, // ignored by flatMap() since length is 3
};
console.log(Array.prototype.flatMap.call(arrayLike, (x) => [x, x * 2]));
// [1, 2, 2, 4, 3, 6]

// Array-like objects returned from the callback won't be flattened
console.log(
  Array.prototype.flatMap.call(arrayLike, (x) => ({
    length: 1,
    0: x,
  })),
);
// [ { '0': 1, length: 1 }, { '0': 2, length: 1 }, { '0': 3, length: 1 } ]
```

Array.prototype.forEach()

The **`forEach()`** method of `Array` instances executes a provided function once for each array element.

Try it

```
const array = ["a", "b", "c"];

array.forEach((element) => console.log(element));

// Expected output: "a"
// Expected output: "b"
// Expected output: "c"
```

Syntax

```
forEach(callbackFn)
forEach(callbackFn, thisArg)
```

Parameters

`callbackFn`

A function to execute for each element in the array. Its return value is discarded. The function is called with the following arguments:

`element`

The current element being processed in the array.

`index`

The index of the current element being processed in the array.

`array`

The array `forEach()` was called upon.

`thisArg` Optional

A value to use as `this` when executing `callbackFn`. See iterative methods.

Return value

None (`undefined`).

Description

The `forEach()` method is an iterative method. It calls a provided `callbackFn` function once for each element in an array in ascending-index order. Unlike `map()`, `forEach()` always returns `undefined` and is not chainable. The typical use case is to execute side effects at the end of a chain. Read the iterative methods section for more information about how these methods work in general.

`callbackFn` is invoked only for array indexes which have assigned values. It is not invoked for empty slots in sparse arrays.

The `forEach()` method is generic. It only expects the `this` value to have a `length` property and integer-keyed properties.

There is no way to stop or break a `forEach()` loop other than by throwing an exception. If you need such behavior, the `forEach()` method is the wrong tool.

Early termination may be accomplished with looping statements like `for`, `for...of`, and `for...in`. Array methods like `every()`, `some()`, `find()`, and `findIndex()` also stops iteration immediately when further iteration is not necessary.

`forEach()` expects a synchronous function — it does not wait for promises. Make sure you are aware of the implications while using promises (or async functions) as `forEach` callbacks.

```
const ratings = [5, 4, 5];
let sum = 0;

const sumFunction = async (a, b) => a + b;

ratings.forEach(async (rating) => {
  sum = await sumFunction(sum, rating);
});

console.log(sum);
// Naively expected output: 14
// Actual output: 0
```

To run a series of asynchronous operations sequentially or concurrently, see promise composition.

Examples

Converting a for loop to forEach

```
const items = ["item1", "item2", "item3"];
const copyItems = [];

// before
for (let i = 0; i < items.length; i++) {
  copyItems.push(items[i]);
}

// after
items.forEach((item) => {
  copyItems.push(item);
});
```

Printing the contents of an array

> **Note:** In order to display the content of an array in the console, you can use `console.table()`, which prints a formatted version of the array.
>
> The following example illustrates an alternative approach, using `forEach()`.

The following code logs a line for each element in an array:

```
const logArrayElements = (element, index /*, array */) => {
  console.log(`a[${index}] = ${element}`);
};

// Notice that index 2 is skipped, since there is no item at
// that position in the array.
[2, 5, , 9].forEach(logArrayElements);
// Logs:
// a[0] = 2
// a[1] = 5
// a[3] = 9
```

Using thisArg

The following (contrived) example updates an object's properties from each entry in the array:

```
class Counter {
  constructor() {
    this.sum = 0;
    this.count = 0;
  }
  add(array) {
    // Only function expressions have their own this bindings.
    array.forEach(function countEntry(entry) {
```

```
      this.sum += entry;
      ++this.count;
    }, this);
  }
}

const obj = new Counter();
obj.add([2, 5, 9]);
console.log(obj.count); // 3
console.log(obj.sum); // 16
```

Since the `thisArg` parameter (`this`) is provided to `forEach()`, it is passed to `callback` each time it's invoked. The callback uses it as its `this` value.

> **Note:** If passing the callback function used an arrow function expression, the `thisArg` parameter could be omitted, since all arrow functions lexically bind the `this` value.

An object copy function

The following code creates a copy of a given object.

There are different ways to create a copy of an object. The following is just one way and is presented to explain how `Array.prototype.forEach()` works by using `Object.*` utility functions.

```
const copy = (obj) => {
  const copy = Object.create(Object.getPrototypeOf(obj));
  const propNames = Object.getOwnPropertyNames(obj);
  propNames.forEach((name) => {
    const desc = Object.getOwnPropertyDescriptor(obj, name);
    Object.defineProperty(copy, name, desc);
  });
  return copy;
};

const obj1 = { a: 1, b: 2 };
const obj2 = copy(obj1); // obj2 looks like obj1 now
```

Flatten an array

The following example is only here for learning purpose. If you want to flatten an array using built-in methods, you can use `Array.prototype.flat()`.

```
const flatten = (arr) => {
  const result = [];
  arr.forEach((item) => {
    if (Array.isArray(item)) {
      result.push(...flatten(item));
    } else {
      result.push(item);
    }
  });
  return result;
};

// Usage
const nested = [1, 2, 3, [4, 5, [6, 7], 8, 9]];
console.log(flatten(nested)); // [1, 2, 3, 4, 5, 6, 7, 8, 9]
```

Using the third argument of callbackFn

The `array` argument is useful if you want to access another element in the array, especially when you don't have an existing variable that refers to the array. The following example first uses `filter()` to extract the positive values and then uses `forEach()` to log its neighbors.

```
const numbers = [3, -1, 1, 4, 1, 5];
numbers
  .filter((num) => num > 0)
  .forEach((num, idx, arr) => {
    // Without the arr argument, there's no way to easily access the
    // intermediate array without saving it to a variable.
    console.log(arr[idx - 1], num, arr[idx + 1]);
  });
// undefined 3 1
// 3 1 4
// 1 4 1
// 4 1 5
// 1 5 undefined
```

Using forEach() on sparse arrays

```
const arraySparse = [1, 3, /* empty */, 7];
let numCallbackRuns = 0;

arraySparse.forEach((element) => {
  console.log({ element });
```

```
  numCallbackRuns++;
});

console.log({ numCallbackRuns });

// { element: 1 }
// { element: 3 }
// { element: 7 }
// { numCallbackRuns: 3 }
```

The callback function is not invoked for the missing value at index 2.

Calling forEach() on non-array objects

The `forEach()` method reads the `length` property of `this` and then accesses each property whose key is a nonnegative integer less than `length`.

```
const arrayLike = {
  length: 3,
  0: 2,
  1: 3,
  2: 4,
  3: 5, // ignored by forEach() since length is 3
};
Array.prototype.forEach.call(arrayLike, (x) => console.log(x));
// 2
// 3
// 4
```

Array.from()

The **`Array.from()`** static method creates a new, shallow-copied `Array` instance from an iterable or array-like object.

Try it

```
console.log(Array.from("foo"));
// Expected output: Array ["f", "o", "o"]

console.log(Array.from([1, 2, 3], (x) => x + x));
// Expected output: Array [2, 4, 6]
```

Syntax

```
Array.from(items)
Array.from(items, mapFn)
Array.from(items, mapFn, thisArg)
```

Parameters

`items`

An iterable or array-like object to convert to an array.

`mapFn` Optional

A function to call on every element of the array. If provided, every value to be added to the array is first passed through this function, and `mapFn`'s return value is added to the array instead. The function is called with the following arguments:

`element`

The current element being processed in the array.

`index`

The index of the current element being processed in the array.

`thisArg` Optional

Value to use as `this` when executing `mapFn`.

Return value

A new `Array` instance.

Description

`Array.from()` lets you create `Array`s from:

- iterable objects (objects such as `Map` and `Set`); or, if the object is not iterable,
- array-like objects (objects with a `length` property and indexed elements).

To convert an ordinary object that's not iterable or array-like to an array (by enumerating its property keys, values, or both), use `Object.keys()`, `Object.values()`, or `Object.entries()`. To convert an async iterable to an array, use `Array.fromAsync()`.

`Array.from()` never creates a sparse array. If the `items` object is missing some index properties, they become `undefined` in the new array.

`Array.from()` has an optional parameter `mapFn`, which allows you to execute a function on each element of the array being created, similar to `map()`. More clearly, `Array.from(obj, mapFn, thisArg)` has the same result as `Array.from(obj).map(mapFn, thisArg)`, except that it does not create an intermediate array, and `mapFn` only receives two arguments (`element`, `index`) without the whole array, because the array is still under construction.

> **Note:** This behavior is more important for typed arrays, since the intermediate array would necessarily have values truncated to fit into the appropriate type. `Array.from()` is implemented to have the same signature as `TypedArray.from()`.

The `Array.from()` method is a generic factory method. For example, if a subclass of `Array` inherits the `from()` method, the inherited `from()` method will return new instances of the subclass instead of `Array` instances. In fact, the `this` value can be any constructor function that accepts a single argument representing the length of the new array. When an iterable is passed as `items`, the constructor is called with no arguments; when an array-like object is passed, the constructor is called with the normalized length of the array-like object. The final `length` will be set again when iteration finishes. If the `this` value is not a constructor function, the plain `Array` constructor is used instead.

Examples

Array from a String

```
Array.from("foo");
// [ "f", "o", "o" ]
```

Array from a Set

```
const set = new Set(["foo", "bar", "baz", "foo"]);
Array.from(set);
// [ "foo", "bar", "baz" ]
```

Array from a Map

```
const map = new Map([
  [1, 2],
  [2, 4],
  [4, 8],
]);
Array.from(map);
// [[1, 2], [2, 4], [4, 8]]

const mapper = new Map([
  ["1", "a"],
  ["2", "b"],
]);
Array.from(mapper.values());
// ['a', 'b'];

Array.from(mapper.keys());
// ['1', '2'];
```

Array from a NodeList

```
// Create an array based on a property of DOM Elements
const images = document.querySelectorAll("img");
const sources = Array.from(images, (image) => image.src);
const insecureSources = sources.filter((link) => link.startsWith("http://"));
```

Array from an Array-like object (arguments)

```
function f() {
  return Array.from(arguments);
}

f(1, 2, 3);

// [ 1, 2, 3 ]
```

Using arrow functions and Array.from()

```
// Using an arrow function as the map function to
// manipulate the elements
Array.from([1, 2, 3], (x) => x + x);
// [2, 4, 6]

// Generate a sequence of numbers
// Since the array is initialized with `undefined` on each position,
// the value of `v` below will be `undefined`
Array.from({ length: 5 }, (v, i) => i);
// [0, 1, 2, 3, 4]
```

Sequence generator (range)

```
// Sequence generator function (commonly referred to as "range", cf. Python, Clojure, etc.)
const range = (start, stop, step) =>
  Array.from(
    { length: Math.ceil((stop - start) / step) },
    (_, i) => start + i * step,
  );

// Generate a sequence of numbers from 0 (inclusive) to 5 (exclusive), incrementing by 1
range(0, 5, 1);
// [0, 1, 2, 3, 4]

// Generate a sequence of numbers from 1 (inclusive) to 10 (exclusive), incrementing by 2
range(1, 10, 2);
// [1, 3, 5, 7, 9]

// Generate the Latin alphabet making use of it being ordered as a sequence
range("A".charCodeAt(0), "Z".charCodeAt(0) + 1, 1).map((x) =>
  String.fromCharCode(x),
);
// ["A", "B", "C", "D", "E", "F", "G", "H", "I", "J", "K", "L", "M", "N", "O", "P", "Q", "R", "S", "T", "U", "V", "W", "X", "Y", "Z"]
```

Calling from() on non-array constructors

The `from()` method can be called on any constructor function that accepts a single argument representing the length of the new array.

```
function NotArray(len) {
  console.log("NotArray called with length", len);
}

// Iterable
console.log(Array.from.call(NotArray, new Set(["foo", "bar", "baz"])));
// NotArray called with length undefined
// NotArray { '0': 'foo', '1': 'bar', '2': 'baz', length: 3 }

// Array-like
console.log(Array.from.call(NotArray, { length: 1, 0: "foo" }));
// NotArray called with length 1
// NotArray { '0': 'foo', length: 1 }
```

When the `this` value is not a constructor, a plain `Array` object is returned.

```
console.log(Array.from.call({}, { length: 1, 0: "foo" })); // [ 'foo' ]
```

- `Array`
- `Array()`
- `Array.of()`
- `Array.fromAsync()`
- `Array.prototype.map()`
- `TypedArray.from()`

Array.fromAsync()

The **`Array.fromAsync()`** static method creates a new, shallow-copied `Array` instance from an async iterable, iterable, or array-like object.

Syntax

```
Array.fromAsync(items)
Array.fromAsync(items, mapFn)
Array.fromAsync(items, mapFn, thisArg)
```

Parameters

`items`

An async iterable, iterable, or array-like object to convert to an array.

`mapFn` Optional

A function to call on every element of the array. If provided, every value to be added to the array is first passed through this function, and `mapFn`'s return value is added to the array instead (after being awaited). The function is called with the following arguments:

`element`

The current element being processed in the array. If `items` is a sync iterable or array-like object, then all elements are first awaited, and `element` will never be a thenable. If `items` is an async iterable, then each yielded value is passed as-is.

`index`

The index of the current element being processed in the array.

`thisArg` Optional

Value to use as `this` when executing `mapFn`.

Return value

A new `Promise` whose fulfillment value is a new `Array` instance.

Description

`Array.fromAsync()` lets you create arrays from:

- async iterable objects (objects such as `ReadableStream` and `AsyncGenerator`); or, if the object is not async iterable,
- iterable objects (objects such as `Map` and `Set`); or, if the object is not iterable,
- array-like objects (objects with a `length` property and indexed elements).

`Array.fromAsync()` iterates the async iterable in a fashion very similar to `for await...of`. `Array.fromAsync(items)` is generally equivalent to the following code, if `items` is an async iterable or sync iterable:

```
const result = [];
for await (const element of items) {
  result.push(element);
}
```

`Array.fromAsync()` is almost equivalent to `Array.from()` in terms of behavior, except the following:

- `Array.fromAsync()` handles async iterable objects.
- `Array.fromAsync()` returns a `Promise` that fulfills to the array instance.
- If `Array.fromAsync()` is called with a non-async iterable object, each element to be added to the array is first awaited.
- If a `mapFn` is provided, its output is also internally awaited.

`Array.fromAsync()` and `Promise.all()` can both turn an iterable of promises into a promise of an array. However, there are two key differences:

- `Array.fromAsync()` awaits each value yielded from the object sequentially. `Promise.all()` awaits all values concurrently.
- `Array.fromAsync()` iterates the iterable lazily, and doesn't retrieve the next value until the current one is settled. `Promise.all()` retrieves all values in advance and awaits them all.

Examples

Array from an async iterable

```
const asyncIterable = (async function* () {
  for (let i = 0; i < 5; i++) {
    await new Promise((resolve) => setTimeout(resolve, 10 * i));
    yield i;
  }
})();

Array.fromAsync(asyncIterable).then((array) => console.log(array));
// [0, 1, 2, 3, 4]
```

When `items` is an async iterable where each result's `value` is also a promise, then those promises are added to the resulting array without being awaited. This is consistent with the behavior of `for await...of`.

```
function createAsyncIter() {
  let i = 0;
  return {
    [Symbol.asyncIterator]() {
      return {
        async next() {
          if (i > 2) return { done: true };
          i++;
          return { value: Promise.resolve(i), done: false };
        },
      };
```

```
    },
  };
}

Array.fromAsync(createAsyncIter()).then((array) => console.log(array));
// (3) [Promise, Promise, Promise]
```

> **Note:** In practice, you will rarely encounter an async iterable that yields promises, because if you implement it using an async generator function, then the `yield` expression automatically unwraps promises.

Array from a sync iterable

```
Array.fromAsync(
  new Map([
    [1, 2],
    [3, 4],
  ]),
).then((array) => console.log(array));
// [[1, 2], [3, 4]]
```

Array from a sync iterable that yields promises

```
Array.fromAsync(
  new Set([Promise.resolve(1), Promise.resolve(2), Promise.resolve(3)]),
).then((array) => console.log(array));
// [1, 2, 3]
```

Array from an array-like object of promises

```
Array.fromAsync({
  length: 3,
  0: Promise.resolve(1),
  1: Promise.resolve(2),
  2: Promise.resolve(3),
}).then((array) => console.log(array));
// [1, 2, 3]
```

Using mapFn with a sync iterable

When `items` is a sync iterable or array-like object, both the input and output of `mapFn` are awaited internally by `Array.fromAsync()`.

```
function delayedValue(v) {
  return new Promise((resolve) => setTimeout(() => resolve(v), 100));
}

Array.fromAsync(
  [delayedValue(1), delayedValue(2), delayedValue(3)],
  (element) => delayedValue(element * 2),
).then((array) => console.log(array));
// [2, 4, 6]
```

Using mapFn with an async iterable

When `items` is an async iterable, the input to `mapFn` is not awaited, but the output is. Using the same `createAsyncIter` function as above:

```
Array.fromAsync(createAsyncIter(), async (element) => (await element) * 2).then(
  (array) => console.log(array),
);
// [2, 4, 6]
```

Curiously, this means that `Array.fromAsync(createAsyncIter())` is not equivalent to `Array.fromAsync(createAsyncIter(), (element) => element)`, because the latter awaits each yielded value, while the former does not.

```
Array.fromAsync(createAsyncIter(), (element) => element).then((array) =>
  console.log(array),
);
// [1, 2, 3]
```

Comparison with Promise.all()

`Array.fromAsync()` awaits each value yielded from the object sequentially. `Promise.all()` awaits all values concurrently.

```
function* makeIterableOfPromises() {
  for (let i = 0; i < 5; i++) {
    yield new Promise((resolve) => setTimeout(resolve, 100));
  }
}

(async () => {
  console.time("Array.fromAsync() time");
```

```
  await Array.fromAsync(makeIterableOfPromises());
  console.timeEnd("Array.fromAsync() time");
  // Array.fromAsync() time: 503.610ms

  console.time("Promise.all() time");
  await Promise.all(makeIterableOfPromises());
  console.timeEnd("Promise.all() time");
  // Promise.all() time: 101.728ms
})();
```

Closing sync iterables on rejection

Similar to `for await...of`, if the object being iterated is a sync iterable, and a yielded promise rejects, the `return()` method of the underlying iterator will be called, if one exists, to allow the iterator to perform cleanup.

```
function* generatorWithRejectedPromises() {
  try {
    yield 0;
    yield Promise.reject(new Error("error"));
  } finally {
    console.log("called finally");
  }
}

(async () => {
  try {
    await Array.fromAsync(generatorWithRejectedPromises());
  } catch (e) {
    console.log("caught", e);
  }
})();
// called finally
// caught Error: error
```

Array.prototype.includes()

The **`includes()`** method of `Array` instances determines whether an array includes a certain value among its entries, returning `true` or `false` as appropriate.

Try it

```
const array = [1, 2, 3];

console.log(array.includes(2));
// Expected output: true

const pets = ["cat", "dog", "bat"];

console.log(pets.includes("cat"));
// Expected output: true

console.log(pets.includes("at"));
// Expected output: false
```

Syntax

```
includes(searchElement)
includes(searchElement, fromIndex)
```

Parameters

`searchElement`

The value to search for.

`fromIndex` Optional

Zero-based index at which to start searching, converted to an integer.

- Negative index counts back from the end of the array — if `-array.length <= fromIndex < 0`, `fromIndex + array.length` is used. However, the array is still searched from front to back in this case.
- If `fromIndex < -array.length` or `fromIndex` is omitted, `0` is used, causing the entire array to be searched.
- If `fromIndex >= array.length`, the array is not searched and `false` is returned.

Return value

A boolean value which is `true` if the value `searchElement` is found within the array (or the part of the array indicated by the index `fromIndex`, if specified).

Description

The `includes()` method compares `searchElement` to elements of the array using the SameValueZero algorithm. This algorithm works like strict equality `===` (where `-0` and `+0` are considered equal), with the exception that `NaN` is considered equal to itself.

When used on sparse arrays, the `includes()` method iterates empty slots as if they have the value `undefined`.

The `includes()` method is generic. It only expects the `this` value to have a `length` property and integer-keyed properties.

Examples

Using includes()

```
[1, 2, 3].includes(2); // true
[1, 2, 3].includes(4); // false
[1, 2, 3].includes(3, 3); // false
[1, 2, 3].includes(3, -1); // true
[1, 2, NaN].includes(NaN); // true
["1", "2", "3"].includes(3); // false
```

fromIndex is greater than or equal to the array length

If `fromIndex` is greater than or equal to the length of the array, `false` is returned. The array will not be searched.

```
const arr = ["a", "b", "c"];

arr.includes("c", 3); // false
arr.includes("c", 100); // false
```

Computed index is less than 0

If `fromIndex` is negative, the computed index is calculated to be used as a position in the array at which to begin searching for `searchElement`. If the computed index is less than or equal to `0`, the entire array will be searched.

```
// array length is 3
// fromIndex is -100
// computed index is 3 + (-100) = -97

const arr = ["a", "b", "c"];

arr.includes("a", -100); // true
arr.includes("b", -100); // true
arr.includes("c", -100); // true
arr.includes("a", -2); // false
```

Using includes() on sparse arrays

You can search for `undefined` in a sparse array and get `true`.

```
console.log([1, , 3].includes(undefined)); // true
```

Calling includes() on non-array objects

The `includes()` method reads the `length` property of `this` and then accesses each property whose key is a nonnegative integer less than `length`.

```
const arrayLike = {
  length: 3,
  0: 2,
  1: 3,
  2: 4,
  3: 1, // ignored by includes() since length is 3
};
console.log(Array.prototype.includes.call(arrayLike, 2));
// true
console.log(Array.prototype.includes.call(arrayLike, 1));
// false
```

- `Array.prototype.findIndex()`
- `TypedArray.prototype.includes()`

- `String.prototype.includes()`

Array.prototype.indexOf()

The **`indexOf()`** method of `Array` instances returns the first index at which a given element can be found in the array, or -1 if it is not present.

Try it

```
const beasts = ["ant", "bison", "camel", "duck", "bison"];

console.log(beasts.indexOf("bison"));
// Expected output: 1

// Start from index 2
console.log(beasts.indexOf("bison", 2));
// Expected output: 4

console.log(beasts.indexOf("giraffe"));
// Expected output: -1
```

Syntax

```
indexOf(searchElement)
indexOf(searchElement, fromIndex)
```

Parameters

`searchElement`

Element to locate in the array.

`fromIndex` Optional

Zero-based index at which to start searching, converted to an integer.

- Negative index counts back from the end of the array — if `-array.length <= fromIndex < 0`, `fromIndex + array.length` is used. Note, the array is still searched from front to back in this case.
- If `fromIndex < -array.length` or `fromIndex` is omitted, `0` is used, causing the entire array to be searched.
- If `fromIndex >= array.length`, the array is not searched and `-1` is returned.

Return value

The first index of `searchElement` in the array; `-1` if not found.

Description

The `indexOf()` method compares `searchElement` to elements of the array using strict equality (the same algorithm used by the `===` operator). `NaN` values are never compared as equal, so `indexOf()` always returns `-1` when `searchElement` is `NaN`.

The `indexOf()` method skips empty slots in sparse arrays.

The `indexOf()` method is generic. It only expects the `this` value to have a `length` property and integer-keyed properties.

Examples

Using indexOf()

The following example uses `indexOf()` to locate values in an array.

```
const array = [2, 9, 9];
array.indexOf(2); // 0
array.indexOf(7); // -1
array.indexOf(9, 2); // 2
array.indexOf(2, -1); // -1
array.indexOf(2, -3); // 0
```

You cannot use `indexOf()` to search for `NaN`.

```
const array = [NaN];
array.indexOf(NaN); // -1
```

Finding all the occurrences of an element

```
const indices = [];
const array = ["a", "b", "a", "c", "a", "d"];
const element = "a";
let idx = array.indexOf(element);
while (idx !== -1) {
  indices.push(idx);
  idx = array.indexOf(element, idx + 1);
}
console.log(indices);
// [0, 2, 4]
```

Finding if an element exists in the array or not and updating the array

```
function updateVegetablesCollection(veggies, veggie) {
  if (veggies.indexOf(veggie) === -1) {
    veggies.push(veggie);
    console.log(`New veggies collection is: ${veggies}`);
  } else {
    console.log(`${veggie} already exists in the veggies collection.`);
  }
}

const veggies = ["potato", "tomato", "chillies", "green-pepper"];

updateVegetablesCollection(veggies, "spinach");
// New veggies collection is: potato,tomato,chillies,green-pepper,spinach
updateVegetablesCollection(veggies, "spinach");
// spinach already exists in the veggies collection.
```

Using indexOf() on sparse arrays

You cannot use `indexOf()` to search for empty slots in sparse arrays.

```
console.log([1, , 3].indexOf(undefined)); // -1
```

Calling indexOf() on non-array objects

The `indexOf()` method reads the `length` property of `this` and then accesses each property whose key is a nonnegative integer less than `length`.

```
const arrayLike = {
  length: 3,
  0: 2,
  1: 3,
  2: 4,
  3: 5, // ignored by indexOf() since length is 3
};
console.log(Array.prototype.indexOf.call(arrayLike, 2));
// 0
console.log(Array.prototype.indexOf.call(arrayLike, 5));
// -1
```

Array.isArray()

The **`Array.isArray()`** static method determines whether the passed value is an `Array`.

Try it

```
console.log(Array.isArray([1, 3, 5]));
// Expected output: true

console.log(Array.isArray("[]"));
// Expected output: false

console.log(Array.isArray(new Array(5)));
// Expected output: true

console.log(Array.isArray(new Int16Array([15, 33])));
// Expected output: false
```

Syntax

```
Array.isArray(value)
```

Parameters

`value`

The value to be checked.

Return value

`true` if `value` is an `Array`; otherwise, `false`. `false` is always returned if `value` is a `TypedArray` instance.

Description

`Array.isArray()` checks if the passed value is an `Array`. It performs a *branded check*, similar to the `in` operator, for a private field initialized by the `Array()` constructor.

It is a more robust alternative to `instanceof Array` because it avoids false positives and false negatives:

- `Array.isArray()` rejects values that aren't actual `Array` instances, even if they have `Array.prototype` in their prototype chain — `instanceof Array` would accept these as it does check the prototype chain.
- `Array.isArray()` accepts `Array` objects constructed in another realm — `instanceof Array` returns `false` for these because the identity of the `Array` constructor is different across realms.

See the article "Determining with absolute accuracy whether or not a JavaScript object is an array" for more details.

Examples

Using Array.isArray()

```
// all following calls return true
Array.isArray([]);
Array.isArray([1]);
Array.isArray(new Array());
Array.isArray(new Array("a", "b", "c", "d"));
Array.isArray(new Array(3));
// Little known fact: Array.prototype itself is an array:
Array.isArray(Array.prototype);

// all following calls return false
Array.isArray();
Array.isArray({});
Array.isArray(null);
Array.isArray(undefined);
Array.isArray(17);
Array.isArray("Array");
Array.isArray(true);
Array.isArray(false);
Array.isArray(new Uint8Array(32));
// This is not an array, because it was not created using the
// array literal syntax or the Array constructor
Array.isArray({ __proto__: Array.prototype });
```

instanceof vs. Array.isArray()

When checking for `Array` instance, `Array.isArray()` is preferred over `instanceof` because it works across realms.

```
const iframe = document.createElement("iframe");
document.body.appendChild(iframe);
const xArray = window.frames[window.frames.length - 1].Array;
const arr = new xArray(1, 2, 3); // [1, 2, 3]

// Correctly checking for Array
Array.isArray(arr); // true
// The prototype of arr is xArray.prototype, which is a
// different object from Array.prototype
arr instanceof Array; // false
```

- `Array`

Array.prototype.join()

The **`join()`** method of `Array` instances returns a new string that is the concatenation of all elements in this array, separated by commas or a specified separator string. If the array has only one item, that item's stringification is returned without using the separator.

Try it

```
const elements = ["Fire", "Air", "Water"];

console.log(elements.join());
// Expected output: "Fire,Air,Water"

console.log(elements.join(""));
// Expected output: "FireAirWater"

console.log(elements.join("-"));
// Expected output: "Fire-Air-Water"
```

Syntax

```
join()
join(separator)
```

Parameters

`separator` Optional

A string to separate each pair of adjacent elements of the array. If omitted, the array elements are separated with a comma (",").

Return value

A string with all array elements joined. If `array.length` is `0`, the empty string is returned.

Description

The string conversions of all array elements are joined into one string. If an element is `undefined` or `null`, it is converted to an empty string instead of the string `"null"` or `"undefined"`.

The `join` method is accessed internally by `Array.prototype.toString()` with no arguments. Overriding `join` of an array instance will override its `toString` behavior as well.

`Array.prototype.join` recursively converts each element, including other arrays, to strings. Because the string returned by `Array.prototype.toString` (which is the same as calling `join()`) does not have delimiters, nested arrays look like they are flattened. You can only control the separator of the first level, while deeper levels always use the default comma.

```
const matrix = [
  [1, 2, 3],
  [4, 5, 6],
  [7, 8, 9],
];

console.log(matrix.join()); // 1,2,3,4,5,6,7,8,9
console.log(matrix.join(";")); // 1,2,3;4,5,6;7,8,9
```

When an array is cyclic (it contains an element that is itself), browsers avoid infinite recursion by ignoring the cyclic reference.

```
const arr = [];
arr.push(1, [3, arr, 4], 2);
console.log(arr.join(";")); // 1;3,,4;2
```

When used on sparse arrays, the `join()` method iterates empty slots as if they have the value `undefined`.

The `join()` method is generic. It only expects the `this` value to have a `length` property and integer-keyed properties.

Examples

Joining an array four different ways

The following example creates an array, `a`, with three elements, then joins the array four times: using the default separator, then a comma and a space, then a plus and an empty string.

```
const a = ["Wind", "Water", "Fire"];
a.join(); // 'Wind,Water,Fire'
a.join(", "); // 'Wind, Water, Fire'
a.join(" + "); // 'Wind + Water + Fire'
a.join(""); // 'WindWaterFire'
```

Using join() on sparse arrays

`join()` treats empty slots the same as `undefined` and produces an extra separator:

```
console.log([1, , 3].join()); // '1,,3'
console.log([1, undefined, 3].join()); // '1,,3'
```

Calling join() on non-array objects

The `join()` method reads the `length` property of `this` and then accesses each property whose key is a nonnegative integer less than `length`.

```
const arrayLike = {
  length: 3,
  0: 2,
  1: 3,
  2: 4,
  3: 5, // ignored by join() since length is 3
};
console.log(Array.prototype.join.call(arrayLike));
// 2,3,4
console.log(Array.prototype.join.call(arrayLike, "."));
// 2.3.4
```

- Indexed collections guide
- `Array`
- `Array.prototype.toString()`
- `TypedArray.prototype.join()`
- `String.prototype.split()`

Array.prototype.keys()

The **`keys()`** method of `Array` instances returns a new *array iterator* object that contains the keys for each index in the array.

Try it

```
const array = ["a", "b", "c"];
const iterator = array.keys();

for (const key of iterator) {
  console.log(key);
}

// Expected output: 0
// Expected output: 1
// Expected output: 2
```

Syntax

```
keys()
```

Parameters

None.

Return value

A new iterable iterator object.

Description

When used on sparse arrays, the `keys()` method iterates empty slots as if they have the value `undefined`.

The `keys()` method is generic. It only expects the `this` value to have a `length` property and integer-keyed properties.

Examples

Using keys() on sparse arrays

Unlike `Object.keys()`, which only includes keys that actually exist in the array, the `keys()` iterator doesn't ignore holes representing missing properties.

```
const arr = ["a", , "c"];
const sparseKeys = Object.keys(arr);
const denseKeys = [...arr.keys()];
console.log(sparseKeys); // ['0', '2']
console.log(denseKeys); // [0, 1, 2]
```

Calling keys() on non-array objects

The `keys()` method reads the `length` property of `this` and then yields all integer indices between 0 and `length - 1`. No index access actually happens.

```
const arrayLike = {
  length: 3,
};
for (const entry of Array.prototype.keys.call(arrayLike)) {
  console.log(entry);
}
// 0
// 1
// 2
```

- `Array.prototype.values()`
- `Array.prototype[Symbol.iterator]()`
- `TypedArray.prototype.keys()`
- Iteration protocols

Array.prototype.lastIndexOf()

The **`lastIndexOf()`** method of `Array` instances returns the last index at which a given element can be found in the array, or -1 if it is not present. The array is searched backwards, starting at `fromIndex`.

Try it

```
const animals = ["Dodo", "Tiger", "Penguin", "Dodo"];

console.log(animals.lastIndexOf("Dodo"));
// Expected output: 3

console.log(animals.lastIndexOf("Tiger"));
// Expected output: 1
```

Syntax

```
lastIndexOf(searchElement)
lastIndexOf(searchElement, fromIndex)
```

Parameters

`searchElement`

Element to locate in the array.

`fromIndex` Optional

Zero-based index at which to start searching backwards, converted to an integer.

- Negative index counts back from the end of the array — if `-array.length <= fromIndex < 0`, `fromIndex + array.length` is used.
- If `fromIndex < -array.length`, the array is not searched and `-1` is returned. You can think of it conceptually as starting at a nonexistent position before the beginning of the array and going backwards from there. There are no array elements on the way, so `searchElement` is never found.
- If `fromIndex >= array.length` or `fromIndex` is omitted or `undefined`, `array.length - 1` is used, causing the entire array to be searched. You can think of it conceptually as starting at a nonexistent position beyond the end of the array and going backwards from there. It eventually reaches the real end position of the array, at which point it starts searching backwards through the actual array elements.

Return value

The last index of `searchElement` in the array; `-1` if not found.

Description

The `lastIndexOf()` method compares `searchElement` to elements of the array using strict equality (the same algorithm used by the `===` operator). `NaN` values are never compared as equal, so `lastIndexOf()` always returns `-1` when `searchElement` is `NaN`.

The `lastIndexOf()` method skips empty slots in sparse arrays.

The `lastIndexOf()` method is generic. It only expects the `this` value to have a `length` property and integer-keyed properties.

Examples

Using lastIndexOf()

The following example uses `lastIndexOf()` to locate values in an array.

```
const numbers = [2, 5, 9, 2];
numbers.lastIndexOf(2); // 3
numbers.lastIndexOf(7); // -1
numbers.lastIndexOf(2, 3); // 3
numbers.lastIndexOf(2, 2); // 0
numbers.lastIndexOf(2, -2); // 0
numbers.lastIndexOf(2, -1); // 3
```

You cannot use `lastIndexOf()` to search for `NaN`.

```
const array = [NaN];
array.lastIndexOf(NaN); // -1
```

Finding all the occurrences of an element

The following example uses `lastIndexOf` to find all the indices of an element in a given array, using `push()` to add them to another array as they are found.

```
const indices = [];
const array = ["a", "b", "a", "c", "a", "d"];
const element = "a";
let idx = array.lastIndexOf(element);
while (idx !== -1) {
  indices.push(idx);
  idx = idx > 0 ? array.lastIndexOf(element, idx - 1) : -1;
}
```

```
console.log(indices);
// [4, 2, 0]
```

Note that we have to handle the case `idx === 0` separately here because the element will always be found regardless of the `fromIndex` parameter if it is the first element of the array. This is different from the `indexOf()` method.

Using lastIndexOf() on sparse arrays

You cannot use `lastIndexOf()` to search for empty slots in sparse arrays.

```
console.log([1, , 3].lastIndexOf(undefined)); // -1
```

Calling lastIndexOf() on non-array objects

The `lastIndexOf()` method reads the `length` property of `this` and then accesses each property whose key is a nonnegative integer less than `length`.

```
const arrayLike = {
  length: 3,
  0: 2,
  1: 3,
  2: 2,
  3: 5, // ignored by lastIndexOf() since length is 3
};
console.log(Array.prototype.lastIndexOf.call(arrayLike, 2));
// 2
console.log(Array.prototype.lastIndexOf.call(arrayLike, 5));
// -1
```

Array: length

The **`length`** data property of an `Array` instance represents the number of slots in that array. The value is an unsigned, 32-bit integer that is always numerically greater than the highest index in the array. It may be greater than the number of elements if the array is sparse.

Try it

```
const clothing = ["shoes", "shirts", "socks", "sweaters"];

console.log(clothing.length);
// Expected output: 4
```

Value

A nonnegative integer less than 2^{32}.

Property attributes of `Array: length`	
Writable	yes
Enumerable	no
Configurable	no

Description

The value of the `length` property is a nonnegative integer with a value less than 2^{32}.

```
const listA = [1, 2, 3];
const listB = new Array(6);

console.log(listA.length);
// 3

console.log(listB.length);
// 6

listB.length = 2 ** 32; // 4294967296
// RangeError: Invalid array length

const listC = new Array(-100); // Negative numbers are not allowed
// RangeError: Invalid array length
```

The array object observes the `length` property, and automatically syncs the `length` value with the array's content. This means:

- Setting `length` to a value smaller than the current length truncates the array — elements beyond the new `length` are deleted.
- Setting any array index (a nonnegative integer smaller than 2^{32}) beyond the current `length` extends the array — the `length` property is increased to reflect the new highest index.
- Setting `length` to an invalid value (e.g., a negative number or a non-integer) throws a `RangeError` exception.

When `length` is set to a bigger value than the current length, the array is extended by adding empty slots, not actual `undefined` values. Empty slots have some special interactions with array methods; see array methods and empty slots.

```
const arr = [1, 2];
console.log(arr);
// [ 1, 2 ]

arr.length = 5; // set array length to 5 while currently 2.
console.log(arr);
// [ 1, 2, <3 empty items> ]

arr.forEach((element) => console.log(element));
// 1
// 2
```

See also Relationship between `length` and numerical properties.

Examples

Iterating over an array

In the following example, the array `numbers` is iterated through by looking at the `length` property. The value in each element is then doubled.

```
const numbers = [1, 2, 3, 4, 5];
const length = numbers.length;
for (let i = 0; i < length; i++) {
  numbers[i] *= 2;
}
// numbers is now [2, 4, 6, 8, 10]
```

Shortening an array

The following example shortens the array `numbers` to a length of 3 if the current length is greater than 3.

```
const numbers = [1, 2, 3, 4, 5];

if (numbers.length > 3) {
  numbers.length = 3;
}

console.log(numbers); // [1, 2, 3]
console.log(numbers.length); // 3
console.log(numbers[3]); // undefined; the extra elements are deleted
```

Create empty array of fixed length

Setting `length` to a value greater than the current length creates a sparse array.

```
const numbers = [];
numbers.length = 3;
console.log(numbers); // [empty x 3]
```

Array with non-writable length

The `length` property is automatically updated by the array when elements are added beyond the current length. If the `length` property is made non-writable, the array will not be able to update it. This causes an error in strict mode.

```
"use strict";

const numbers = [1, 2, 3, 4, 5];
Object.defineProperty(numbers, "length", { writable: false });
numbers[5] = 6; // TypeError: Cannot assign to read only property 'length' of object '[object Array]'
numbers.push(5); // // TypeError: Cannot assign to read only property 'length' of object '[object Array]'
```

See also

- Indexed collections guide
- `Array`
- `TypedArray.prototype.length`
- `String: length`
- RangeError: invalid array length

Array.prototype.map()

The **`map()`** method of `Array` instances creates a new array populated with the results of calling a provided function on every element in the calling array.

Try it

```
const array = [1, 4, 9, 16];

// Pass a function to map
const mapped = array.map((x) => x * 2);

console.log(mapped);
// Expected output: Array [2, 8, 18, 32]
```

Syntax

```
map(callbackFn)
map(callbackFn, thisArg)
```

Parameters

`callbackFn`

A function to execute for each element in the array. Its return value is added as a single element in the new array. The function is called with the following arguments:

`element`

The current element being processed in the array.

`index`

The index of the current element being processed in the array.

`array`

The array `map()` was called upon.

`thisArg` Optional

A value to use as `this` when executing `callbackFn`. See iterative methods.

Return value

A new array with each element being the result of the callback function.

Description

The `map()` method is an iterative method. It calls a provided `callbackFn` function once for each element in an array and constructs a new array from the results. Read the iterative methods section for more information about how these methods work in general.

`callbackFn` is invoked only for array indexes which have assigned values. It is not invoked for empty slots in sparse arrays.

The `map()` method is generic. It only expects the `this` value to have a `length` property and integer-keyed properties.

Since `map` builds a new array, calling it without using the returned array is an anti-pattern; use `forEach` or `for...of` instead.

Examples

Mapping an array of numbers to an array of square roots

The following code takes an array of numbers and creates a new array containing the square roots of the numbers in the first array.

```
const numbers = [1, 4, 9];
const roots = numbers.map((num) => Math.sqrt(num));

// roots is now     [1, 2, 3]
// numbers is still [1, 4, 9]
```

Using map to reformat objects in an array

The following code takes an array of objects and creates a new array containing the newly reformatted objects.

```
const kvArray = [
  { key: 1, value: 10 },
  { key: 2, value: 20 },
  { key: 3, value: 30 },
];

const reformattedArray = kvArray.map(({ key, value }) => ({ [key]: value }));

console.log(reformattedArray); // [{ 1: 10 }, { 2: 20 }, { 3: 30 }]
console.log(kvArray);
// [
//   { key: 1, value: 10 },
//   { key: 2, value: 20 },
```

```
//   { key: 3, value: 30 }
// ]
```

Using parseInt() with map()

It is common to use the callback with one argument (the element being traversed). Certain functions are also commonly used with one argument, even though they take additional optional arguments. These habits may lead to confusing behaviors. Consider:

```
["1", "2", "3"].map(parseInt);
```

While one might expect `[1, 2, 3]`, the actual result is `[1, NaN, NaN]`.

`parseInt` is often used with one argument, but takes two. The first is an expression and the second is the radix to the callback function, `Array.prototype.map` passes 3 arguments: the element, the index, and the array. The third argument is ignored by `parseInt` — but *not* the second one! This is the source of possible confusion.

Here is a concise example of the iteration steps:

```
/* first iteration  (index is 0): */ parseInt("1", 0); // 1
/* second iteration (index is 1): */ parseInt("2", 1); // NaN
/* third iteration  (index is 2): */ parseInt("3", 2); // NaN
```

To solve this, define another function that only takes one argument:

```
["1", "2", "3"].map((str) => parseInt(str, 10)); // [1, 2, 3]
```

You can also use the `Number` function, which only takes one argument:

```
["1", "2", "3"].map(Number); // [1, 2, 3]

// But unlike parseInt(), Number() will also return a float or (resolved) exponential notation:
["1.1", "2.2e2", "3e300"].map(Number); // [1.1, 220, 3e+300]

// For comparison, if we use parseInt() on the array above:
["1.1", "2.2e2", "3e300"].map((str) => parseInt(str, 10)); // [1, 2, 3]
```

See A JavaScript optional argument hazard by Allen Wirfs-Brock for more discussions.

Mapped array contains undefined

When `undefined` or nothing is returned, the resulting array contains `undefined`. If you want to delete the element instead, chain a `filter()` method, or use the `flatMap()` method and return an empty array to signify deletion.

```
const numbers = [1, 2, 3, 4];
const filteredNumbers = numbers.map((num, index) => {
  if (index < 3) {
    return num;
  }
});

// index goes from 0, so the filteredNumbers are 1,2,3 and undefined.
// filteredNumbers is [1, 2, 3, undefined]
// numbers is still [1, 2, 3, 4]
```

Side-effectful mapping

The callback can have side effects.

```
const cart = [5, 15, 25];
let total = 0;
const withTax = cart.map((cost) => {
  total += cost;
  return cost * 1.2;
});
console.log(withTax); // [6, 18, 30]
console.log(total); // 45
```

This is not recommended, because copying methods are best used with pure functions. In this case, we can choose to iterate the array twice.

```
const cart = [5, 15, 25];
const total = cart.reduce((acc, cost) => acc + cost, 0);
const withTax = cart.map((cost) => cost * 1.2);
```

Sometimes this pattern goes to its extreme and the *only* useful thing that `map()` does is causing side effects.

```
const products = [
  { name: "sports car" },
  { name: "laptop" },
  { name: "phone" },
];

products.map((product) => {
```

```
  product.price = 100;
});
```

As mentioned previously, this is an anti-pattern. If you don't use the return value of `map()`, use `forEach()` or a `for...of` loop instead.

```
products.forEach((product) => {
  product.price = 100;
});
```

Or, if you want to create a new array instead:

```
const productsWithPrice = products.map((product) => ({
  ...product,
  price: 100,
}));
```

Using the third argument of callbackFn

The `array` argument is useful if you want to access another element in the array, especially when you don't have an existing variable that refers to the array. The following example first uses `filter()` to extract the positive values and then uses `map()` to create a new array where each element is the average of its neighbors and itself.

```
const numbers = [3, -1, 1, 4, 1, 5, 9, 2, 6];
const averaged = numbers
  .filter((num) => num > 0)
  .map((num, idx, arr) => {
    // Without the arr argument, there's no way to easily access the
    // intermediate array without saving it to a variable.
    const prev = arr[idx - 1];
    const next = arr[idx + 1];
    let count = 1;
    let total = num;
    if (prev !== undefined) {
      count++;
      total += prev;
    }
    if (next !== undefined) {
      count++;
      total += next;
    }
    const average = total / count;
    // Keep two decimal places
    return Math.round(average * 100) / 100;
  });
console.log(averaged); // [2, 2.67, 2, 3.33, 5, 5.33, 5.67, 4]
```

The `array` argument is *not* the array that is being built — there is no way to access the array being built from the callback function.

Using map() on sparse arrays

A sparse array remains sparse after `map()`. The indices of empty slots are still empty in the returned array, and the callback function won't be called on them.

```
console.log(
  [1, , 3].map((x, index) => {
    console.log(`Visit ${index}`);
    return x * 2;
  }),
);
// Visit 0
// Visit 2
// [2, empty, 6]
```

Calling map() on non-array objects

The `map()` method reads the `length` property of `this` and then accesses each property whose key is a nonnegative integer less than `length`.

```
const arrayLike = {
  length: 3,
  0: 2,
  1: 3,
  2: 4,
  3: 5, // ignored by map() since length is 3
};
console.log(Array.prototype.map.call(arrayLike, (x) => x ** 2));
// [ 4, 9, 16 ]
```

This example shows how to iterate through a collection of objects collected by `querySelectorAll()`, returning an array containing the values of all the selected `option` elements. Because `querySelectorAll()` returns a `NodeList`, which is an array-like object without the `map()` method, we use `Array.prototype.map.call()`, passing `elems` as the `this` value and the callback as the second argument.

```
const elems = document.querySelectorAll("select option:checked");
const values = Array.prototype.map.call(elems, ({ value }) => value);
```

You can also use `Array.from()` to transform `elems` to an array, and then access the `map()` method.

Array.of()

The **`Array.of()`** static method creates a new `Array` instance from a variable number of arguments, regardless of number or type of the arguments.

Try it

```
console.log(Array.of("foo", 2, "bar", true));
// Expected output: Array ["foo", 2, "bar", true]

console.log(Array.of());
// Expected output: Array []
```

Syntax

```
Array.of()
Array.of(element1)
Array.of(element1, element2)
Array.of(element1, element2, /* …, */ elementN)
```

Parameters

`element1, ..., elementN`

Elements used to create the array.

Return value

A new `Array` instance.

Description

The difference between `Array.of()` and the `Array()` constructor is in the handling of single arguments: `Array.of(7)` creates an array with a single element, `7`, whereas `Array(7)` creates an empty array with a `length` property of `7`. (That implies an array of 7 empty slots, not slots with actual `undefined` values.)

```
Array.of(7); // [7]
Array(7); // array of 7 empty slots

Array.of(1, 2, 3); // [1, 2, 3]
Array(1, 2, 3); // [1, 2, 3]
```

The `Array.of()` method is a generic factory method. For example, if a subclass of `Array` inherits the `of()` method, the inherited `of()` method will return new instances of the subclass instead of `Array` instances. In fact, the `this` value can be any constructor function that accepts a single argument representing the length of the new array, and the constructor will be called with the number of arguments passed to `of()`. The final `length` will be set again when all elements are assigned. If the `this` value is not a constructor function, the plain `Array` constructor is used instead.

Examples

Using Array.of()

```
Array.of(1); // [1]
Array.of(1, 2, 3); // [1, 2, 3]
Array.of(undefined); // [undefined]
```

Calling of() on non-array constructors

The `of()` method can be called on any constructor function that accepts a single argument representing the length of the new array.

```
function NotArray(len) {
  console.log("NotArray called with length", len);
}

console.log(Array.of.call(NotArray, 1, 2, 3));
// NotArray called with length 3
// NotArray { '0': 1, '1': 2, '2': 3, length: 3 }

console.log(Array.of.call(Object)); // [Number: 0] { length: 0 }
```

When the `this` value is not a constructor, a plain `Array` object is returned.

```
console.log(Array.of.call({}, 1)); // [ 1 ]
```

Array.prototype.pop()

The **`pop()`** method of `Array` instances removes the **last** element from an array and returns that element. This method changes the length of the array.

Try it

```
const plants = ["broccoli", "cauliflower", "cabbage", "kale", "tomato"];

console.log(plants.pop());
// Expected output: "tomato"

console.log(plants);
// Expected output: Array ["broccoli", "cauliflower", "cabbage", "kale"]

plants.pop();

console.log(plants);
// Expected output: Array ["broccoli", "cauliflower", "cabbage"]
```

Syntax

```
pop()
```

Parameters

None.

Return value

The removed element from the array; `undefined` if the array is empty.

Description

The `pop()` method removes the last element from an array and returns that value to the caller. If you call `pop()` on an empty array, it returns `undefined`.

`Array.prototype.shift()` has similar behavior to `pop()`, but applied to the first element in an array.

The `pop()` method is a mutating method. It changes the length and the content of `this`. In case you want the value of `this` to be the same, but return a new array with the last element removed, you can use `arr.slice(0, -1)` instead.

The `pop()` method is generic. It only expects the `this` value to have a `length` property and integer-keyed properties. Although strings are also array-like, this method is not suitable to be applied on them, as strings are immutable.

Examples

Removing the last element of an array

The following code creates the `myFish` array containing four elements, then removes its last element.

```
const myFish = ["angel", "clown", "mandarin", "sturgeon"];

const popped = myFish.pop();

console.log(myFish); // ['angel', 'clown', 'mandarin' ]

console.log(popped); // 'sturgeon'
```

Calling pop() on non-array objects

The `pop()` method reads the `length` property of `this`. If the normalized length is 0, `length` is set to `0` again (whereas it may be negative or `undefined` before). Otherwise, the property at `length - 1` is returned and deleted.

```
const arrayLike = {
  length: 3,
  unrelated: "foo",
  2: 4,
};
console.log(Array.prototype.pop.call(arrayLike));
// 4
console.log(arrayLike);
```

```
// { length: 2, unrelated: 'foo' }

const plainObj = {};
// There's no length property, so the length is 0
Array.prototype.pop.call(plainObj);
console.log(plainObj);
// { length: 0 }
```

Using an object in an array-like fashion

`push` and `pop` are intentionally generic, and we can use that to our advantage — as the following example shows.

Note that in this example, we don't create an array to store a collection of objects. Instead, we store the collection on the object itself and use `call` on `Array.prototype.push` and `Array.prototype.pop` to trick those methods into thinking we're dealing with an array.

```
const collection = {
  length: 0,
  addElements(...elements) {
    // obj.length will be incremented automatically
    // every time an element is added.

    // Returning what push returns; that is
    // the new value of length property.
    return [].push.call(this, ...elements);
  },
  removeElement() {
    // obj.length will be decremented automatically
    // every time an element is removed.

    // Returning what pop returns; that is
    // the removed element.
    return [].pop.call(this);
  },
};

collection.addElements(10, 20, 30);
console.log(collection.length); // 3
collection.removeElement();
console.log(collection.length); // 2
```

- `Array`
- `Array.prototype.push()`
- `Array.prototype.shift()`
- `Array.prototype.unshift()`
- `Array.prototype.concat()`
- `Array.prototype.splice()`

Array.prototype.push()

The **`push()`** method of `Array` instances adds the specified elements to the end of an array and returns the new length of the array.

Try it

```
const animals = ["pigs", "goats", "sheep"];

const count = animals.push("cows");
console.log(count);
// Expected output: 4
console.log(animals);
// Expected output: Array ["pigs", "goats", "sheep", "cows"]

animals.push("chickens", "cats", "dogs");
console.log(animals);
// Expected output: Array ["pigs", "goats", "sheep", "cows", "chickens", "cats", "dogs"]
```

Syntax

```
push()
push(element1)
push(element1, element2)
push(element1, element2, /* …, */ elementN)
```

Parameters

`element1, ..., elementN`

The element(s) to add to the end of the array.

Return value

The new `length` property of the object upon which the method was called.

Description

The `push()` method appends values to an array.

`Array.prototype.unshift()` has similar behavior to `push()`, but applied to the start of an array.

The `push()` method is a mutating method. It changes the length and the content of `this`. In case you want the value of `this` to be the same, but return a new array with elements appended to the end, you can use `arr.concat([element0, element1, /* ... ,*/ elementN])` instead. Notice that the elements are wrapped in an extra array — otherwise, if the element is an array itself, it would be spread instead of pushed as a single element due to the behavior of `concat()`.

The `push()` method is generic. It only expects the `this` value to have a `length` property and integer-keyed properties. Although strings are also array-like, this method is not suitable to be applied on them, as strings are immutable.

Examples

Adding elements to an array

The following code creates the `sports` array containing two elements, then appends two elements to it. The `total` variable contains the new length of the array.

```
const sports = ["soccer", "baseball"];
const total = sports.push("football", "swimming");

console.log(sports); // ['soccer', 'baseball', 'football', 'swimming']
console.log(total); // 4
```

Merging two arrays

This example uses spread syntax to push all elements from a second array into the first one.

```
const vegetables = ["parsnip", "potato"];
const moreVegs = ["celery", "beetroot"];

// Merge the second array into the first one
vegetables.push(...moreVegs);

console.log(vegetables); // ['parsnip', 'potato', 'celery', 'beetroot']
```

Merging two arrays can also be done with the `concat()` method, which will make a new combined array instead of adding to the original. The spread syntax only works if the number of elements in the array is less than the maximum number of function arguments allowed by the engine. For longer arrays, use `concat()` or call `push()` multiple times in a loop.

Calling push() on non-array objects

The `push()` method reads the `length` property of `this`. It then sets each index of `this` starting at `length` with the arguments passed to `push()`. Finally, it sets the `length` to the previous length plus the number of pushed elements.

```
const arrayLike = {
  length: 3,
  unrelated: "foo",
  2: 4,
};
Array.prototype.push.call(arrayLike, 1, 2);
console.log(arrayLike);
// { '2': 4, '3': 1, '4': 2, length: 5, unrelated: 'foo' }

const plainObj = {};
// There's no length property, so the length is 0
Array.prototype.push.call(plainObj, 1, 2);
console.log(plainObj);
// { '0': 1, '1': 2, length: 2 }
```

Using an object in an array-like fashion

As mentioned above, `push` is intentionally generic, and we can use that to our advantage. `Array.prototype.push` can work on an object just fine, as this example shows.

Note that we don't create an array to store a collection of objects. Instead, we store the collection on the object itself and use `call` on `Array.prototype.push` to trick the method into thinking we are dealing with an array—and it just works, thanks to the way JavaScript allows us to establish the execution context in any way we want.

```
const obj = {
  length: 0,

  addElem(elem) {
    // obj.length is automatically incremented
    // every time an element is added.
    [].push.call(this, elem);
  },
};

// Let's add some empty objects just to illustrate.
obj.addElem({});
```

```
obj.addElem({});
console.log(obj.length); // 2
```

Note that although `obj` is not an array, the method `push` successfully incremented `obj`'s `length` property just like if we were dealing with an actual array.

Array.prototype.reduce()

The **`reduce()`** method of `Array` instances executes a user-supplied "reducer" callback function on each element of the array, in order, passing in the return value from the calculation on the preceding element. The final result of running the reducer across all elements of the array is a single value.

The first time that the callback is run there is no "return value of the previous calculation". If supplied, an initial value may be used in its place. Otherwise the array element at index 0 is used as the initial value and iteration starts from the next element (index 1 instead of index 0).

Try it

```
const array = [1, 2, 3, 4];

// 0 + 1 + 2 + 3 + 4
const initialValue = 0;
const sumWithInitial = array.reduce(
  (accumulator, currentValue) => accumulator + currentValue,
  initialValue,
);

console.log(sumWithInitial);
// Expected output: 10
```

Syntax

```
reduce(callbackFn)
reduce(callbackFn, initialValue)
```

Parameters

`callbackFn`

A function to execute for each element in the array. Its return value becomes the value of the `accumulator` parameter on the next invocation of `callbackFn`. For the last invocation, the return value becomes the return value of `reduce()`. The function is called with the following arguments:

`accumulator`

The value resulting from the previous call to `callbackFn`. On the first call, its value is `initialValue` if the latter is specified; otherwise its value is `array[0]`.

`currentValue`

The value of the current element. On the first call, its value is `array[0]` if `initialValue` is specified; otherwise its value is `array[1]`.

`currentIndex`

The index position of `currentValue` in the array. On the first call, its value is `0` if `initialValue` is specified, otherwise `1`.

`array`

The array `reduce()` was called upon.

`initialValue` Optional

A value to which `accumulator` is initialized the first time the callback is called. If `initialValue` is specified, `callbackFn` starts executing with the first value in the array as `currentValue`. If `initialValue` is *not* specified, `accumulator` is initialized to the first value in the array, and `callbackFn` starts executing with the second value in the array as `currentValue`. In this case, if the array is empty (so that there's no first value to return as `accumulator`), an error is thrown.

Return value

The value that results from running the "reducer" callback function to completion over the entire array.

Exceptions

`TypeError`

Thrown if the array contains no elements and `initialValue` is not provided.

Description

The `reduce()` method is an iterative method. It runs a "reducer" callback function over all elements in the array, in ascending-index order, and accumulates them into a single value. Every time, the return value of `callbackFn` is passed into `callbackFn` again on next invocation as `accumulator`. The final value of `accumulator` (which is the value returned from `callbackFn` on the final iteration of the array) becomes the return value of `reduce()`. Read the iterative methods section for more information about how these methods work in general.

`callbackFn` is invoked only for array indexes which have assigned values. It is not invoked for empty slots in sparse arrays.

Unlike other iterative methods, `reduce()` does not accept a `thisArg` argument. `callbackFn` is always called with `undefined` as `this`, which gets substituted with `globalThis` if `callbackFn` is non-strict.

`reduce()` is a central concept in functional programming, where it's not possible to mutate any value, so in order to accumulate all values in an array, one must return a new accumulator value on every iteration. This convention propagates to JavaScript's `reduce()`: you should use spreading or other copying methods where possible to create new arrays and objects as the accumulator, rather than mutating the existing one. If you decided to mutate the accumulator instead of copying it, remember to still return the modified object in the callback, or the next iteration will receive undefined. However, note that copying the accumulator may in turn lead to increased memory usage and degraded performance — see When to not use reduce() for more details. In such cases, to avoid bad performance and unreadable code, it's better to use a `for` loop instead.

The `reduce()` method is generic. It only expects the `this` value to have a `length` property and integer-keyed properties.

Edge cases

If the array only has one element (regardless of position) and no `initialValue` is provided, or if `initialValue` is provided but the array is empty, the solo value will be returned *without* calling `callbackFn`.

If `initialValue` is provided and the array is not empty, then the reduce method will always invoke the callback function starting at index 0.

If `initialValue` is not provided then the reduce method will act differently for arrays with length larger than 1, equal to 1 and 0, as shown in the following example:

```
const getMax = (a, b) => Math.max(a, b);

// callback is invoked for each element in the array starting at index 0
[1, 100].reduce(getMax, 50); // 100
[50].reduce(getMax, 10); // 50

// callback is invoked once for element at index 1
[1, 100].reduce(getMax); // 100

// callback is not invoked
[50].reduce(getMax); // 50
[].reduce(getMax, 1); // 1

[].reduce(getMax); // TypeError
```

Examples

How reduce() works without an initial value

The code below shows what happens if we call `reduce()` with an array and no initial value.

```
const array = [15, 16, 17, 18, 19];

function reducer(accumulator, currentValue, index) {
  const returns = accumulator + currentValue;
  console.log(
    `accumulator: ${accumulator}, currentValue: ${currentValue}, index: ${index}, returns: ${returns}`,
  );
  return returns;
}

array.reduce(reducer);
```

The callback would be invoked four times, with the arguments and return values in each call being as follows:

	`accumulator`	`currentValue`	`index`	**Return value**
First call	15	16	1	31
Second call	31	17	2	48
Third call	48	18	3	66
Fourth call	66	19	4	85

The `array` parameter never changes through the process — it's always `[15, 16, 17, 18, 19]`. The value returned by `reduce()` would be that of the last callback invocation (`85`).

How reduce() works with an initial value

Here we reduce the same array using the same algorithm, but with an `initialValue` of `10` passed as the second argument to `reduce()`:

```
[15, 16, 17, 18, 19].reduce(
  (accumulator, currentValue) => accumulator + currentValue,
```

```
  10,
);
```

The callback would be invoked five times, with the arguments and return values in each call being as follows:

	`accumulator`	`currentValue`	`index`	**Return value**
First call	`10`	`15`	`0`	`25`
Second call	`25`	`16`	`1`	`41`
Third call	`41`	`17`	`2`	`58`
Fourth call	`58`	`18`	`3`	`76`
Fifth call	`76`	`19`	`4`	`95`

The value returned by `reduce()` in this case would be `95`.

Sum of values in an object array

To sum up the values contained in an array of objects, you **must** supply an `initialValue`, so that each item passes through your function.

```
const objects = [{ x: 1 }, { x: 2 }, { x: 3 }];
const sum = objects.reduce(
  (accumulator, currentValue) => accumulator + currentValue.x,
  0,
);

console.log(sum); // 6
```

Function sequential piping

The `pipe` function takes a sequence of functions and returns a new function. When the new function is called with an argument, the sequence of functions are called in order, which each one receiving the return value of the previous function.

```
const pipe =
  (...functions) =>
  (initialValue) =>
    functions.reduce((acc, fn) => fn(acc), initialValue);

// Building blocks to use for composition
const double = (x) => 2 * x;
const triple = (x) => 3 * x;
const quadruple = (x) => 4 * x;

// Composed functions for multiplication of specific values
const multiply6 = pipe(double, triple);
const multiply9 = pipe(triple, triple);
const multiply16 = pipe(quadruple, quadruple);
const multiply24 = pipe(double, triple, quadruple);

// Usage
multiply6(6); // 36
multiply9(9); // 81
multiply16(16); // 256
multiply24(10); // 240
```

Running promises in sequence

Promise sequencing is essentially function piping demonstrated in the previous section, except done asynchronously.

```
// Compare this with pipe: fn(acc) is changed to acc.then(fn),
// and initialValue is ensured to be a promise
const asyncPipe =
  (...functions) =>
  (initialValue) =>
    functions.reduce((acc, fn) => acc.then(fn), Promise.resolve(initialValue));

// Building blocks to use for composition
const p1 = async (a) => a * 5;
const p2 = async (a) => a * 2;
// The composed functions can also return non-promises, because the values are
// all eventually wrapped in promises
const f3 = (a) => a * 3;
const p4 = async (a) => a * 4;

asyncPipe(p1, p2, f3, p4)(10).then(console.log); // 1200
```

`asyncPipe` can also be implemented using `async`/`await`, which better demonstrates its similarity with `pipe`:

```
const asyncPipe =
  (...functions) =>
  (initialValue) =>
    functions.reduce(async (acc, fn) => fn(await acc), initialValue);
```

Using reduce() with sparse arrays

`reduce()` skips missing elements in sparse arrays, but it does not skip `undefined` values.

```
console.log([1, 2, , 4].reduce((a, b) => a + b)); // 7
console.log([1, 2, undefined, 4].reduce((a, b) => a + b)); // NaN
```

Calling reduce() on non-array objects

The `reduce()` method reads the `length` property of `this` and then accesses each property whose key is a nonnegative integer less than `length`.

```
const arrayLike = {
  length: 3,
  0: 2,
  1: 3,
  2: 4,
  3: 99, // ignored by reduce() since length is 3
};
console.log(Array.prototype.reduce.call(arrayLike, (x, y) => x + y));
// 9
```

When to not use reduce()

Multipurpose higher-order functions like `reduce()` can be powerful but sometimes difficult to understand, especially for less-experienced JavaScript developers. If code becomes clearer when using other array methods, developers must weigh the readability tradeoff against the other benefits of using `reduce()`.

Note that `reduce()` is always equivalent to a `for...of` loop, except that instead of mutating a variable in the upper scope, we now return the new value for each iteration:

```
const val = array.reduce((acc, cur) => update(acc, cur), initialValue);

// Is equivalent to:
let val = initialValue;
for (const cur of array) {
  val = update(val, cur);
}
```

As previously stated, the reason why people may want to use `reduce()` is to mimic functional programming practices of immutable data. Therefore, developers who uphold the immutability of the accumulator often copy the entire accumulator for each iteration, like this:

```
const names = ["Alice", "Bob", "Tiff", "Bruce", "Alice"];
const countedNames = names.reduce((allNames, name) => {
  const currCount = Object.hasOwn(allNames, name) ? allNames[name] : 0;
  return {
    ...allNames,
    [name]: currCount + 1,
  };
}, {});
```

This code is ill-performing, because each iteration has to copy the entire `allNames` object, which could be big, depending how many unique names there are. This code has worst-case `O(N^2)` performance, where `N` is the length of `names`.

A better alternative is to *mutate* the `allNames` object on each iteration. However, if `allNames` gets mutated anyway, you may want to convert the `reduce()` to a `for` loop instead, which is much clearer:

```
const names = ["Alice", "Bob", "Tiff", "Bruce", "Alice"];
const countedNames = names.reduce((allNames, name) => {
  const currCount = allNames[name] ?? 0;
  allNames[name] = currCount + 1;
  // return allNames, otherwise the next iteration receives undefined
  return allNames;
}, Object.create(null));
```

```
const names = ["Alice", "Bob", "Tiff", "Bruce", "Alice"];
const countedNames = Object.create(null);
for (const name of names) {
  const currCount = countedNames[name] ?? 0;
  countedNames[name] = currCount + 1;
}
```

Therefore, if your accumulator is an array or an object and you are copying the array or object on each iteration, you may accidentally introduce quadratic complexity into your code, causing performance to quickly degrade on large data. This has happened in real-world code — see for example Making Tanstack Table 1000x faster with a 1 line change.

Some of the acceptable use cases of `reduce()` are given above (most notably, summing an array, promise sequencing, and function piping). There are other cases where better alternatives than `reduce()` exist.

- Flattening an array of arrays. Use `flat()` instead.

  ```
  const flattened = array.reduce((acc, cur) => acc.concat(cur), []);
  ```

```
const flattened = array.flat();
```

- Grouping objects by a property. Use `Object.groupBy()` instead.

```
const groups = array.reduce((acc, obj) => {
  const key = obj.name;
  const curGroup = acc[key] ?? [];
  return { ...acc, [key]: [...curGroup, obj] };
}, {});
```

```
const groups = Object.groupBy(array, (obj) => obj.name);
```

- Concatenating arrays contained in an array of objects. Use `flatMap()` instead.

```
const friends = [
  { name: "Anna", books: ["Bible", "Harry Potter"] },
  { name: "Bob", books: ["War and peace", "Romeo and Juliet"] },
  { name: "Alice", books: ["The Lord of the Rings", "The Shining"] },
];
const allBooks = friends.reduce((acc, cur) => [...acc, ...cur.books], []);
```

```
const allBooks = friends.flatMap((person) => person.books);
```

- Removing duplicate items in an array. Use `Set` and `Array.from()` instead.

```
const uniqArray = array.reduce(
  (acc, cur) => (acc.includes(cur) ? acc : [...acc, cur]),
  [],
);
```

```
const uniqArray = Array.from(new Set(array));
```

- Eliminating or adding elements in an array. Use `flatMap()` instead.

```
// Takes an array of numbers and splits perfect squares into its square roots
const roots = array.reduce((acc, cur) => {
  if (cur < 0) return acc;
  const root = Math.sqrt(cur);
  if (Number.isInteger(root)) return [...acc, root, root];
  return [...acc, cur];
}, []);
```

```
const roots = array.flatMap((val) => {
  if (val < 0) return [];
  const root = Math.sqrt(val);
  if (Number.isInteger(root)) return [root, root];
  return [val];
});
```

  If you are only eliminating elements from an array, you also can use `filter()`.

- Searching for elements or testing if elements satisfy a condition. Use `find()` and `findIndex()`, or `some()` and `every()` instead. These methods have the additional benefit that they return as soon as the result is certain, without iterating the entire array.

```
const allEven = array.reduce((acc, cur) => acc && cur % 2 === 0, true);
```

```
const allEven = array.every((val) => val % 2 === 0);
```

In cases where `reduce()` is the best choice, documentation and semantic variable naming can help mitigate readability drawbacks.

Array.prototype.reduceRight()

The **`reduceRight()`** method of `Array` instances applies a function against an accumulator and each value of the array (from right-to-left) to reduce it to a single value.

See also `Array.prototype.reduce()` for left-to-right.

Try it

```
const array = [
  [0, 1],
  [2, 3],
  [4, 5],
];

const result = array.reduceRight((accumulator, currentValue) =>
  accumulator.concat(currentValue),
);

console.log(result);
// Expected output: Array [4, 5, 2, 3, 0, 1]
```

Syntax

```
reduceRight(callbackFn)
reduceRight(callbackFn, initialValue)
```

Parameters

`callbackFn`

A function to execute for each element in the array. Its return value becomes the value of the `accumulator` parameter on the next invocation of `callbackFn`. For the last invocation, the return value becomes the return value of `reduceRight()`. The function is called with the following arguments:

`accumulator`

The value resulting from the previous call to `callbackFn`. On the first call, its value is `initialValue` if the latter is specified; otherwise its value is the last element of the array.

`currentValue`

The value of the current element. On the first call, its value is the last element if `initialValue` is specified; otherwise its value is the second-to-last element.

`currentIndex`

The index position of `currentValue` in the array. On the first call, its value is `array.length - 1` if `initialValue` is specified, otherwise `array.length - 2`.

`array`

The array `reduceRight()` was called upon.

`initialValue` Optional

Value to use as accumulator to the first call of the `callbackFn`. If no initial value is supplied, the last element in the array will be used and skipped. Calling `reduceRight()` on an empty array without an initial value creates a `TypeError`.

Return value

The value that results from the reduction.

Description

The `reduceRight()` method is an iterative method. It runs a "reducer" callback function over all elements in the array, in descending-index order, and accumulates them into a single value. Read the iterative methods section for more information about how these methods work in general.

`callbackFn` is invoked only for array indexes which have assigned values. It is not invoked for empty slots in sparse arrays.

Unlike other iterative methods, `reduceRight()` does not accept a `thisArg` argument. `callbackFn` is always called with `undefined` as `this`, which gets substituted with `globalThis` if `callbackFn` is non-strict.

The `reduceRight()` method is generic. It only expects the `this` value to have a `length` property and integer-keyed properties.

All caveats about `reduce` discussed in when to not use reduce() apply to `reduceRight` as well. Because JavaScript has no lazy evaluation semantics, there is no performance difference between `reduce` and `reduceRight`.

Examples

How reduceRight() works without an initial value

The call to the reduceRight `callbackFn` would look something like this:

```
arr.reduceRight((accumulator, currentValue, index, array) => {
  // …
});
```

The first time the function is called, the `accumulator` and `currentValue` can be one of two values. If an `initialValue` was provided in the call to `reduceRight`, then `accumulator` will be equal to `initialValue` and `currentValue` will be equal to the last value in the array. If no `initialValue` was provided, then `accumulator` will be equal to the last value in the array and `currentValue` will be equal to the second-to-last value.

If the array is empty and no `initialValue` was provided, `TypeError` would be thrown. If the array has only one element (regardless of position) and no `initialValue` was provided, or if `initialValue` is provided but the array is empty, the solo value would be returned without calling `callbackFn`.

Some example run-throughs of the function would look like this:

```
[0, 1, 2, 3, 4].reduceRight(
  (accumulator, currentValue, index, array) => accumulator + currentValue,
);
```

The callback would be invoked four times, with the arguments and return values in each call being as follows:

	`accumulator`	`currentValue`	`index`	**Return value**
First call	`4`	`3`	`3`	`7`
Second call	`7`	`2`	`2`	`9`
Third call	`9`	`1`	`1`	`10`
Fourth call	`10`	`0`	`0`	`10`

The `array` parameter never changes through the process — it's always `[0, 1, 2, 3, 4]`. The value returned by `reduceRight` would be that of the last callback invocation (`10`).

How reduceRight() works with an initial value

Here we reduce the same array using the same algorithm, but with an `initialValue` of `10` passed as the second argument to `reduceRight()`:

```
[0, 1, 2, 3, 4].reduceRight(
  (accumulator, currentValue, index, array) => accumulator + currentValue,
  10,
);
```

	`accumulator`	`currentValue`	`index`	**Return value**
First call	`10`	`4`	`4`	`14`
Second call	`14`	`3`	`3`	`17`
Third call	`17`	`2`	`2`	`19`
Fourth call	`19`	`1`	`1`	`20`
Fifth call	`20`	`0`	`0`	`20`

The value returned by `reduceRight` this time would be, of course, `20`.

Sum up all values within an array

```
const sum = [0, 1, 2, 3].reduceRight((a, b) => a + b);
// sum is 6
```

Run a list of asynchronous functions with callbacks in series each passing their results to the next

```
const waterfall =
  (...functions) =>
  (callback, ...args) =>
    functions.reduceRight(
      (composition, fn) =>
        (...results) =>
          fn(composition, ...results),
      callback,
    )(...args);

const randInt = (max) => Math.floor(Math.random() * max);

const add5 = (callback, x) => {
  setTimeout(callback, randInt(1000), x + 5);
};
const mul3 = (callback, x) => {
  setTimeout(callback, randInt(1000), x * 3);
};
const sub2 = (callback, x) => {
  setTimeout(callback, randInt(1000), x - 2);
};
const split = (callback, x) => {
  setTimeout(callback, randInt(1000), x, x);
};
const add = (callback, x, y) => {
  setTimeout(callback, randInt(1000), x + y);
};
const div4 = (callback, x) => {
  setTimeout(callback, randInt(1000), x / 4);
};

const computation = waterfall(add5, mul3, sub2, split, add, div4);
computation(console.log, 5); // Logs 14
```

```
// same as:

const computation2 = (input, callback) => {
  const f6 = (x) => div4(callback, x);
  const f5 = (x, y) => add(f6, x, y);
  const f4 = (x) => split(f5, x);
  const f3 = (x) => sub2(f4, x);
  const f2 = (x) => mul3(f3, x);
  add5(f2, input);
};
```

Difference between reduce and reduceRight

```
const a = ["1", "2", "3", "4", "5"];
const left = a.reduce((prev, cur) => prev + cur);
const right = a.reduceRight((prev, cur) => prev + cur);

console.log(left); // "12345"
console.log(right); // "54321"
```

Defining composable functions

Function composition is a mechanism for combining functions, in which the output of each function is passed into the next one, and the output of the last function is the final result. In this example we use `reduceRight()` to implement function composition.

See also Function composition on Wikipedia.

```
const compose =
  (...args) =>
  (value) =>
    args.reduceRight((acc, fn) => fn(acc), value);

// Increment passed number
const inc = (n) => n + 1;

// Doubles the passed value
const double = (n) => n * 2;

// using composition function
console.log(compose(double, inc)(2)); // 6

// using composition function
console.log(compose(inc, double)(2)); // 5
```

Using reduceRight() with sparse arrays

`reduceRight()` skips missing elements in sparse arrays, but it does not skip `undefined` values.

```
console.log([1, 2, , 4].reduceRight((a, b) => a + b)); // 7
console.log([1, 2, undefined, 4].reduceRight((a, b) => a + b)); // NaN
```

Calling reduceRight() on non-array objects

The `reduceRight()` method reads the `length` property of `this` and then accesses each property whose key is a nonnegative integer less than `length`.

```
const arrayLike = {
  length: 3,
  0: 2,
  1: 3,
  2: 4,
  3: 99, // ignored by reduceRight() since length is 3
};
console.log(Array.prototype.reduceRight.call(arrayLike, (x, y) => x - y));
// -1, which is 4 - 3 - 2
```

Array.prototype.reverse()

The **`reverse()`** method of `Array` instances reverses an array *in place* and returns the reference to the same array, the first array element now becoming the last, and the last array element becoming the first. In other words, elements order in the array will be turned towards the direction opposite to that previously stated.

To reverse the elements in an array without mutating the original array, use `toReversed()`.

Try it

```
const array = ["one", "two", "three"];
console.log("array:", array);
// Expected output: "array:" Array ["one", "two", "three"]

const reversed = array.reverse();
console.log("reversed:", reversed);
// Expected output: "reversed:" Array ["three", "two", "one"]

// Careful: reverse is destructive -- it changes the original array.
console.log("array:", array);
// Expected output: "array:" Array ["three", "two", "one"]
```

Syntax

```
reverse()
```

Parameters

None.

Return value

The reference to the original array, now reversed. Note that the array is reversed *in place*, and no copy is made.

Description

The `reverse()` method transposes the elements of the calling array object in place, mutating the array, and returning a reference to the array.

The `reverse()` method preserves empty slots. If the source array is sparse, the empty slots' corresponding new indices are deleted and also become empty slots.

The `reverse()` method is generic. It only expects the `this` value to have a `length` property and integer-keyed properties. Although strings are also array-like, this method is not suitable to be applied on them, as strings are immutable.

Examples

Reversing the elements in an array

The following example creates an array `items`, containing three elements, then reverses the array. The call to `reverse()` returns a reference to the reversed array `items`.

```
const items = [1, 2, 3];
console.log(items); // [1, 2, 3]

items.reverse();
console.log(items); // [3, 2, 1]
```

The reverse() method returns the reference to the same array

The `reverse()` method returns reference to the original array, so mutating the returned array will mutate the original array as well.

```
const numbers = [3, 2, 4, 1, 5];
const reversed = numbers.reverse();
// numbers and reversed are both in reversed order [5, 1, 4, 2, 3]
reversed[0] = 5;
console.log(numbers[0]); // 5
```

In case you want `reverse()` to not mutate the original array, but return a shallow-copied array like other array methods (e.g., `map()`) do, use the `toReversed()` method. Alternatively, you can do a shallow copy before calling `reverse()`, using the spread syntax or `Array.from()`.

```
const numbers = [3, 2, 4, 1, 5];
// [...numbers] creates a shallow copy, so reverse() does not mutate the original
const reverted = [...numbers].reverse();
reverted[0] = 5;
console.log(numbers[0]); // 3
```

Using reverse() on sparse arrays

Sparse arrays remain sparse after calling `reverse()`. Empty slots are copied over to their respective new indices as empty slots.

```
console.log([1, , 3].reverse()); // [3, empty, 1]
console.log([1, , 3, 4].reverse()); // [4, 3, empty, 1]
```

Calling reverse() on non-array objects

The `reverse()` method reads the `length` property of `this`. It then visits each property having an integer key between `0` and `length / 2`, and swaps the two corresponding indices on both ends, deleting any destination property for which the source property did not exist.

```
const arrayLike = {
  length: 3,
  unrelated: "foo",
  2: 4,
  3: 33, // ignored by reverse() since length is 3
};
console.log(Array.prototype.reverse.call(arrayLike));
// { 0: 4, 3: 33, length: 3, unrelated: 'foo' }
// The index 2 is deleted because there was no index 0 present originally
// The index 3 is unchanged since the length is 3
```

Array.prototype.shift()

The **`shift()`** method of `Array` instances removes the **first** element from an array and returns that removed element. This method changes the length of the array.

Try it

```
const array = [1, 2, 3];

const firstElement = array.shift();

console.log(array);
// Expected output: Array [2, 3]

console.log(firstElement);
// Expected output: 1
```

Syntax

```
shift()
```

Parameters

None.

Return value

The removed element from the array; `undefined` if the array is empty.

Description

The `shift()` method shifts all values to the left by 1 and decrements the length by 1, resulting in the first element being removed. If the `length` property is 0, `undefined` is returned.

The `pop()` method has similar behavior to `shift()`, but applied to the last element in an array.

The `shift()` method is a mutating method. It changes the length and the content of `this`. In case you want the value of `this` to be the same, but return a new array with the first element removed, you can use `arr.slice(1)` instead.

The `shift()` method is generic. It only expects the `this` value to have a `length` property and integer-keyed properties. Although strings are also array-like, this method is not suitable to be applied on them, as strings are immutable.

Examples

Removing an element from an array

The following code displays the `myFish` array before and after removing its first element. It also displays the removed element:

```
const myFish = ["angel", "clown", "mandarin", "surgeon"];

console.log("myFish before:", myFish);
// myFish before: ['angel', 'clown', 'mandarin', 'surgeon']

const shifted = myFish.shift();

console.log("myFish after:", myFish);
// myFish after: ['clown', 'mandarin', 'surgeon']

console.log("Removed this element:", shifted);
// Removed this element: angel
```

Using shift() method in while loop

The shift() method is often used in condition inside while loop. In the following example every iteration will remove the next element from an array, until it is empty:

```
const names = ["Andrew", "Tyrone", "Paul", "Maria", "Gayatri"];

while (typeof (i = names.shift()) !== "undefined") {
  console.log(i);
}
// Andrew, Tyrone, Paul, Maria, Gayatri
```

Calling shift() on non-array objects

The `shift()` method reads the `length` property of `this`. If the normalized length is 0, `length` is set to `0` again (whereas it may be negative or `undefined` before). Otherwise, the property at `0` is returned, and the rest of the properties are shifted left by one. The property at `length - 1` is deleted, and the `length` property is decremented by one.

```
const arrayLike = {
  length: 3,
  unrelated: "foo",
  2: 4,
};
console.log(Array.prototype.shift.call(arrayLike));
// undefined, because it is an empty slot
console.log(arrayLike);
// { '1': 4, length: 2, unrelated: 'foo' }

const plainObj = {};
// There's no length property, so the length is 0
Array.prototype.shift.call(plainObj);
console.log(plainObj);
// { length: 0 }
```

See also

- Indexed collections guide
- `Array`
- `Array.prototype.push()`
- `Array.prototype.pop()`
- `Array.prototype.unshift()`
- `Array.prototype.concat()`
- `Array.prototype.splice()`

Array.prototype.slice()

The **`slice()`** method of `Array` instances returns a shallow copy of a portion of an array into a new array object selected from `start` to `end` (`end` not included) where `start` and `end` represent the index of items in that array. The original array will not be modified.

Try it

```
const animals = ["ant", "bison", "camel", "duck", "elephant"];

console.log(animals.slice(2));
// Expected output: Array ["camel", "duck", "elephant"]

console.log(animals.slice(2, 4));
// Expected output: Array ["camel", "duck"]

console.log(animals.slice(1, 5));
// Expected output: Array ["bison", "camel", "duck", "elephant"]

console.log(animals.slice(-2));
// Expected output: Array ["duck", "elephant"]

console.log(animals.slice(2, -1));
// Expected output: Array ["camel", "duck"]

console.log(animals.slice());
// Expected output: Array ["ant", "bison", "camel", "duck", "elephant"]
```

Syntax

```
slice()
slice(start)
slice(start, end)
```

Parameters

`start` Optional

Zero-based index at which to start extraction, converted to an integer.

- Negative index counts back from the end of the array — if `-array.length <= start < 0`, `start + array.length` is used.
- If `start < -array.length` or `start` is omitted, `0` is used.
- If `start >= array.length`, an empty array is returned.

`end` Optional

Zero-based index at which to end extraction, converted to an integer. `slice()` extracts up to but not including `end`.

- Negative index counts back from the end of the array — if `-array.length <= end < 0`, `end + array.length` is used.
- If `end < -array.length`, `0` is used.
- If `end >= array.length` or `end` is omitted or `undefined`, `array.length` is used, causing all elements until the end to be extracted.
- If `end` implies a position before or at the position that `start` implies, an empty array is returned.

Return value

A new array containing the extracted elements.

Description

The `slice()` method is a copying method. It does not alter `this` but instead returns a shallow copy that contains some of the same elements as the ones from the original array.

The `slice()` method preserves empty slots. If the sliced portion is sparse, the returned array is sparse as well.

The `slice()` method is generic. It only expects the `this` value to have a `length` property and integer-keyed properties.

Examples

Return a portion of an existing array

```
const fruits = ["Banana", "Orange", "Lemon", "Apple", "Mango"];
const citrus = fruits.slice(1, 3);

// fruits contains ['Banana', 'Orange', 'Lemon', 'Apple', 'Mango']
// citrus contains ['Orange','Lemon']
```

In this example, `slice(1, 3)` extracts elements from index `1` up to, but not including, index `3`, resulting in a new array `['Orange', 'Lemon']`.

Omitting the end parameter

```
const fruits = ["Apple", "Banana", "Orange", "Mango", "Pineapple"];

const tropical = fruits.slice(2);
console.log(tropical); // ['Orange', 'Mango', 'Pineapple']
```

In this example, `slice(2)` extracts elements from index `2` to the end of the array.

Using negative indices

```
const fruits = ["Apple", "Banana", "Orange", "Mango", "Pineapple"];

const lastTwo = fruits.slice(-2);
console.log(lastTwo); // ['Mango', 'Pineapple']
```

In this example, `slice(-2)` extracts the last two elements of the array. When using a negative index with the `slice` method, negative indices are counted from the end of the array, starting at `-1` for the last element, `-2` for the second-to-last element, and so on. The negative index `-2` itself is included because it is the starting point of the extraction.

```
|     |     |     |     |     |
|  S  |  L  |  I  |  C  |  E  |
|     |     |     |     |     |
  -5    -4    -3    -2    -1

<--- read from reverse
```

Using a positive start index and a negative end index

```
const fruits = ["Apple", "Banana", "Orange", "Mango", "Pineapple"];

// Using positive start index and negative end index
const sliceExample = fruits.slice(1, -1);
console.log(sliceExample); // ['Banana', 'Orange', 'Mango']
```

In this example, `slice(1, -1)` starts extracting from index `1` and goes up to, but does not include, the element at index `-1` (which is the last element). This results in a new array with `['Banana', 'Orange', 'Mango']`. The `slice` method always excludes the element at the final index specified, regardless of whether it is positive or negative.

```
read from start --->

   0     1     2     3     4
|     |     |     |     |     |
|  S  |  L  |  I  |  C  |  E  |
```

```
|    |    |    |    |    |
  -5   -4   -3   -2   -1

<--- read from reverse
```

Using slice with arrays of objects

In the following example, `slice` creates a new array, `newCar`, from `myCar`. Both include a reference to the object `myHonda`. When the color of `myHonda` is changed to purple, both arrays reflect the change.

```
// Using slice, create newCar from myCar.
const myHonda = {
  color: "red",
  wheels: 4,
  engine: { cylinders: 4, size: 2.2 },
};
const myCar = [myHonda, 2, "cherry condition", "purchased 1997"];
const newCar = myCar.slice(0, 2);

console.log("myCar =", myCar);
console.log("newCar =", newCar);
console.log("myCar[0].color =", myCar[0].color);
console.log("newCar[0].color =", newCar[0].color);

// Change the color of myHonda.
myHonda.color = "purple";
console.log("The new color of my Honda is", myHonda.color);

console.log("myCar[0].color =", myCar[0].color);
console.log("newCar[0].color =", newCar[0].color);
```

This script writes:

```
myCar = [
  { color: 'red', wheels: 4, engine: { cylinders: 4, size: 2.2 } },
  2,
  'cherry condition',
  'purchased 1997'
]
newCar = [ { color: 'red', wheels: 4, engine: { cylinders: 4, size: 2.2 } }, 2 ]
myCar[0].color = red
newCar[0].color = red
The new color of my Honda is purple
myCar[0].color = purple
newCar[0].color = purple
```

Calling slice() on non-array objects

The `slice()` method reads the `length` property of `this`. It then reads the integer-keyed properties from `start` to `end` and defines them on a newly created array.

```
const arrayLike = {
  length: 3,
  0: 2,
  1: 3,
  2: 4,
  3: 33, // ignored by slice() since length is 3
};
console.log(Array.prototype.slice.call(arrayLike, 1, 3));
// [ 3, 4 ]
```

Using slice() to convert array-like objects to arrays

The `slice()` method is often used with `bind()` and `call()` to create a utility method that converts an array-like object into an array.

```
// slice() is called with `this` passed as the first argument
const slice = Function.prototype.call.bind(Array.prototype.slice);

function list() {
  return slice(arguments);
}

const listResult = list(1, 2, 3); // [1, 2, 3]
```

Using slice() on sparse arrays

The array returned from `slice()` may be sparse if the source is sparse.

```
console.log([1, 2, , 4, 5].slice(1, 4)); // [2, empty, 4]
```

Array.prototype.some()

The **`some()`** method of `Array` instances returns `true` if it finds an element in the array that satisfies the provided testing function. Otherwise, it returns `false`.

Try it

```
const array = [1, 2, 3, 4, 5];

// Checks whether an element is even
const even = (element) => element % 2 === 0;

console.log(array.some(even));
// Expected output: true
```

Syntax

```
some(callbackFn)
some(callbackFn, thisArg)
```

Parameters

`callbackFn`

A function to execute for each element in the array. It should return a truthy value to indicate the element passes the test, and a falsy value otherwise. The function is called with the following arguments:

`element`

The current element being processed in the array.

`index`

The index of the current element being processed in the array.

`array`

The array `some()` was called upon.

`thisArg` Optional

A value to use as `this` when executing `callbackFn`. See iterative methods.

Return value

`false` unless `callbackFn` returns a truthy value for an array element, in which case `true` is immediately returned.

Description

The `some()` method is an iterative method. It calls a provided `callbackFn` function once for each element in an array, until the `callbackFn` returns a truthy value. If such an element is found, `some()` immediately returns `true` and stops iterating through the array. Otherwise, if `callbackFn` returns a falsy value for all elements, `some()` returns `false`. Read the iterative methods section for more information about how these methods work in general.

`some()` acts like the "there exists" quantifier in mathematics. In particular, for an empty array, it returns `false` for any condition.

`callbackFn` is invoked only for array indexes which have assigned values. It is not invoked for empty slots in sparse arrays.

`some()` does not mutate the array on which it is called, but the function provided as `callbackFn` can. Note, however, that the length of the array is saved *before* the first invocation of `callbackFn`. Therefore:

- `callbackFn` will not visit any elements added beyond the array's initial length when the call to `some()` began.
- Changes to already-visited indexes do not cause `callbackFn` to be invoked on them again.
- If an existing, yet-unvisited element of the array is changed by `callbackFn`, its value passed to the `callbackFn` will be the value at the time that element gets visited. Deleted elements are not visited.

> **Warning:** Concurrent modifications of the kind described above frequently lead to hard-to-understand code and are generally to be avoided (except in special cases).

The `some()` method is generic. It only expects the `this` value to have a `length` property and integer-keyed properties.

Examples

Testing value of array elements

The following example tests whether any element in the array is bigger than 10.

```
function isBiggerThan10(element, index, array) {
  return element > 10;
}

[2, 5, 8, 1, 4].some(isBiggerThan10); // false
[12, 5, 8, 1, 4].some(isBiggerThan10); // true
```

Testing array elements using arrow functions

Arrow functions provide a shorter syntax for the same test.

```
[2, 5, 8, 1, 4].some((x) => x > 10); // false
[12, 5, 8, 1, 4].some((x) => x > 10); // true
```

Checking whether a value exists in an array

To mimic the function of the `includes()` method, this custom function returns `true` if the element exists in the array:

```
const fruits = ["apple", "banana", "mango", "guava"];

function checkAvailability(arr, val) {
  return arr.some((arrVal) => val === arrVal);
}

checkAvailability(fruits, "grapefruit"); // false
checkAvailability(fruits, "banana"); // true
```

Converting any value to Boolean

```
const TRUTHY_VALUES = [true, "true", 1];

function getBoolean(value) {
  if (typeof value === "string") {
    value = value.toLowerCase().trim();
  }

  return TRUTHY_VALUES.some((t) => t === value);
}

getBoolean(false); // false
getBoolean("false"); // false
getBoolean(1); // true
getBoolean("true"); // true
```

Using the third argument of callbackFn

The `array` argument is useful if you want to access another element in the array, especially when you don't have an existing variable that refers to the array. The following example first uses `filter()` to extract the positive values and then uses `some()` to check whether the array is strictly increasing.

```
const numbers = [3, -1, 1, 4, 1, 5];
const isIncreasing = !numbers
  .filter((num) => num > 0)
  .some((num, idx, arr) => {
    // Without the arr argument, there's no way to easily access the
    // intermediate array without saving it to a variable.
    if (idx === 0) return false;
    return num <= arr[idx - 1];
  });
console.log(isIncreasing); // false
```

Using some() on sparse arrays

`some()` will not run its predicate on empty slots.

```
console.log([1, , 3].some((x) => x === undefined)); // false
console.log([1, , 1].some((x) => x !== 1)); // false
console.log([1, undefined, 1].some((x) => x !== 1)); // true
```

Calling some() on non-array objects

The `some()` method reads the `length` property of `this` and then accesses each property whose key is a nonnegative integer less than `length` until they all have been accessed or `callbackFn` returns `true`.

```
const arrayLike = {
  length: 3,
  0: "a",
  1: "b",
  2: "c",
  3: 3, // ignored by some() since length is 3
};
```

```
console.log(Array.prototype.some.call(arrayLike, (x) => typeof x === "number"));
// false
```

Array.prototype.sort()

The **`sort()`** method of `Array` instances sorts the elements of an array *in place* and returns the reference to the same array, now sorted. The default sort order is ascending, built upon converting the elements into strings, then comparing their sequences of UTF-16 code unit values.

The time and space complexity of the sort cannot be guaranteed as it depends on the implementation.

To sort the elements in an array without mutating the original array, use `toSorted()`.

Try it

```
const months = ["March", "Jan", "Feb", "Dec"];
months.sort();
console.log(months);
// Expected output: Array ["Dec", "Feb", "Jan", "March"]

const array = [1, 30, 4, 21, 100000];
array.sort();
console.log(array);
// Expected output: Array [1, 100000, 21, 30, 4]
```

Syntax

```
sort()
sort(compareFn)
```

Parameters

`compareFn` Optional

A function that determines the order of the elements. The function is called with the following arguments:

`a`

The first element for comparison. Will never be `undefined`.

`b`

The second element for comparison. Will never be `undefined`.

It should return a number where:

- A negative value indicates that `a` should come before `b`.
- A positive value indicates that `a` should come after `b`.
- Zero or `NaN` indicates that `a` and `b` are considered equal.

To memorize this, remember that `(a, b) => a - b` sorts numbers in ascending order.

If omitted, the array elements are converted to strings, then sorted according to each character's Unicode code point value.

Return value

The reference to the original array, now sorted. Note that the array is sorted *in place*, and no copy is made.

Description

If `compareFn` is not supplied, all non-`undefined` array elements are sorted by converting them to strings and comparing strings in UTF-16 code units order. For example, "banana" comes before "cherry". In a numeric sort, 9 comes before 80, but because numbers are converted to strings, "80" comes before "9" in the Unicode order. All `undefined` elements are sorted to the end of the array.

The `sort()` method preserves empty slots. If the source array is sparse, the empty slots are moved to the end of the array, and always come after all the `undefined`.

> **Note:** In UTF-16, Unicode characters above `\uFFFF` are encoded as two surrogate code units, of the range `\uD800` - `\uDFFF`. The value of each code unit is taken separately into account for the comparison. Thus the character formed by the surrogate pair `\uD855\uDE51` will be sorted before the character `\uFF3A`.

If `compareFn` is supplied, all non-`undefined` array elements are sorted according to the return value of the compare function (all `undefined` elements are sorted to the end of the array, with no call to `compareFn`).

`compareFn(a, b)` return value	sort order
> 0	sort `a` after `b`, e.g., `[b, a]`
< 0	sort `a` before `b`, e.g., `[a, b]`
=== 0	keep original order of `a` and `b`

So, the compare function has the following form:

```
function compareFn(a, b) {
  if (a is less than b by some ordering criterion) {
    return -1;
  } else if (a is greater than b by the ordering criterion) {
    return 1;
  }
  // a must be equal to b
  return 0;
}
```

More formally, the comparator is expected to have the following properties, in order to ensure proper sort behavior:

- *Pure*: The comparator does not mutate the objects being compared or any external state. (This is important because there's no guarantee *when* and *how* the comparator will be called, so any particular call should not produce visible effects to the outside.)
- *Stable*: The comparator returns the same result with the same pair of input.
- *Reflexive*: `compareFn(a, a) === 0`.
- *Anti-symmetric*: `compareFn(a, b)` and `compareFn(b, a)` must both be `0` or have opposite signs.
- *Transitive*: If `compareFn(a, b)` and `compareFn(b, c)` are both positive, zero, or negative, then `compareFn(a, c)` has the same positivity as the previous two.

A comparator conforming to the constraints above will always be able to return all of `1`, `0`, and `-1`, or consistently return `0`. For example, if a comparator only returns `1` and `0`, or only returns `0` and `-1`, it will not be able to sort reliably because *anti-symmetry* is broken. A comparator that always returns `0` will cause the array to not be changed at all, but is reliable nonetheless.

The default lexicographic comparator satisfies all constraints above.

To compare numbers instead of strings, the compare function can subtract `b` from `a`. The following function will sort the array in ascending order (if it doesn't contain `NaN`):

```
function compareNumbers(a, b) {
  return a - b;
}
```

The `sort()` method is generic. It only expects the `this` value to have a `length` property and integer-keyed properties. Although strings are also array-like, this method is not suitable to be applied on them, as strings are immutable.

Examples

Creating, displaying, and sorting an array

The following example creates four arrays and displays the original array, then the sorted arrays. The numeric arrays are sorted without a compare function, then sorted using one.

```
const stringArray = ["Blue", "Humpback", "Beluga"];
const numberArray = [40, 1, 5, 200];
const numericStringArray = ["80", "9", "700"];
const mixedNumericArray = ["80", "9", "700", 40, 1, 5, 200];

function compareNumbers(a, b) {
  return a - b;
}

stringArray.join(); // 'Blue,Humpback,Beluga'
stringArray.sort(); // ['Beluga', 'Blue', 'Humpback']

numberArray.join(); // '40,1,5,200'
numberArray.sort(); // [1, 200, 40, 5]
numberArray.sort(compareNumbers); // [1, 5, 40, 200]

numericStringArray.join(); // '80,9,700'
numericStringArray.sort(); // ['700', '80', '9']
numericStringArray.sort(compareNumbers); // ['9', '80', '700']

mixedNumericArray.join(); // '80,9,700,40,1,5,200'
mixedNumericArray.sort(); // [1, 200, 40, 5, '700', '80', '9']
mixedNumericArray.sort(compareNumbers); // [1, 5, '9', 40, '80', 200, '700']
```

Sorting array of objects

Arrays of objects can be sorted by comparing the value of one of their properties.

```
const items = [
  { name: "Edward", value: 21 },
  { name: "Sharpe", value: 37 },
  { name: "And", value: 45 },
  { name: "The", value: -12 },
  { name: "Magnetic", value: 13 },
  { name: "Zeros", value: 37 },
];

// sort by value
items.sort((a, b) => a.value - b.value);

// sort by name
items.sort((a, b) => {
  const nameA = a.name.toUpperCase(); // ignore upper and lowercase
  const nameB = b.name.toUpperCase(); // ignore upper and lowercase
  if (nameA < nameB) {
    return -1;
  }
  if (nameA > nameB) {
    return 1;
  }

  // names must be equal
  return 0;
});
```

Sorting non-ASCII characters

For sorting strings with non-ASCII characters, i.e., strings with accented characters (e, é, è, a, ä, etc.), strings from languages other than English, use `String.prototype.localeCompare()`. This function can compare those characters so they appear in the right order.

```
const items = ["réservé", "premier", "communiqué", "café", "adieu", "éclair"];
items.sort((a, b) => a.localeCompare(b));

// items is ['adieu', 'café', 'communiqué', 'éclair', 'premier', 'réservé']
```

Sorting with map

The `compareFn` can be invoked multiple times per element within the array. Depending on the `compareFn`'s nature, this may yield a high overhead. The more work a `compareFn` does and the more elements there are to sort, it may be more efficient to use `map()` for sorting. The idea is to traverse the array once to extract the actual values used for sorting into a temporary array, sort the temporary array, and then traverse the temporary array to achieve the right order.

```
// the array to be sorted
const data = ["delta", "alpha", "charlie", "bravo"];

// temporary array holds objects with position and sort-value
const mapped = data.map((v, i) => ({ i, value: someSlowOperation(v) }));

// sorting the mapped array containing the reduced values
mapped.sort((a, b) => {
  if (a.value > b.value) {
    return 1;
  }
  if (a.value < b.value) {
    return -1;
  }
  return 0;
});

const result = mapped.map((v) => data[v.i]);
```

There is an open source library available called mapsort which applies this approach.

sort() returns the reference to the same array

The `sort()` method returns a reference to the original array, so mutating the returned array will mutate the original array as well.

```
const numbers = [3, 1, 4, 1, 5];
const sorted = numbers.sort((a, b) => a - b);
// numbers and sorted are both [1, 1, 3, 4, 5]
sorted[0] = 10;
console.log(numbers[0]); // 10
```

In case you want `sort()` to not mutate the original array, but return a shallow-copied array like other array methods (e.g., `map()`) do, use the `toSorted()` method. Alternatively, you can do a shallow copy before calling `sort()`, using the spread syntax or `Array.from()`.

```
const numbers = [3, 1, 4, 1, 5];
// [...numbers] creates a shallow copy, so sort() does not mutate the original
const sorted = [...numbers].sort((a, b) => a - b);
sorted[0] = 10;
console.log(numbers[0]); // 3
```

Sort stability

Since version 10 (or ECMAScript 2019), the specification dictates that `Array.prototype.sort` is stable.

For example, say you had a list of students alongside their grades. Note that the list of students is already pre-sorted by name in alphabetical order:

```
const students = [
  { name: "Alex", grade: 15 },
  { name: "Devlin", grade: 15 },
  { name: "Eagle", grade: 13 },
  { name: "Sam", grade: 14 },
];
```

After sorting this array by `grade` in ascending order:

```
students.sort((firstItem, secondItem) => firstItem.grade - secondItem.grade);
```

The `students` variable will then have the following value:

```
[
  { name: "Eagle", grade: 13 },
  { name: "Sam", grade: 14 },
  { name: "Alex", grade: 15 }, // original maintained for similar grade (stable sorting)
  { name: "Devlin", grade: 15 }, // original maintained for similar grade (stable sorting)
];
```

It's important to note that students that have the same grade (for example, Alex and Devlin), will remain in the same order as before calling the sort. This is what a stable sorting algorithm guarantees.

Before version 10 (or ECMAScript 2019), sort stability was not guaranteed, meaning that you could end up with the following:

```
[
  { name: "Eagle", grade: 13 },
  { name: "Sam", grade: 14 },
  { name: "Devlin", grade: 15 }, // original order not maintained
  { name: "Alex", grade: 15 }, // original order not maintained
];
```

Sorting with non-well-formed comparator

If a comparing function does not satisfy all of purity, stability, reflexivity, anti-symmetry, and transitivity rules, as explained in the description, the program's behavior is not well-defined.

For example, consider this code:

```
const arr = [3, 1, 4, 1, 5, 9];
const compareFn = (a, b) => (a > b ? 1 : 0);
arr.sort(compareFn);
```

The `compareFn` function here is not well-formed, because it does not satisfy anti-symmetry: if `a > b`, it returns `1`; but by swapping `a` and `b`, it returns `0` instead of a negative value. Therefore, the resulting array will be different across engines. For example, V8 (used by Chrome, Node.js, etc.) and JavaScriptCore (used by Safari) would not sort the array at all and return `[3, 1, 4, 1, 5, 9]`, while SpiderMonkey (used by Firefox) will return the array sorted ascendingly, as `[1, 1, 3, 4, 5, 9]`.

However, if the `compareFn` function is changed slightly so that it returns `-1` or `0`:

```
const arr = [3, 1, 4, 1, 5, 9];
const compareFn = (a, b) => (a > b ? -1 : 0);
arr.sort(compareFn);
```

Then V8 and JavaScriptCore sorts it descendingly, as `[9, 5, 4, 3, 1, 1]`, while SpiderMonkey returns it as-is: `[3, 1, 4, 1, 5, 9]`.

Due to this implementation inconsistency, you are always advised to make your comparator well-formed by following the five constraints.

Using sort() on sparse arrays

Empty slots are moved to the end of the array.

```
console.log(["a", "c", , "b"].sort()); // ['a', 'b', 'c', empty]
console.log([, undefined, "a", "b"].sort()); // ["a", "b", undefined, empty]
```

Calling sort() on non-array objects

The `sort()` method reads the `length` property of `this`. It then collects all existing integer-keyed properties in the range of `0` to `length - 1`, sorts them, and writes them back. If there are missing properties in the range, the corresponding trailing properties are deleted, as if the non-existent properties are sorted towards the end.

```
const arrayLike = {
  length: 3,
  unrelated: "foo",
  0: 5,
  2: 4,
};
```

```
console.log(Array.prototype.sort.call(arrayLike));
// { '0': 4, '1': 5, length: 3, unrelated: 'foo' }
```

Array.prototype.splice()

The **`splice()`** method of `Array` instances changes the contents of an array by removing or replacing existing elements and/or adding new elements in place.

To create a new array with a segment removed and/or replaced without mutating the original array, use `toSpliced()`. To access part of an array without modifying it, see `slice()`.

Try it

```
const months = ["Jan", "March", "April", "June"];
months.splice(1, 0, "Feb");
// Inserts at index 1
console.log(months);
// Expected output: Array ["Jan", "Feb", "March", "April", "June"]

months.splice(4, 1, "May");
// Replaces 1 element at index 4
console.log(months);
// Expected output: Array ["Jan", "Feb", "March", "April", "May"]
```

Syntax

```
splice(start)
splice(start, deleteCount)
splice(start, deleteCount, item1)
splice(start, deleteCount, item1, item2)
splice(start, deleteCount, item1, item2, /* …, */ itemN)
```

Parameters

`start`

Zero-based index at which to start changing the array, converted to an integer.

- Negative index counts back from the end of the array — if `-array.length <= start < 0`, `start + array.length` is used.
- If `start < -array.length`, `0` is used.
- If `start >= array.length`, no element will be deleted, but the method will behave as an adding function, adding as many elements as provided.
- If `start` is omitted (and `splice()` is called with no arguments), nothing is deleted. This is different from passing `undefined`, which is converted to `0`.

`deleteCount` Optional

An integer indicating the number of elements in the array to remove from `start`.

If `deleteCount` is omitted, or if its value is greater than or equal to the number of elements after the position specified by `start`, then all the elements from `start` to the end of the array will be deleted. However, if you wish to pass any `itemN` parameter, you should pass `Infinity` as `deleteCount` to delete all elements after `start`, because an explicit `undefined` gets converted to `0`.

If `deleteCount` is `0` or negative, no elements are removed. In this case, you should specify at least one new element (see below).

`item1`, …, `itemN` Optional

The elements to add to the array, beginning from `start`.

If you do not specify any elements, `splice()` will only remove elements from the array.

Return value

An array containing the deleted elements.

If only one element is removed, an array of one element is returned.

If no elements are removed, an empty array is returned.

Description

The `splice()` method is a mutating method. It may change the content of `this`. If the specified number of elements to insert differs from the number of elements being removed, the array's `length` will be changed as well. At the same time, it uses `[Symbol.species]` to create a new array instance to be returned.

If the deleted portion is sparse, the array returned by `splice()` is sparse as well, with those corresponding indices being empty slots.

The `splice()` method is generic. It only expects the `this` value to have a `length` property and integer-keyed properties. Although strings are also array-like, this method is not suitable to be applied on them, as strings are immutable.

Examples

Remove 0 (zero) elements before index 2, and insert "drum"

```
const myFish = ["angel", "clown", "mandarin", "sturgeon"];
const removed = myFish.splice(2, 0, "drum");

// myFish is ["angel", "clown", "drum", "mandarin", "sturgeon"]
// removed is [], no elements removed
```

Remove 0 (zero) elements before index 2, and insert "drum" and "guitar"

```
const myFish = ["angel", "clown", "mandarin", "sturgeon"];
const removed = myFish.splice(2, 0, "drum", "guitar");

// myFish is ["angel", "clown", "drum", "guitar", "mandarin", "sturgeon"]
// removed is [], no elements removed
```

Remove 0 (zero) elements at index 0, and insert "angel"

`splice(0, 0, ...elements)` inserts elements at the start of the array like `unshift()`.

```
const myFish = ["clown", "mandarin", "sturgeon"];
const removed = myFish.splice(0, 0, "angel");

// myFish is ["angel", "clown", "mandarin", "sturgeon"]
// no items removed
```

Remove 0 (zero) elements at last index, and insert "sturgeon"

`splice(array.length, 0, ...elements)` inserts elements at the end of the array like `push()`.

```
const myFish = ["angel", "clown", "mandarin"];
const removed = myFish.splice(myFish.length, 0, "sturgeon");

// myFish is ["angel", "clown", "mandarin", "sturgeon"]
// no items removed
```

Remove 1 element at index 3

```
const myFish = ["angel", "clown", "drum", "mandarin", "sturgeon"];
const removed = myFish.splice(3, 1);

// myFish is ["angel", "clown", "drum", "sturgeon"]
// removed is ["mandarin"]
```

Remove 1 element at index 2, and insert "trumpet"

```
const myFish = ["angel", "clown", "drum", "sturgeon"];
const removed = myFish.splice(2, 1, "trumpet");

// myFish is ["angel", "clown", "trumpet", "sturgeon"]
// removed is ["drum"]
```

Remove 2 elements from index 0, and insert "parrot", "anemone" and "blue"

```
const myFish = ["angel", "clown", "trumpet", "sturgeon"];
const removed = myFish.splice(0, 2, "parrot", "anemone", "blue");

// myFish is ["parrot", "anemone", "blue", "trumpet", "sturgeon"]
// removed is ["angel", "clown"]
```

Remove 2 elements, starting from index 2

```
const myFish = ["parrot", "anemone", "blue", "trumpet", "sturgeon"];
const removed = myFish.splice(2, 2);

// myFish is ["parrot", "anemone", "sturgeon"]
// removed is ["blue", "trumpet"]
```

Remove 1 element from index -2

```
const myFish = ["angel", "clown", "mandarin", "sturgeon"];
const removed = myFish.splice(-2, 1);
```

```
// myFish is ["angel", "clown", "sturgeon"]
// removed is ["mandarin"]
```

Remove all elements, starting from index 2

```
const myFish = ["angel", "clown", "mandarin", "sturgeon"];
const removed = myFish.splice(2);

// myFish is ["angel", "clown"]
// removed is ["mandarin", "sturgeon"]
```

Using splice() on sparse arrays

The `splice()` method preserves the array's sparseness.

```
const arr = [1, , 3, 4, , 6];
console.log(arr.splice(1, 2)); // [empty, 3]
console.log(arr); // [1, 4, empty, 6]
```

Calling splice() on non-array objects

The `splice()` method reads the `length` property of `this`. It then updates the integer-keyed properties and the `length` property as needed.

```
const arrayLike = {
  length: 3,
  unrelated: "foo",
  0: 5,
  2: 4,
};
console.log(Array.prototype.splice.call(arrayLike, 0, 1, 2, 3));
// [ 5 ]
console.log(arrayLike);
// { '0': 2, '1': 3, '3': 4, length: 4, unrelated: 'foo' }
```

Array.prototype[Symbol.iterator]()

The **`[Symbol.iterator]()`** method of `Array` instances implements the iterable protocol and allows arrays to be consumed by most syntaxes expecting iterables, such as the spread syntax and `for...of` loops. It returns an array iterator object that yields the value of each index in the array.

The initial value of this property is the same function object as the initial value of the `Array.prototype.values` property.

Try it

```
const array = ["a", "b", "c"];
const iterator = array[Symbol.iterator]();

for (const value of iterator) {
  console.log(value);
}

// Expected output: "a"
// Expected output: "b"
// Expected output: "c"
```

Syntax

```
array[Symbol.iterator]()
```

Parameters

None.

Return value

The same return value as `Array.prototype.values()`: a new iterable iterator object that yields the value of each index in the array.

Examples

Iteration using for...of loop

Note that you seldom need to call this method directly. The existence of the `[Symbol.iterator]()` method makes arrays iterable, and iterating syntaxes like the `for...of` loop automatically call this method to obtain the iterator to loop over.

HTML

```
<ul id="letterResult"></ul>
```

JavaScript

```
const arr = ["a", "b", "c"];
const letterResult = document.getElementById("letterResult");
for (const letter of arr) {
  const li = document.createElement("li");
  li.textContent = letter;
  letterResult.appendChild(li);
}
```

Result

Manually hand-rolling the iterator

You may still manually call the `next()` method of the returned iterator object to achieve maximum control over the iteration process.

```
const arr = ["a", "b", "c", "d", "e"];
const arrIter = arr[Symbol.iterator]();
console.log(arrIter.next().value); // a
console.log(arrIter.next().value); // b
console.log(arrIter.next().value); // c
console.log(arrIter.next().value); // d
console.log(arrIter.next().value); // e
```

Handling strings and string arrays with the same function

Because both strings and arrays implement the iterable protocol, a generic function can be designed to handle both inputs in the same fashion. This is better than calling `Array.prototype.values()` directly, which requires the input to be an array, or at least an object with such a method.

```
function logIterable(it) {
  if (typeof it[Symbol.iterator] !== "function") {
    console.log(it, "is not iterable.");
    return;
  }
  for (const letter of it) {
    console.log(letter);
  }
}

// Array
logIterable(["a", "b", "c"]);
// a
// b
// c

// String
logIterable("abc");
// a
// b
// c

// Number
logIterable(123);
// 123 is not iterable.
```

Array[Symbol.species]

The **`Array[Symbol.species]`** static accessor property returns the constructor used to construct return values from array methods.

> **Warning:** The existence of `[Symbol.species]` allows execution of arbitrary code and may create security vulnerabilities. It also makes certain optimizations much harder. Engine implementers are investigating whether to remove this feature. Avoid relying on it if possible. Modern array methods, such as `toReversed()`, do not

> use `[Symbol.species]` and always return a new `Array` base class instance.

Syntax

```
Array[Symbol.species]
```

Return value

The value of the constructor (`this`) on which `get [Symbol.species]` was called. The return value is used to construct return values from array methods that create new arrays.

Description

The `[Symbol.species]` accessor property returns the default constructor for `Array` objects. Subclass constructors may override it to change the constructor assignment. The default implementation is basically:

```
// Hypothetical underlying implementation for illustration
class Array {
  static get [Symbol.species]() {
    return this;
  }
}
```

Because of this polymorphic implementation, `[Symbol.species]` of derived subclasses would also return the constructor itself by default.

```
class SubArray extends Array {}
SubArray[Symbol.species] === SubArray; // true
```

When calling array methods that do not mutate the existing array but return a new array instance (for example, `filter()` and `map()`), the array's `constructor[Symbol.species]` will be accessed. The returned constructor will be used to construct the return value of the array method. This makes it technically possible to make array methods return objects unrelated to arrays.

```
class NotAnArray {
  constructor(length) {
    this.length = length;
  }
}

const arr = [0, 1, 2];
arr.constructor = { [Symbol.species]: NotAnArray };
arr.map((i) => i); // NotAnArray { '0': 0, '1': 1, '2': 2, length: 3 }
arr.filter((i) => i); // NotAnArray { '0': 1, '1': 2, length: 0 }
arr.concat([1, 2]); // NotAnArray { '0': 0, '1': 1, '2': 2, '3': 1, '4': 2, length: 5 }
```

Examples

Species in ordinary objects

The `[Symbol.species]` property returns the default constructor function, which is the `Array` constructor for `Array`.

```
Array[Symbol.species]; // [Function: Array]
```

Species in derived objects

In an instance of a custom `Array` subclass, such as `MyArray`, the `MyArray` species is the `MyArray` constructor. However, you might want to overwrite this, in order to return parent `Array` objects in your derived class methods:

```
class MyArray extends Array {
  // Overwrite MyArray species to the parent Array constructor
  static get [Symbol.species]() {
    return Array;
  }
}
```

Array.prototype[Symbol.unscopables]

The **`[Symbol.unscopables]`** data property of `Array.prototype` is shared by all `Array` instances. It contains property names that were not included in the ECMAScript standard prior to the ES2015 version and that are ignored for `with` statement-binding purposes.

Value

A `null`-prototype object with property names given below and their values set to `true`.

Property attributes of `Array.prototype[Symbol.unscopables]`	
Writable	no
Enumerable	no
Configurable	yes

Description

The default `Array` properties that are ignored for `with` statement-binding purposes are:

- `at()`
- `copyWithin()`
- `entries()`
- `fill()`
- `find()`
- `findIndex()`
- `findLast()`
- `findLastIndex()`
- `flat()`
- `flatMap()`
- `includes()`
- `keys()`
- `toReversed()`
- `toSorted()`
- `toSpliced()`
- `values()`

`Array.prototype[Symbol.unscopables]` is an empty object only containing all the above property names with the value `true`. Its prototype is `null`, so `Object.prototype` properties like `toString` won't accidentally be made unscopable, and a `toString()` within the `with` statement will continue to be called on the array.

See `Symbol.unscopables` for how to set unscopable properties for your own objects.

Examples

Imagine the `values.push('something')` call below is in code that was written prior to ECMAScript 2015.

```
var values = [];

with (values) {
  values.push("something");
}
```

When ECMAScript 2015 introduced the `Array.prototype.values()` method, the `with` statement in the above code started to interpret `values` as the `values.values` array method instead of the external `values` variable. The `values.push('something')` call would break because it's now accessing `push` on the `values.values` method. This caused a bug to be reported to Firefox (Firefox Bug 883914).

So the `[Symbol.unscopables]` data property for `Array.prototype` causes the `Array` properties introduced in ECMAScript 2015 to be ignored for `with` statement-binding purposes — allowing code that was written prior to ECMAScript 2015 to continue working as expected, rather than breaking.

Array.prototype.toLocaleString()

The **`toLocaleString()`** method of `Array` instances returns a string representing the elements of the array. The elements are converted to strings using their `toLocaleString` methods and these strings are separated by a locale-specific string (such as a comma ",").

Try it

```
const array = [1, "a", new Date("21 Dec 1997 14:12:00 UTC")];
const localeString = array.toLocaleString("en", { timeZone: "UTC" });

console.log(localeString);
// Expected output: "1,a,12/21/1997, 2:12:00 PM",
// This assumes "en" locale and UTC timezone - your results may vary
```

Syntax

```
toLocaleString()
toLocaleString(locales)
toLocaleString(locales, options)
```

Parameters

`locales` Optional

A string with a BCP 47 language tag, or an array of such strings. For the general form and interpretation of the `locales` argument, see the parameter description on the `Intl` main page.

`options` Optional

An object with configuration properties. What you can pass here depends on what elements are being converted. For example, for numbers, see `Number.prototype.toLocaleString()`.

Return value

A string representing the elements of the array.

Description

The `Array.prototype.toLocaleString` method traverses its content, calling the `toLocaleString` method of every element with the `locales` and `options` parameters provided, and concatenates them with an implementation-defined separator (such as a comma ",").

> **Note:** The `locales` or `options` arguments do not control the separator used between array elements; they are simply passed to the `toLocaleString()` method of each element. The actual separator (usually a comma) depends solely on the host's current locale. If you expect localized list formatting, consider using `Intl.ListFormat` instead.

If an element is `undefined`, `null`, it is converted to an empty string instead of the string `"null"` or `"undefined"`.

When used on sparse arrays, the `toLocaleString()` method iterates empty slots as if they have the value `undefined`.

The `toLocaleString()` method is generic. It only expects the `this` value to have a `length` property and integer-keyed properties.

Examples

Using locales and options

The elements of the array are converted to strings using their `toLocaleString` methods. For example, this snippet implicitly calls the `Number.prototype.toLocaleString()` method to display the currency for the strings and numbers in the `prices` array:

```
const prices = ["￥7", 500, 8123, 12];
prices.toLocaleString("ja-JP", { style: "currency", currency: "JPY" });

// "￥7,￥500,￥8,123,￥12"
```

List separators

The list separator is not affected by the `locales` parameter. To configure it, use `Intl.ListFormat` instead.

```
const nums = [8888, 9999];
console.log(nums.toLocaleString("zh")); // "8,888,9,999"

const formatter = new Intl.ListFormat("zh", {
  type: "conjunction",
  style: "narrow",
});
console.log(formatter.format(nums.map((x) => x.toLocaleString("zh"))));
// "8,888、9,999"
```

Using toLocaleString() on sparse arrays

`toLocaleString()` treats empty slots the same as `undefined` and produces an extra separator:

```
console.log([1, , 3].toLocaleString()); // '1,,3'
```

Calling toLocaleString() on non-array objects

The `toLocaleString()` method reads the `length` property of `this` and then accesses each property whose key is a nonnegative integer less than `length`.

```
const arrayLike = {
  length: 3,
  0: 1,
  1: 2,
  2: 3,
  3: 4, // ignored by toLocaleString() since length is 3
};
console.log(Array.prototype.toLocaleString.call(arrayLike));
// 1,2,3
```

- `Temporal.PlainDate.prototype.toLocaleString()`

Array.prototype.toReversed()

The **`toReversed()`** method of `Array` instances is the copying counterpart of the `reverse()` method. It returns a new array with the elements in reversed order.

Syntax

```
toReversed()
```

Parameters

None.

Return value

A new array containing the elements in reversed order.

Description

The `toReversed()` method transposes the elements of the calling array object in reverse order and returns a new array.

When used on sparse arrays, the `toReversed()` method iterates empty slots as if they have the value `undefined`.

The `toReversed()` method is generic. It only expects the `this` value to have a `length` property and integer-keyed properties.

Examples

Reversing the elements in an array

The following example creates an array `items`, containing three elements, then creates a new array that's the reverse of `items`. The `items` array remains unchanged.

```
const items = [1, 2, 3];
console.log(items); // [1, 2, 3]

const reversedItems = items.toReversed();
console.log(reversedItems); // [3, 2, 1]
console.log(items); // [1, 2, 3]
```

Using toReversed() on sparse arrays

The return value of `toReversed()` is never sparse. Empty slots become `undefined` in the returned array.

```
console.log([1, , 3].toReversed()); // [3, undefined, 1]
console.log([1, , 3, 4].toReversed()); // [4, 3, undefined, 1]
```

Calling toReversed() on non-array objects

The `toReversed()` method reads the `length` property of `this`. It then visits each property having an integer key between `length - 1` and `0` in descending order, adding the value of the current property to the end of the array to be returned.

```
const arrayLike = {
  length: 3,
  unrelated: "foo",
  2: 4,
};
console.log(Array.prototype.toReversed.call(arrayLike));
// [4, undefined, undefined]
// The '0' and '1' indices are not present so they become undefined
```

See also

- Polyfill of `Array.prototype.toReversed` in `core-js`
- es-shims polyfill of `Array.prototype.toReversed`
- Indexed collections guide
- `Array.prototype.reverse()`
- `Array.prototype.toSorted()`
- `Array.prototype.toSpliced()`
- `Array.prototype.with()`
- `TypedArray.prototype.toReversed()`

Array.prototype.toSorted()

The **`toSorted()`** method of `Array` instances is the copying version of the `sort()` method. It returns a new array with the elements sorted in ascending order.

Syntax

```
toSorted()
toSorted(compareFn)
```

Parameters

`compareFn` Optional

> A function that determines the order of the elements. If omitted, the array elements are converted to strings, then sorted according to each character's Unicode code point value. See `sort()` for more information.

Return value

A new array with the elements sorted in ascending order.

Description

See `sort()` for more information on the `compareFn` parameter.

When used on sparse arrays, the `toSorted()` method iterates empty slots as if they have the value `undefined`.

The `toSorted()` method is generic. It only expects the `this` value to have a `length` property and integer-keyed properties.

Examples

Sorting an array

```
const months = ["Mar", "Jan", "Feb", "Dec"];
const sortedMonths = months.toSorted();
console.log(sortedMonths); // ['Dec', 'Feb', 'Jan', 'Mar']
console.log(months); // ['Mar', 'Jan', 'Feb', 'Dec']

const values = [1, 10, 21, 2];
const sortedValues = values.toSorted((a, b) => a - b);
console.log(sortedValues); // [1, 2, 10, 21]
console.log(values); // [1, 10, 21, 2]
```

For more usage examples, see `sort()`.

Using toSorted() on sparse arrays

Empty slots are sorted as if they have the value `undefined`. They are always sorted to the end of the array and `compareFn` is not called for them.

```
console.log(["a", "c", , "b"].toSorted()); // ['a', 'b', 'c', undefined]
console.log([, undefined, "a", "b"].toSorted()); // ["a", "b", undefined, undefined]
```

Calling toSorted() on non-array objects

The `toSorted()` method reads the `length` property of `this`. It then collects all existing integer-keyed properties in the range of `0` to `length - 1`, sorts them, and writes them into a new array.

```
const arrayLike = {
  length: 3,
  unrelated: "foo",
  0: 5,
  2: 4,
  3: 3, // ignored by toSorted() since length is 3
};
console.log(Array.prototype.toSorted.call(arrayLike));
// [4, 5, undefined]
```

- `Array.prototype.toReversed()`
- `Array.prototype.toSpliced()`
- `Array.prototype.with()`
- `TypedArray.prototype.toSorted()`

Array.prototype.toSpliced()

The **`toSpliced()`** method of `Array` instances is the copying version of the `splice()` method. It returns a new array with some elements removed and/or replaced at a given index.

Syntax

```
toSpliced(start)
toSpliced(start, skipCount)
toSpliced(start, skipCount, item1)
```

```
toSpliced(start, skipCount, item1, item2)
toSpliced(start, skipCount, item1, item2, /* …, */ itemN)
```

Parameters

`start`

Zero-based index at which to start changing the array, converted to an integer.

- Negative index counts back from the end of the array — if `-array.length <= start < 0`, `start + array.length` is used.
- If `start < -array.length` or `start` is omitted, `0` is used.
- If `start >= array.length`, no element will be deleted, but the method will behave as an adding function, adding as many elements as provided.

`skipCount` Optional

An integer indicating the number of elements in the array to remove (or, to skip) from `start`.

If `skipCount` is omitted, or if its value is greater than or equal to the number of elements after the position specified by `start`, then all the elements from `start` to the end of the array will be deleted. However, if you wish to pass any `itemN` parameter, you should pass `Infinity` as `skipCount` to delete all elements after `start`, because an explicit `undefined` gets converted to `0`.

If `skipCount` is `0` or negative, no elements are removed. In this case, you should specify at least one new element (see below).

`item1`, ..., `itemN` Optional

The elements to add to the array, beginning from `start`.

If you do not specify any elements, `toSpliced()` will only remove elements from the array.

Return value

A new array that consists of all elements before `start`, `item1`, `item2`, ..., `itemN`, and all elements after `start + skipCount`.

Description

The `toSpliced()` method, like `splice()`, does multiple things at once: it removes the given number of elements from the array, starting at a given index, and then inserts the given elements at the same index. However, it returns a new array instead of modifying the original array. The deleted elements therefore are not returned from this method, but they remain accessible in the original array.

The `toSpliced()` method never produces a sparse array. If the source array is sparse, the empty slots will be replaced with `undefined` in the new array.

The `toSpliced()` method is generic. It only expects the `this` value to have a `length` property and integer-keyed properties.

Examples

Deleting, adding, and replacing elements

You can use `toSpliced()` to delete, add, and replace elements in an array and create a new array more efficiently than using `slice()` and `concat()`.

```
const months = ["Jan", "Mar", "Apr", "May"];

// Inserting an element at index 1
const months2 = months.toSpliced(1, 0, "Feb");
console.log(months2); // ["Jan", "Feb", "Mar", "Apr", "May"]

// Deleting two elements starting from index 2
const months3 = months2.toSpliced(2, 2);
console.log(months3); // ["Jan", "Feb", "May"]

// Replacing one element at index 1 with two new elements
const months4 = months3.toSpliced(1, 1, "Feb", "Mar");
console.log(months4); // ["Jan", "Feb", "Mar", "May"]

// Original array is not modified
console.log(months); // ["Jan", "Mar", "Apr", "May"]
```

Using toSpliced() on sparse arrays

The `toSpliced()` method always creates a dense array.

```
const arr = [1, , 3, 4, , 6];
console.log(arr.toSpliced(1, 2)); // [1, 4, undefined, 6]
```

Calling toSpliced() on non-array objects

The `toSpliced()` method reads the `length` property of `this`. It then reads the integer-keyed properties needed and writes them into the new array.

```
const arrayLike = {
  length: 3,
  unrelated: "foo",
  0: 5,
  2: 4,
};
```

```
console.log(Array.prototype.toSpliced.call(arrayLike, 0, 1, 2, 3));
// [2, 3, undefined, 4]
```

See also

- Polyfill of `Array.prototype.toSpliced` in `core-js`
- es-shims polyfill of `Array.prototype.toSpliced`
- `Array.prototype.splice()`
- `Array.prototype.toReversed()`
- `Array.prototype.toSorted()`
- `Array.prototype.with()`

Array.prototype.toString()

The **`toString()`** method of `Array` instances returns a string representing the specified array and its elements.

Try it

```
const array = [1, 2, "a", "1a"];

console.log(array.toString());
// Expected output: "1,2,a,1a"
```

Syntax

```
toString()
```

Parameters

None.

Return value

A string representing the elements of the array.

Description

The `Array` object overrides the `toString` method of `Object`. The `toString` method of arrays calls `join()` internally, which joins the array and returns one string containing each array element separated by commas. If the `join` method is unavailable or is not a function, `Object.prototype.toString` is used instead, returning `[object Array]`.

```
const arr = [];
arr.join = 1; // re-assign `join` with a non-function
console.log(arr.toString()); // [object Array]

console.log(Array.prototype.toString.call({ join: () => 1 })); // 1
```

JavaScript calls the `toString` method automatically when an array is to be represented as a text value or when an array is referred to in a string concatenation.

`Array.prototype.toString` recursively converts each element, including other arrays, to strings. Because the string returned by `Array.prototype.toString` does not have delimiters, nested arrays look like they are flattened.

```
const matrix = [
  [1, 2, 3],
  [4, 5, 6],
  [7, 8, 9],
];

console.log(matrix.toString()); // 1,2,3,4,5,6,7,8,9
```

When an array is cyclic (it contains an element that is itself), browsers avoid infinite recursion by ignoring the cyclic reference.

```
const arr = [];
arr.push(1, [3, arr, 4], 2);
console.log(arr.toString()); // 1,3,,4,2
```

Examples

Using toString()

```
const array = [1, 2, "a", "1a"];

console.log(array.toString()); // "1,2,a,1a"
```

Using toString() on sparse arrays

Following the behavior of `join()`, `toString()` treats empty slots the same as `undefined` and produces an extra separator:

```
console.log([1, , 3].toString()); // '1,,3'
```

Calling toString() on non-array objects

`toString()` is generic. It expects `this` to have a `join()` method; or, failing that, uses `Object.prototype.toString()` instead.

```
console.log(Array.prototype.toString.call({ join: () => 1 }));
// 1; a number
console.log(Array.prototype.toString.call({ join: () => undefined }));
// undefined
console.log(Array.prototype.toString.call({ join: "not function" }));
// "[object Object]"
```

- `TypedArray.prototype.toString()`
- `String.prototype.toString()`

Array.prototype.unshift()

The **`unshift()`** method of `Array` instances adds the specified elements to the beginning of an array and returns the new length of the array.

Try it

```
const array = [1, 2, 3];

console.log(array.unshift(4, 5));
// Expected output: 5

console.log(array);
// Expected output: Array [4, 5, 1, 2, 3]
```

Syntax

```
unshift()
unshift(element1)
unshift(element1, element2)
unshift(element1, element2, /* …, */ elementN)
```

Parameters

`element1, ..., elementN`

The elements to add to the front of the `arr`.

Return value

The new `length` property of the object upon which the method was called.

Description

The `unshift()` method inserts the given values to the beginning of an array-like object.

`Array.prototype.push()` has similar behavior to `unshift()`, but applied to the end of an array.

Please note that, if multiple elements are passed as parameters, they're inserted in chunk at the beginning of the object, in the exact same order they were passed as parameters. Hence, calling `unshift()` with `n` arguments **once**, or calling it `n` times with **1** argument (with a loop, for example), don't yield the same results.

See example:

```
let arr = [4, 5, 6];

arr.unshift(1, 2, 3);
console.log(arr);
// [1, 2, 3, 4, 5, 6]

arr = [4, 5, 6]; // resetting the array

arr.unshift(1);
arr.unshift(2);
arr.unshift(3);

console.log(arr);
// [3, 2, 1, 4, 5, 6]
```

The `unshift()` method is generic. It only expects the `this` value to have a `length` property and integer-keyed properties. Although strings are also array-like, this method is not suitable to be applied on them, as strings are immutable.

Examples

Using unshift()

```
const arr = [1, 2];

arr.unshift(0); // result of the call is 3, which is the new array length
// arr is [0, 1, 2]

arr.unshift(-2, -1); // the new array length is 5
// arr is [-2, -1, 0, 1, 2]

arr.unshift([-4, -3]); // the new array length is 6
// arr is [[-4, -3], -2, -1, 0, 1, 2]

arr.unshift([-7, -6], [-5]); // the new array length is 8
// arr is [ [-7, -6], [-5], [-4, -3], -2, -1, 0, 1, 2 ]
```

Calling unshift() on non-array objects

The `unshift()` method reads the `length` property of `this`. It shifts all indices in the range `0` to `length - 1` right by the number of arguments (incrementing their values by this number). Then, it sets each index starting at `0` with the arguments passed to `unshift()`. Finally, it sets the `length` to the previous length plus the number of prepended elements.

```
const arrayLike = {
  length: 3,
  unrelated: "foo",
  2: 4,
};
Array.prototype.unshift.call(arrayLike, 1, 2);
console.log(arrayLike);
// { '0': 1, '1': 2, '4': 4, length: 5, unrelated: 'foo' }

const plainObj = {};
// There's no length property, so the length is 0
Array.prototype.unshift.call(plainObj, 1, 2);
console.log(plainObj);
// { '0': 1, '1': 2, length: 2 }
```

Array.prototype.values()

The **`values()`** method of `Array` instances returns a new *array iterator* object that iterates the value of each item in the array.

Try it

```
const array = ["a", "b", "c"];
const iterator = array.values();

for (const value of iterator) {
  console.log(value);
}

// Expected output: "a"
// Expected output: "b"
// Expected output: "c"
```

Syntax

```
values()
```

Parameters

None.

Return value

A new iterable iterator object.

Description

`Array.prototype.values()` is the default implementation of `Array.prototype[Symbol.iterator]()`.

```
Array.prototype.values === Array.prototype[Symbol.iterator]; // true
```

When used on sparse arrays, the `values()` method iterates empty slots as if they have the value `undefined`.

The `values()` method is generic. It only expects the `this` value to have a `length` property and integer-keyed properties.

Examples

Iteration using for...of loop

Because `values()` returns an iterable iterator, you can use a `for...of` loop to iterate it.

```
const arr = ["a", "b", "c", "d", "e"];
const iterator = arr.values();

for (const letter of iterator) {
  console.log(letter);
} // "a" "b" "c" "d" "e"
```

Iteration using next()

Because the return value is also an iterator, you can directly call its `next()` method.

```
const arr = ["a", "b", "c", "d", "e"];
const iterator = arr.values();
iterator.next(); // { value: "a", done: false }
iterator.next(); // { value: "b", done: false }
iterator.next(); // { value: "c", done: false }
iterator.next(); // { value: "d", done: false }
iterator.next(); // { value: "e", done: false }
iterator.next(); // { value: undefined, done: true }
console.log(iterator.next().value); // undefined
```

Reusing the iterable

> **Warning:** The array iterator object should be a one-time use object. Do not reuse it.

The iterable returned from `values()` is not reusable. When `next().done = true` or `currentIndex > length`, the `for...of` loop ends, and further iterating it has no effect.

```
const arr = ["a", "b", "c", "d", "e"];
const values = arr.values();
for (const letter of values) {
  console.log(letter);
}
// "a" "b" "c" "d" "e"
for (const letter of values) {
  console.log(letter);
}
// No output
```

If you use a `break` statement to end the iteration early, the iterator can resume from the current position when continuing to iterate it.

```
const arr = ["a", "b", "c", "d", "e"];
const values = arr.values();
for (const letter of values) {
  console.log(letter);
  if (letter === "b") {
    break;
  }
}
// "a" "b"

for (const letter of values) {
  console.log(letter);
}
// "c" "d" "e"
```

Mutations during iteration

There are no values stored in the array iterator object returned from `values()`; instead, it stores the address of the array used in its creation, and reads the currently visited index on each iteration. Therefore, its iteration output depends on the value stored in that index at the time of stepping. If the values in the array changed, the array iterator object's values change too.

```
const arr = ["a", "b", "c", "d", "e"];
const iterator = arr.values();
console.log(iterator); // Array Iterator { }
console.log(iterator.next().value); // "a"
arr[1] = "n";
console.log(iterator.next().value); // "n"
```

Unlike iterative methods, the array iterator object does not save the array's length at the time of its creation, but reads it once on each iteration. Therefore, if the array grows during iteration, the iterator will visit the new elements too. This may lead to infinite loops.

```
const arr = [1, 2, 3];
for (const e of arr) {
  arr.push(e * 10);
}
// RangeError: invalid array length
```

Iterating sparse arrays

`values()` will visit empty slots as if they are `undefined`.

```
for (const element of [, "a"].values()) {
  console.log(element);
}
// undefined
// 'a'
```

Calling values() on non-array objects

The `values()` method reads the `length` property of `this` and then accesses each property whose key is a nonnegative integer less than `length`.

```
const arrayLike = {
  length: 3,
  0: "a",
  1: "b",
  2: "c",
  3: "d", // ignored by values() since length is 3
};
for (const entry of Array.prototype.values.call(arrayLike)) {
  console.log(entry);
}
// a
// b
// c
```

Array.prototype.with()

The **`with()`** method of `Array` instances is the copying version of using the bracket notation to change the value of a given index. It returns a new array with the element at the given index replaced with the given value.

Syntax

```
arrayInstance.with(index, value)
```

Parameters

`index`

Zero-based index at which to change the array, converted to an integer.

- Negative index counts back from the end of the array — if `-array.length <= index < 0`, `index + array.length` is used.
- If the index after normalization is out of bounds, a `RangeError` is thrown.

`value`

Any value to be assigned to the given index.

Return value

A new array with the element at `index` replaced with `value`.

Exceptions

`RangeError`

Thrown if `index >= array.length` or `index < -array.length`.

Description

The `with()` method changes the value of a given index in the array, returning a new array with the element at the given index replaced with the given value. The original array is not modified. This allows you to chain array methods while doing manipulations.

By combining `with()` with `at()`, you can both write and read (respectively) an array using negative indices.

The `with()` method never produces a sparse array. If the source array is sparse, the empty slots will be replaced with `undefined` in the new array.

The `with()` method is generic. It only expects the `this` value to have a `length` property and integer-keyed properties.

Examples

Creating a new array with a single element changed

```
const arr = [1, 2, 3, 4, 5];
console.log(arr.with(2, 6)); // [1, 2, 6, 4, 5]
console.log(arr); // [1, 2, 3, 4, 5]
```

Chaining array methods

With the `with()` method, you can update a single element in an array and then apply other array methods.

```
const arr = [1, 2, 3, 4, 5];
console.log(arr.with(2, 6).map((x) => x ** 2)); // [1, 4, 36, 16, 25]
```

Using with() on sparse arrays

The `with()` method always creates a dense array.

```
const arr = [1, , 3, 4, , 6];
console.log(arr.with(0, 2)); // [2, undefined, 3, 4, undefined, 6]
```

Calling with() on non-array objects

The `with()` method creates and returns a new array. It reads the `length` property of `this` and then accesses each property whose key is a nonnegative integer less than `length`. As each property of `this` is accessed, the array element having an index equal to the key of the property is set to the value of the property. Finally, the array value at `index` is set to `value`.

```
const arrayLike = {
  length: 3,
  unrelated: "foo",
  0: 5,
  2: 4,
  3: 3, // ignored by with() since length is 3
};
console.log(Array.prototype.with.call(arrayLike, 0, 1));
// [ 1, undefined, 4 ]
```

ArrayBuffer

The **`ArrayBuffer`** object is used to represent a generic raw binary data buffer.

It is an array of bytes, often referred to in other languages as a "byte array". You cannot directly manipulate the contents of an `ArrayBuffer`; instead, you create one of the typed array objects or a `DataView` object which represents the buffer in a specific format, and use that to read and write the contents of the buffer.

The `ArrayBuffer()` constructor creates a new `ArrayBuffer` of the given length in bytes. You can also get an array buffer from existing data, for example, from a Base64 string or from a local file.

`ArrayBuffer` is a transferable object.

Description

Resizing ArrayBuffers

`ArrayBuffer` objects can be made resizable by including the `maxByteLength` option when calling the `ArrayBuffer()` constructor. You can query whether an `ArrayBuffer` is resizable and what its maximum size is by accessing its `resizable` and `maxByteLength` properties, respectively. You can assign a new size to a resizable `ArrayBuffer` with a `resize()` call. New bytes are initialized to 0.

These features make resizing `ArrayBuffer`s more efficient — otherwise, you have to make a copy of the buffer with a new size. It also gives JavaScript parity with WebAssembly in this regard (Wasm linear memory can be resized with `WebAssembly.Memory.prototype.grow()`).

Transferring ArrayBuffers

`ArrayBuffer` objects can be transferred between different execution contexts, like Web Workers or Service Workers, using the structured clone algorithm. This is done by passing the `ArrayBuffer` as a transferable object in a call to `Worker.postMessage()` or `ServiceWorker.postMessage()`. In pure JavaScript, you can also transfer the ownership of memory from one `ArrayBuffer` to another using its `transfer()` or `transferToFixedLength()` method.

When an `ArrayBuffer` is transferred, its original copy becomes *detached* — this means it is no longer usable. At any moment, there will only be one copy of the `ArrayBuffer` that actually has access to the underlying memory. Detached buffers have the following behaviors:

- `byteLength` becomes 0 (in both the buffer and the associated typed array views).
- Methods, such as `resize()` and `slice()`, throw a `TypeError` when invoked. The associated typed array views' methods also throw a `TypeError`.

You can check whether an `ArrayBuffer` is detached by its `detached` property.

Constructor

`ArrayBuffer()`

Creates a new `ArrayBuffer` object.

Static properties

`ArrayBuffer[Symbol.species]`

The constructor function that is used to create derived objects.

Static methods

`ArrayBuffer.isView()`

Returns `true` if `arg` is one of the ArrayBuffer views, such as typed array objects or a `DataView`. Returns `false` otherwise.

Instance properties

These properties are defined on `ArrayBuffer.prototype` and shared by all `ArrayBuffer` instances.

`ArrayBuffer.prototype.byteLength`

The size, in bytes, of the `ArrayBuffer`. This is established when the array is constructed and can only be changed using the `ArrayBuffer.prototype.resize()` method if the `ArrayBuffer` is resizable.

`ArrayBuffer.prototype.constructor`

The constructor function that created the instance object. For `ArrayBuffer` instances, the initial value is the `ArrayBuffer` constructor.

`ArrayBuffer.prototype.detached`

Read-only. Returns `true` if the `ArrayBuffer` has been detached (transferred), or `false` if not.

`ArrayBuffer.prototype.maxByteLength`

The read-only maximum length, in bytes, that the `ArrayBuffer` can be resized to. This is established when the array is constructed and cannot be changed.

`ArrayBuffer.prototype.resizable`

Read-only. Returns `true` if the `ArrayBuffer` can be resized, or `false` if not.

`ArrayBuffer.prototype[Symbol.toStringTag]`

The initial value of the `[Symbol.toStringTag]` property is the string `"ArrayBuffer"`. This property is used in `Object.prototype.toString()`.

Instance methods

`ArrayBuffer.prototype.resize()`

Resizes the `ArrayBuffer` to the specified size, in bytes.

`ArrayBuffer.prototype.slice()`

Returns a new `ArrayBuffer` whose contents are a copy of this `ArrayBuffer`'s bytes from `begin` (inclusive) up to `end` (exclusive). If either `begin` or `end` is negative, it refers to an index from the end of the array, as opposed to from the beginning.

`ArrayBuffer.prototype.transfer()`

Creates a new `ArrayBuffer` with the same byte content as this buffer, then detaches this buffer.

`ArrayBuffer.prototype.transferToFixedLength()`

Creates a new non-resizable `ArrayBuffer` with the same byte content as this buffer, then detaches this buffer.

Examples

Creating an ArrayBuffer

In this example, we create a 8-byte buffer with an `Int32Array` view referring to the buffer:

```
const buffer = new ArrayBuffer(8);
const view = new Int32Array(buffer);
```

See also

- Polyfill of `ArrayBuffer` in `core-js`
- JavaScript typed arrays guide
- `SharedArrayBuffer`
- RangeError: invalid array length

ArrayBuffer() constructor

The **`ArrayBuffer()`** constructor creates `ArrayBuffer` objects.

Try it

```
// Create an ArrayBuffer with a size in bytes
const buffer = new ArrayBuffer(8);

console.log(buffer.byteLength);
// Expected output: 8
```

Syntax

```
new ArrayBuffer(length)
new ArrayBuffer(length, options)
```

> **Note:** `ArrayBuffer()` can only be constructed with `new`. Attempting to call it without `new` throws a `TypeError`.

Parameters

`length`

The size, in bytes, of the array buffer to create.

`options` Optional

An object, which can contain the following properties:

`maxByteLength` Optional

The maximum size, in bytes, that the array buffer can be resized to.

Return value

A new `ArrayBuffer` object of the specified size, with its `maxByteLength` property set to the specified `maxByteLength` if one was specified. Its contents are initialized to 0.

Exceptions

`RangeError`

Thrown in one of the following cases:

- `length` or `maxByteLength` is larger than `Number.MAX_SAFE_INTEGER` ($\geq 2^{53}$) or negative.
- `length` is larger than `maxByteLength`.

Examples

Creating an ArrayBuffer

In this example, we create a 8-byte buffer with an `Int32Array` view referring to the buffer:

```
const buffer = new ArrayBuffer(8);
const view = new Int32Array(buffer);
```

Creating a resizable ArrayBuffer

In this example, we create a 8-byte buffer that is resizable to a max length of 16 bytes, then `resize()` it to 12 bytes:

```
const buffer = new ArrayBuffer(8, { maxByteLength: 16 });

buffer.resize(12);
```

> **Note:** It is recommended that `maxByteLength` is set to the smallest value possible for your use case. It should never exceed `1073741824` (1GB) to reduce the risk of out-of-memory errors.

See also

- Polyfill of `ArrayBuffer` in `core-js`
- JavaScript typed arrays guide
- `SharedArrayBuffer`

ArrayBuffer.prototype.byteLength

The **`byteLength`** accessor property of `ArrayBuffer` instances returns the length (in bytes) of this array buffer.

Try it

```
// Create an ArrayBuffer with a size in bytes
const buffer = new ArrayBuffer(8);

// Use byteLength to check the size
const bytes = buffer.byteLength;

console.log(bytes);
// Expected output: 8
```

Description

The `byteLength` property is an accessor property whose set accessor function is `undefined`, meaning that you can only read this property. The value is established when the array is constructed and cannot be changed. This property returns 0 if this `ArrayBuffer` has been detached.

Examples

Using byteLength

```
const buffer = new ArrayBuffer(8);
buffer.byteLength; // 8
```

See also

- `ArrayBuffer`

ArrayBuffer.prototype.detached

The **`detached`** accessor property of `ArrayBuffer` instances returns a boolean indicating whether or not this buffer has been detached (transferred).

Description

The `detached` property is an accessor property whose set accessor function is `undefined`, meaning that you can only read this property. The value is `false` when the `ArrayBuffer` is first created. The value becomes `true` if the `ArrayBuffer` is transferred, which detaches the instance from its underlying memory. Once a buffer becomes detached, it is no longer usable.

Examples

Using detached

```
const buffer = new ArrayBuffer(8);
console.log(buffer.detached); // false
const newBuffer = buffer.transfer();
console.log(buffer.detached); // true
console.log(newBuffer.detached); // false
```

See also

- Polyfill of `ArrayBuffer.prototype.detached` in `core-js`
- es-shims polyfill of `ArrayBuffer.prototype.detached`
- `ArrayBuffer`
- `ArrayBuffer.prototype.transfer()`
- `ArrayBuffer.prototype.transferToFixedLength()`

ArrayBuffer.isView()

The **`ArrayBuffer.isView()`** static method determines whether the passed value is one of the `ArrayBuffer` views, such as typed array objects or a `DataView`.

Try it

```
// Create an ArrayBuffer with a size in bytes
const buffer = new ArrayBuffer(16);

console.log(ArrayBuffer.isView(new Int32Array()));
// Expected output: true
```

Syntax

```
ArrayBuffer.isView(value)
```

Parameters

`value`

The value to be checked.

Return value

`true` if the given argument is one of the `ArrayBuffer` views; otherwise, `false`.

Examples

Using isView

```
ArrayBuffer.isView(); // false
ArrayBuffer.isView([]); // false
ArrayBuffer.isView({}); // false
ArrayBuffer.isView(null); // false
ArrayBuffer.isView(undefined); // false
ArrayBuffer.isView(new ArrayBuffer(10)); // false

ArrayBuffer.isView(new Uint8Array()); // true
ArrayBuffer.isView(new Float32Array()); // true
ArrayBuffer.isView(new Int8Array(10).subarray(0, 3)); // true

const buffer = new ArrayBuffer(2);
const dv = new DataView(buffer);
ArrayBuffer.isView(dv); // true
```

See also

- JavaScript typed arrays guide

ArrayBuffer.prototype.maxByteLength

The **`maxByteLength`** accessor property of `ArrayBuffer` instances returns the maximum length (in bytes) that this array buffer can be resized to.

Try it

```
const buffer = new ArrayBuffer(8, { maxByteLength: 16 });

console.log(buffer.byteLength);
// Expected output: 8

console.log(buffer.maxByteLength);
// Expected output: 16
```

Description

The `maxByteLength` property is an accessor property whose set accessor function is `undefined`, meaning that you can only read this property. The value is established when the array is constructed, set via the `maxByteLength` option of the `ArrayBuffer()` constructor, and cannot be changed.

This property returns 0 if this `ArrayBuffer` has been detached. If this `ArrayBuffer` was constructed without specifying a `maxByteLength` value, this property returns a value equal to the value of the `ArrayBuffer`'s `byteLength`.

Examples

Using maxByteLength

In this example, we create an 8-byte buffer that is resizable to a max length of 16 bytes, then return its `maxByteLength`:

```
const buffer = new ArrayBuffer(8, { maxByteLength: 16 });

buffer.maxByteLength; // 16
```

See also

- `ArrayBuffer`
- `ArrayBuffer.prototype.byteLength`
- `ArrayBuffer.prototype.resize()`

ArrayBuffer.prototype.resizable

The **`resizable`** accessor property of `ArrayBuffer` instances returns whether this array buffer can be resized or not.

Try it

```
const buffer1 = new ArrayBuffer(8, { maxByteLength: 16 });
const buffer2 = new ArrayBuffer(8);

console.log(buffer1.resizable);
// Expected output: true

console.log(buffer2.resizable);
// Expected output: false
```

Description

The `resizable` property is an accessor property whose set accessor function is `undefined`, meaning that you can only read this property. The value is established when the array is constructed. If the `maxByteLength` option was set in the constructor, `resizable` will return `true`; if not, it will return `false`.

Examples

Using resizable

In this example, we create a 8-byte buffer that is resizable to a max length of 16 bytes, then check its `resizable` property, resizing it if `resizable` returns `true`:

```
const buffer = new ArrayBuffer(8, { maxByteLength: 16 });

if (buffer.resizable) {
  console.log("Buffer is resizable!");
  buffer.resize(12);
}
```

See also

- `ArrayBuffer`
- `ArrayBuffer.prototype.maxByteLength`
- `ArrayBuffer.prototype.resize()`

ArrayBuffer.prototype.resize()

The **`resize()`** method of `ArrayBuffer` instances resizes the `ArrayBuffer` to the specified size, in bytes.

Try it

```
const buffer = new ArrayBuffer(8, { maxByteLength: 16 });

console.log(buffer.byteLength);
// Expected output: 8

buffer.resize(12);

console.log(buffer.byteLength);
// Expected output: 12
```

Syntax

```
resize(newLength)
```

Parameters

`newLength`

The new length, in bytes, to resize the `ArrayBuffer` to.

Return value

None (`undefined`).

Exceptions

`TypeError`

Thrown if the `ArrayBuffer` is detached or is not resizable.

`RangeError`

Thrown if `newLength` is larger than the `maxByteLength` of the `ArrayBuffer`.

Description

The `resize()` method resizes an `ArrayBuffer` to the size specified by the `newLength` parameter, provided that the `ArrayBuffer` is resizable and the new size is less than or equal to the `maxByteLength` of the `ArrayBuffer`. New bytes are initialized to 0.

Note that you can use `resize()` to shrink as well as grow an `ArrayBuffer` — it is permissible for `newLength` to be smaller than the `ArrayBuffer`'s current `byteLength`.

Examples

Using resize()

In this example, we create a 8-byte buffer that is resizable to a max length of 16 bytes, then check its `resizable` property, resizing it if `resizable` returns `true`:

```
const buffer = new ArrayBuffer(8, { maxByteLength: 16 });

if (buffer.resizable) {
  console.log("Buffer is resizable!");
  buffer.resize(12);
}
```

See also

- `ArrayBuffer`
- `ArrayBuffer.prototype.resizable`
- `ArrayBuffer.prototype.maxByteLength`

ArrayBuffer.prototype.slice()

The **`slice()`** method of `ArrayBuffer` instances returns a new `ArrayBuffer` whose contents are a copy of this `ArrayBuffer`'s bytes from `start`, inclusive, up to `end`, exclusive. If either `start` or `end` is negative, it refers to an index from the end of the array, as opposed to from the beginning.

Try it

```
// Create an ArrayBuffer with a size in bytes
const buffer = new ArrayBuffer(16);
const int32View = new Int32Array(buffer);
// Produces Int32Array [0, 0, 0, 0]

int32View[1] = 42;
const sliced = new Int32Array(buffer.slice(4, 12));
// Produces Int32Array [42, 0]

console.log(sliced[0]);
// Expected output: 42
```

Syntax

```
slice()
slice(start)
slice(start, end)
```

Parameters

`start` Optional

Zero-based index at which to start extraction, converted to an integer.

- Negative index counts back from the end of the buffer — if `-buffer.length <= start < 0`, `start + buffer.length` is used.
- If `start < -buffer.length` or `start` is omitted, `0` is used.
- If `start >= buffer.length`, an empty buffer is returned.

`end` Optional

Zero-based index at which to end extraction, converted to an integer. `slice()` extracts up to but not including `end`.

- Negative index counts back from the end of the buffer — if `-buffer.length <= end < 0`, `end + buffer.length` is used.
- If `end < -buffer.length`, `0` is used.
- If `end >= buffer.length` or `end` is omitted is `undefined`, `buffer.length` is used, causing all elements until the end to be extracted.
- If `end` implies a position before or at the position that `start` implies, an empty buffer is returned.

Return value

A new `ArrayBuffer` containing the extracted elements. It is not resizable, even if the original was.

Examples

Copying an ArrayBuffer

```
const buf1 = new ArrayBuffer(8);
const buf2 = buf1.slice(0);
```

See also

- `ArrayBuffer`
- `SharedArrayBuffer.prototype.slice()`

ArrayBuffer[Symbol.species]

The **`ArrayBuffer[Symbol.species]`** static accessor property returns the constructor used to construct return values from array buffer methods.

> **Warning:** The existence of `[Symbol.species]` allows execution of arbitrary code and may create security vulnerabilities. It also makes certain optimizations much harder. Engine implementers are investigating whether to remove this feature. Avoid relying on it if possible.

Syntax

```
ArrayBuffer[Symbol.species]
```

Return value

The value of the constructor (`this`) on which `get [Symbol.species]` was called. The return value is used to construct return values from array buffer methods that create new array buffers.

Description

The `[Symbol.species]` accessor property returns the default constructor for `ArrayBuffer` objects. Subclass constructors may override it to change the constructor assignment. The default implementation is basically:

```
// Hypothetical underlying implementation for illustration
class ArrayBuffer {
  static get [Symbol.species]() {
    return this;
  }
}
```

Because of this polymorphic implementation, `[Symbol.species]` of derived subclasses would also return the constructor itself by default.

```
class SubArrayBuffer extends ArrayBuffer {}
SubArrayBuffer[Symbol.species] === SubArrayBuffer; // true
```

When calling array buffer methods that do not mutate the existing object but return a new array buffer instance (for example, `slice()`), the object's `constructor[Symbol.species]` will be accessed. The returned constructor will be used to construct the return value of the array buffer method.

Examples

Species in ordinary objects

The `[Symbol.species]` property returns the default constructor function, which is the `ArrayBuffer` constructor for `ArrayBuffer`.

```
ArrayBuffer[Symbol.species]; // function ArrayBuffer()
```

Species in derived objects

In an instance of a custom `ArrayBuffer` subclass, such as `MyArrayBuffer`, the `MyArrayBuffer` species is the `MyArrayBuffer` constructor. However, you might want to overwrite this, in order to return parent `ArrayBuffer` objects in your derived class methods:

```
class MyArrayBuffer extends ArrayBuffer {
  // Overwrite MyArrayBuffer species to the parent ArrayBuffer constructor
  static get [Symbol.species]() {
    return ArrayBuffer;
  }
}
```

See also

- `ArrayBuffer`
- `Symbol.species`

ArrayBuffer.prototype.transfer()

The **`transfer()`** method of `ArrayBuffer` instances creates a new `ArrayBuffer` with the same byte content as this buffer, then detaches this buffer.

Syntax

```
transfer()
transfer(newByteLength)
```

Parameters

`newByteLength` Optional

The `byteLength` of the new `ArrayBuffer`. Defaults to the `byteLength` of this `ArrayBuffer`.

- If `newByteLength` is smaller than the `byteLength` of this `ArrayBuffer`, the "overflowing" bytes are dropped.
- If `newByteLength` is larger than the `byteLength` of this `ArrayBuffer`, the extra bytes are filled with zeros.
- If this `ArrayBuffer` is resizable, `newByteLength` must not be greater than its `maxByteLength`.

Return value

A new `ArrayBuffer` object. Its contents are initialized to the contents of this `ArrayBuffer`, and extra bytes, if any, are filled with zeros. The new `ArrayBuffer` is resizable if and only if this `ArrayBuffer` is resizable, in which case its `maxByteLength` is the same as this `ArrayBuffer`'s. The original `ArrayBuffer` is detached.

Exceptions

`RangeError`

Thrown if this `ArrayBuffer` is resizable and `newByteLength` is greater than the `maxByteLength` of this `ArrayBuffer`.

`TypeError`

Thrown if this `ArrayBuffer` is already detached, or if it can only be detached by designated operations. Currently, only certain web APIs are capable of creating `ArrayBuffer` objects with designated detaching methods, such as `GPUBuffer.getMappedRange()` and `WebAssembly.Memory.buffer`.

Description

The `transfer()` method performs the same operation as the structured clone algorithm. It copies the bytes of this `ArrayBuffer` into a new `ArrayBuffer` object, then detaches this `ArrayBuffer` object. See transferring ArrayBuffers for more information.

`transfer()` preserves the resizability of this `ArrayBuffer`. If you want the new `ArrayBuffer` to be non-resizable, use `transferToFixedLength()` instead. There's no way to transfer a buffer that makes a fixed-length buffer become resizable.

`transfer()` is very efficient because implementations may implement this method as a zero-copy move or a `realloc` — there does not need to be an actual copy of the data.

Examples

Transferring an ArrayBuffer

```
// Create an ArrayBuffer and write a few bytes
const buffer = new ArrayBuffer(8);
const view = new Uint8Array(buffer);
view[1] = 2;
view[7] = 4;

// Copy the buffer to the same size
const buffer2 = buffer.transfer();
console.log(buffer.detached); // true
console.log(buffer2.byteLength); // 8
const view2 = new Uint8Array(buffer2);
console.log(view2[1]); // 2
console.log(view2[7]); // 4

// Copy the buffer to a smaller size
const buffer3 = buffer2.transfer(4);
console.log(buffer3.byteLength); // 4
const view3 = new Uint8Array(buffer3);
console.log(view3[1]); // 2
console.log(view3[7]); // undefined

// Copy the buffer to a larger size
const buffer4 = buffer3.transfer(8);
console.log(buffer4.byteLength); // 8
const view4 = new Uint8Array(buffer4);
console.log(view4[1]); // 2
console.log(view4[7]); // 0

// Already detached, throws TypeError
buffer.transfer(); // TypeError: Cannot perform ArrayBuffer.prototype.transfer on a detached ArrayBuffer
```

Transferring a resizable ArrayBuffer

```
const buffer = new ArrayBuffer(8, { maxByteLength: 16 });
const view = new Uint8Array(buffer);
view[1] = 2;
view[7] = 4;

// Copy the buffer to a smaller size
const buffer2 = buffer.transfer(4);
console.log(buffer2.byteLength); // 4
console.log(buffer2.maxByteLength); // 16
const view2 = new Uint8Array(buffer2);
console.log(view2[1]); // 2
console.log(view2[7]); // undefined
buffer2.resize(8);
console.log(view2[7]); // 0

// Copy the buffer to a larger size within maxByteLength
const buffer3 = buffer2.transfer(12);
console.log(buffer3.byteLength); // 12

// Copy the buffer to a larger size than maxByteLength
buffer3.transfer(20); // RangeError: Invalid array buffer length
```

See also

- Polyfill of `ArrayBuffer.prototype.transfer` in `core-js`
- es-shims polyfill of `ArrayBuffer.prototype.transfer`
- `ArrayBuffer`
- `ArrayBuffer.prototype.detached`
- `ArrayBuffer.prototype.transferToFixedLength()`

ArrayBuffer.prototype.transferToFixedLength()

The **`transferToFixedLength()`** method of `ArrayBuffer` instances creates a new non-resizable `ArrayBuffer` with the same byte content as this buffer, then detaches this buffer.

Syntax

```
transferToFixedLength()
transferToFixedLength(newByteLength)
```

Parameters

`newByteLength`

The `byteLength` of the new `ArrayBuffer`. Defaults to the `byteLength` of this `ArrayBuffer`.

- If `newByteLength` is smaller than the `byteLength` of this `ArrayBuffer`, the "overflowing" bytes are dropped.
- If `newByteLength` is larger than the `byteLength` of this `ArrayBuffer`, the extra bytes are filled with zeros.

Return value

A new `ArrayBuffer` object. Its contents are initialized to the contents of this `ArrayBuffer`, and extra bytes, if any, are filled with zeros. The new `ArrayBuffer` is always non-resizable. The original `ArrayBuffer` is detached.

Exceptions

`TypeError`

Thrown if this `ArrayBuffer` is already detached, or if it can only be detached by designated operations. Currently, only certain web APIs are capable of creating `ArrayBuffer` objects with designated detaching methods, such as `GPUBuffer.getMappedRange()` and `WebAssembly.Memory.buffer`.

Description

Unlike `transfer()`, `transferToFixedLength()` always creates a non-resizable `ArrayBuffer`. This means `newByteLength` can be larger than the `maxByteLength`, even if this `ArrayBuffer` is resizable. See transferring ArrayBuffers for more information.

Examples

Transferring a resizable ArrayBuffer to fixed-length

```
const buffer = new ArrayBuffer(8, { maxByteLength: 16 });
const view = new Uint8Array(buffer);
view[1] = 2;
view[7] = 4;

const buffer2 = buffer.transferToFixedLength();
console.log(buffer2.byteLength); // 8
console.log(buffer2.resizable); // false
const view2 = new Uint8Array(buffer2);
console.log(view2[1]); // 2
console.log(view2[7]); // 4
```

Using `transferToFixedLength`, `newByteLength` can be larger than the `maxByteLength` of the original `ArrayBuffer`.

```
const buffer = new ArrayBuffer(8, { maxByteLength: 16 });
const view = new Uint8Array(buffer);
view[1] = 2;
view[7] = 4;

const buffer2 = buffer.transferToFixedLength(20);
console.log(buffer2.byteLength); // 20
console.log(buffer2.resizable); // false
const view2 = new Uint8Array(buffer2);
console.log(view2[1]); // 2
console.log(view2[7]); // 4
```

AsyncDisposableStack

The **`AsyncDisposableStack`** object represents a stack of async disposers to run when the stack itself is disposed. Disposer functions are executed in reverse order of registration, with strong error handling guarantees. Calling its `move()` method will transfer responsibility for calling the current registered disposers to a new `AsyncDisposableStack` and prevent registering any additional disposers.

See `DisposableStack` for general information about using disposable stacks.

Constructor

`AsyncDisposableStack()`

Creates a new `AsyncDisposableStack` object.

Instance properties

These properties are defined on `AsyncDisposableStack.prototype` and shared by all `AsyncDisposableStack` instances.

`AsyncDisposableStack.prototype.constructor`

The constructor function that created the instance object. For `AsyncDisposableStack` instances, the initial value is the `AsyncDisposableStack` constructor.

`AsyncDisposableStack.prototype.disposed`

Read-only. Returns `true` if the `AsyncDisposableStack` has been disposed, or `false` if not.

`AsyncDisposableStack.prototype[Symbol.toStringTag]`

The initial value of the `[Symbol.toStringTag]` property is the string `"AsyncDisposableStack"`. This property is used in `Object.prototype.toString()`.

Instance methods

`AsyncDisposableStack.prototype.adopt()`

Registers a value that doesn't implement the async disposable protocol to the stack by providing a custom disposer function.

`AsyncDisposableStack.prototype.disposeAsync()`

Disposes this stack by calling all disposers registered to it in reverse order of registration.

`AsyncDisposableStack.prototype.defer()`

Takes a callback function to be called when the stack is disposed.

`AsyncDisposableStack.prototype.move()`

Creates a new `AsyncDisposableStack` instance that contains the same disposers as this stack, and then marks this stack as disposed, without calling any disposers.

`AsyncDisposableStack.prototype.use()`

Registers a value that implements the async disposable protocol to the stack.

`AsyncDisposableStack.prototype[Symbol.asyncDispose]`

An alias for the `disposeAsync()` method.

See also

- Polyfill of `AsyncDisposableStack` in `core-js`
- JavaScript resource management
- `Symbol.asyncDispose`
- `await using`
- `DisposableStack`

AsyncDisposableStack.prototype.adopt()

The **`adopt()`** method of `AsyncDisposableStack` instances registers a value that doesn't implement the async disposable protocol to the stack by providing a custom disposer function.

See `DisposableStack.prototype.adopt()` for general information about the `adopt()` method.

Syntax

```
adopt(value, onDispose)
```

Parameters

`value`

Any value to be registered to the stack.

`onDispose`

A function that will be called when the stack is disposed. The function receives `value` as its only argument, and it can return a promise which gets awaited.

Return value

The same `value` that was passed in.

Exceptions

`TypeError`

Thrown if `onDispose` is not a function.

`ReferenceError`

Thrown if the stack is already disposed.

Examples

Using adopt()

This function creates a file handle (as a Node.js `FileHandle`), that gets closed when the function completes. We suppose that the file handle does not implement the async disposable protocol (in reality it does), so we use `adopt()` to register it to the stack. Because the `handle.close()` method returns a promise, we need to use an `AsyncDisposableStack` so that the disposal gets awaited.

```
async function readFile(path) {
  await using disposer = new AsyncDisposableStack();
  const handle = disposer.adopt(
    await fs.open(path),
    async (handle) => await handle.close(),
  );
  const data = await handle.read();
  // The handle.close() method is called and awaited here before exiting
  return data;
}
```

See also

- JavaScript resource management
- `AsyncDisposableStack`
- `AsyncDisposableStack.prototype.defer()`
- `AsyncDisposableStack.prototype.use()`

AsyncDisposableStack() constructor

The **`AsyncDisposableStack()`** constructor creates `AsyncDisposableStack` objects.

Syntax

```
new AsyncDisposableStack()
```

> **Note:** `AsyncDisposableStack()` can only be constructed with `new`. Attempting to call it without `new` throws a `TypeError`.

Parameters

None.

Return value

A new `AsyncDisposableStack` object.

Examples

Creating an AsyncDisposableStack

```
const disposer = new AsyncDisposableStack();
disposer.defer(() => console.log("Disposed!"));
await disposer.disposeAsync();
// Logs: Disposed!
```

See also

- JavaScript resource management

AsyncDisposableStack.prototype.defer()

The **`defer()`** method of `AsyncDisposableStack` instances takes a callback function to be called and awaited when the stack is disposed.

See `DisposableStack.prototype.defer()` for general information about the `defer()` method.

Syntax

```
defer(onDispose)
```

Parameters

`onDispose`

A function that will be called when the stack is disposed. The function receives no arguments and can return a promise which gets awaited.

Return value

None (`undefined`).

Exceptions

`TypeError`

Thrown if `onDispose` is not a function.

`ReferenceError`

Thrown if the stack is already disposed.

Examples

Using defer()

One use case of `defer()` is to do something unrelated to resource freeing during scope exit, such as logging a message.

```
async function doSomething() {
  await using disposer = new AsyncDisposableStack();
  disposer.defer(async () => {
    await fs.writeFile("log.txt", "All resources freed successfully");
  });
  // Other code that claims and frees more data
}
```

See also

- JavaScript resource management
- `AsyncDisposableStack`
- `AsyncDisposableStack.prototype.adopt()`
- `AsyncDisposableStack.prototype.use()`

AsyncDisposableStack.prototype.disposeAsync()

The **`disposeAsync()`** method of `AsyncDisposableStack` instances disposes this stack by calling all disposers registered to it in reverse order of registration, awaiting for each one's completion before calling the next one. If the stack is already disposed, this method does nothing.

It performs the same action as `await using disposer = new AsyncDisposableStack()` at scope exit. It can be used if you need to clean up at a point other than scope exit.

Syntax

```
disposeAsync()
```

Parameters

None.

Return value

A new `Promise` that resolves with `undefined` when all registered disposers have completed in sequence.

Exceptions

`disposeAsync()` never synchronously throws an error. The returned promise may reject with one of the following errors:

`SuppressedError`

Thrown if multiple disposers in the stack threw an error. If only one error is thrown, it is rethrown as-is. Otherwise, for each additional error, a new `SuppressedError` is created, with the original error as the `suppressed` property, and the new error as the `error` property.

Examples

Disposing a stack

Here we push three disposers to the stack, using the `use()`, `adopt()`, and `defer()` methods. When `disposeAsync()` is called, the disposers are called in reverse order of registration.

Note that usually you don't need to call `disposeAsync()` manually. Declare the stack with `await using`, and its `[Symbol.asyncDispose]()` method will be automatically called when the stack goes out of scope.

```
class Resource {
  #doDisposal() {
    // Imagine more meaningful disposal logic here
    return new Promise((resolve) => {
      setTimeout(resolve, 1000);
    });
  }
  async dispose() {
    await this.#doDisposal();
    console.log("Resource disposed");
  }
  async [Symbol.asyncDispose]() {
    await this.#doDisposal();
    console.log("Resource disposed via Symbol.asyncDispose");
  }
}

async function doSomething() {
  const disposer = new AsyncDisposableStack();
  const resource = disposer.use(new Resource());
  const resource2 = disposer.adopt(new Resource(), (resource) =>
```

```
    resource.dispose(),
  );
  disposer.defer(() => console.log("Deferred disposer"));
  disposer.disposeAsync();
  // Logs in order:
  // Deferred disposer
  // Resource disposed
  // Resource disposed via Symbol.dispose
}

doSomething();
```

See also

- JavaScript resource management
- `AsyncDisposableStack`
- `AsyncDisposableStack.prototype.adopt()`
- `AsyncDisposableStack.prototype.defer()`
- `AsyncDisposableStack.prototype.use()`
- `AsyncDisposableStack.prototype[Symbol.asyncDispose]()`

AsyncDisposableStack.prototype.disposed

The **`disposed`** accessor property of `AsyncDisposableStack` instances returns a boolean indicating whether or not this `AsyncDisposableStack` has been disposed or moved by doing any of the following:

- Calling its `disposeAsync()` method
- Calling its `move()` method
- Declaring it with `await using` and letting the variable go out of scope, which automatically calls the `[Symbol.asyncDispose]()` method.

Examples

Checking if a stack is disposed

```
const disposer = new AsyncDisposableStack();
console.log(disposer.disposed); // false
await disposer.disposeAsync();
console.log(disposer.disposed); // true
```

See also

- JavaScript resource management

AsyncDisposableStack.prototype.move()

The **`move()`** method of `AsyncDisposableStack` instances creates a new `AsyncDisposableStack` instance that contains the same disposers as this stack, and then marks this stack as disposed, without calling any disposers.

Syntax

```
move()
```

Parameters

None.

Return value

A new `AsyncDisposableStack` instance.

Exceptions

`ReferenceError`

Thrown if the stack is already disposed.

Examples

Claiming ownership of a stack

```
async function consumeStack(stack) {
  await using newStack = stack.move(); // newStack now owns the disposers
  console.log(stack.disposed); // true
  console.log(newStack.disposed); // false
  // newStack is disposed here immediately before the function exits
}

const stack = new AsyncDisposableStack();
console.log(stack.disposed); // false
await consumeStack(stack);
console.log(stack.disposed); // true
```

Allowing resources to be disposed within two code paths

The major use case of `move()` is when you have one or more resources which could either be disposed right here or could be persisted for later use. In this case, you can put the resources in an `AsyncDisposableStack` and then call `move()` when you need to persist the resources for later usage.

```
class PluginHost {
  #disposed = false;
  #disposables;
  #channel;
  #socket;

  static async init() {
    // Create an AsyncDisposableStack that is disposed when init exits.
    // If construction succeeds, we move everything out of `stack` and into
    // `#disposables` to be disposed later.
    await using stack = new AsyncDisposableStack();

    const channel = stack.use(await getChannel());

    const socket = stack.use(await getSocket());

    // If we made it here, then there were no errors during construction and
    // we can safely move the disposables out of `stack`.
    return new PluginHost(channel, socket, stack.move());

    // If construction failed, then `stack` would be disposed before reaching
    // the line above, which would dispose `channel` and `socket` in turn.
  }

  constructor(channel, socket, disposables) {
    this.#channel = channel;
    this.#socket = socket;
    this.#disposables = disposables;
  }

  async [Symbol.asyncDispose]() {
    if (this.#disposed) {
      return;
    }
    this.#disposed = true;
    // Put `this.#disposables` into a `using` variable, so it is automatically
    // disposed when the function exits.
    await using disposables = this.#disposables;

    // NOTE: we can free `#socket` and `#channel` here since they will be
    // disposed by the call to `disposables[Symbol.asyncDispose]()`, below.
    // This isn't strictly a requirement for every disposable, but is
    // good housekeeping since these objects will no longer be useable.
    this.#socket = undefined;
    this.#channel = undefined;
    this.#disposables = undefined;
  }
}
```

See also

- JavaScript resource management
- `AsyncDisposableStack`
- `AsyncDisposableStack.prototype.disposeAsync()`

AsyncDisposableStack.prototype[Symbol.asyncDispose]()

The **`[Symbol.asyncDispose]()`** method of `AsyncDisposableStack` instances implements the *async disposable protocol* and allows it to be disposed when used with `await using`. It is an alias for the `disposeAsync()` method.

Syntax

```
asyncDisposableStack[Symbol.asyncDispose]()
```

Parameters

None.

Return value

None (`undefined`).

Examples

Declaring a stack with <code>await using</code>

The `Symbol.asyncDispose` method is intended to be automatically called in an `await using` declaration.

```
async function doSomething() {
  await using disposer = new AsyncDisposableStack();
  const resource = disposer.use(new Resource());
```

```
  resource.doSomething();
  // disposer is disposed here immediately before the function exits
  // which causes the resource to be disposed
}
```

See also

- JavaScript resource management
- `AsyncDisposableStack`
- `AsyncDisposableStack.prototype.disposeAsync()`

AsyncDisposableStack.prototype.use()

The **`use()`** method of `AsyncDisposableStack` instances registers a value that implements the async disposable protocol to the stack.

See `DisposableStack.prototype.use()` for general information about the `use()` method.

Syntax

```
use(value)
```

Parameters

`value`

The value to register to the stack. Must either contain a `[Symbol.asyncDispose]()` or `[Symbol.dispose]()` method, or be `null` or `undefined`.

Return value

The same `value` that was passed in.

Exceptions

`TypeError`

Thrown if `value` is not `null` or `undefined`, and does not contain a `[Symbol.asyncDispose]()` or `[Symbol.dispose]()` method.

`ReferenceError`

Thrown if the stack is already disposed.

Examples

Using use()

This function reads a file (as a Node.js `FileHandle`) and returns its contents. The file handle is automatically closed when the function completes, given that the `FileHandle` class implements a `[Symbol.asyncDispose]()` method that asynchronously closes the file.

```
async function readFileContents(path) {
  await using disposer = new AsyncDisposableStack();
  const handle = disposer.use(await fs.open(path));
  const data = await handle.read();
  return data;
  // The disposer is disposed here, which causes handle to be closed too
}
```

- JavaScript resource management
- `AsyncDisposableStack`
- `AsyncDisposableStack.prototype.adopt()`
- `AsyncDisposableStack.prototype.defer()`

AsyncFunction

The **`AsyncFunction`** object provides methods for async functions. In JavaScript, every async function is actually an `AsyncFunction` object.

Note that `AsyncFunction` is *not* a global object. It can be obtained with the following code:

```
const AsyncFunction = async function () {}.constructor;
```

`AsyncFunction` is a subclass of `Function`.

Constructor

`AsyncFunction()`

Creates a new `AsyncFunction` object.

Instance properties

Also inherits instance properties from its parent `Function`.

These properties are defined on `AsyncFunction.prototype` and shared by all `AsyncFunction` instances.

`AsyncFunction.prototype.constructor`

The constructor function that created the instance object. For `AsyncFunction` instances, the initial value is the `AsyncFunction` constructor.

`AsyncFunction.prototype[Symbol.toStringTag]`

The initial value of the `[Symbol.toStringTag]` property is the string `"AsyncFunction"`. This property is used in `Object.prototype.toString()`.

> **Note:** `AsyncFunction` instances do not have the `prototype` property.

Instance methods

Inherits instance methods from its parent `Function`.

AsyncFunction() constructor

> **Warning:** The arguments passed to this constructor are dynamically parsed and executed as JavaScript. APIs like this are known as injection sinks, and are potentially a vector for cross-site-scripting (XSS) attacks.
>
> You can mitigate this risk by always passing `TrustedScript` objects instead of strings and enforcing trusted types.
>
> See Security considerations in the `Function()` constructor reference for more information.

The **`AsyncFunction()`** constructor creates `AsyncFunction` objects.

Note that `AsyncFunction` is *not* a global object. It can be obtained with the following code:

```
const AsyncFunction = async function () {}.constructor;
```

The `AsyncFunction()` constructor is not intended to be used directly, and all caveats mentioned in the `Function()` description apply to `AsyncFunction()`.

Syntax

```
new AsyncFunction(functionBody)
new AsyncFunction(arg1, functionBody)
new AsyncFunction(arg1, arg2, functionBody)
new AsyncFunction(arg1, arg2, /* …, */ argN, functionBody)

AsyncFunction(functionBody)
AsyncFunction(arg1, functionBody)
AsyncFunction(arg1, arg2, functionBody)
AsyncFunction(arg1, arg2, /* …, */ argN, functionBody)
```

> **Note:** `AsyncFunction()` can be called with or without `new`. Both create a new `AsyncFunction` instance.

Parameters

See `Function()`.

Examples

Note that these examples omit the use of trusted types for brevity. For code showing the recommended approach, see Using `TrustedScript` in `eval()`.

Creating an async function from an AsyncFunction() constructor

```
function resolveAfter2Seconds(x) {
  return new Promise((resolve) => {
    setTimeout(() => {
      resolve(x);
    }, 2000);
  });
}

const AsyncFunction = async function () {}.constructor;

const fn = new AsyncFunction(
  "a",
```

```
  "b",
  "return await resolveAfter2Seconds(a) + await resolveAfter2Seconds(b);",
);

fn(10, 20).then((v) => {
  console.log(v); // prints 30 after 4 seconds
});
```

See also

- `async function`
- `async function` expression
- `Function()` constructor

AsyncGenerator

The **`AsyncGenerator`** object is returned by an async generator function and it conforms to both the async iterable protocol and the async iterator protocol.

Async generator methods always yield `Promise` objects.

`AsyncGenerator` is a subclass of the hidden `AsyncIterator` class.

Constructor

There's no JavaScript entity that corresponds to the `AsyncGenerator` constructor. Instances of `AsyncGenerator` must be returned from async generator functions:

```
async function* createAsyncGenerator() {
  yield Promise.resolve(1);
  yield await Promise.resolve(2);
  yield 3;
}
const asyncGen = createAsyncGenerator();
asyncGen.next().then((res) => console.log(res.value)); // 1
asyncGen.next().then((res) => console.log(res.value)); // 2
asyncGen.next().then((res) => console.log(res.value)); // 3
```

There's only a hidden object which is the prototype object shared by all objects created by async generator functions. This object is often stylized as `AsyncGenerator.prototype` to make it look like a class, but it should be more appropriately called `AsyncGeneratorFunction.prototype.prototype`, because `AsyncGeneratorFunction` is an actual JavaScript entity. To understand the prototype chain of `AsyncGenerator` instances, see `AsyncGeneratorFunction.prototype.prototype`.

Instance properties

These properties are defined on `AsyncGenerator.prototype` and shared by all `AsyncGenerator` instances.

`AsyncGenerator.prototype.constructor`

> The constructor function that created the instance object. For `AsyncGenerator` instances, the initial value is `AsyncGeneratorFunction.prototype`.
>
> > **Note:** `AsyncGenerator` objects do not store a reference to the async generator function that created them.

`AsyncGenerator.prototype[Symbol.toStringTag]`

> The initial value of the `[Symbol.toStringTag]` property is the string `"AsyncGenerator"`. This property is used in `Object.prototype.toString()`.

Instance methods

Also inherits instance methods from its parent `AsyncIterator`.

`AsyncGenerator.prototype.next()`

> Returns a `Promise` which will be resolved with the given value yielded by the `yield` expression.

`AsyncGenerator.prototype.return()`

> Acts as if a `return` statement is inserted in the generator's body at the current suspended position, which finishes the generator and allows the generator to perform any cleanup tasks when combined with a `try...finally` block.

`AsyncGenerator.prototype.throw()`

> Acts as if a `throw` statement is inserted in the generator's body at the current suspended position, which informs the generator of an error condition and allows it to handle the error, or perform cleanup and close itself.

Examples

Async generator iteration

The following example iterates over an async generator, logging values 1–6 to the console at decreasing time intervals. Notice how each time a Promise is yielded, but it's automatically resolved within the `for await...of` loop.

```
// An async task. Pretend it's doing something more useful
// in practice.
function delayedValue(time, value) {
```

```
  return new Promise((resolve /*, reject */) => {
    setTimeout(() => resolve(value), time);
  });
}

async function* generate() {
  yield delayedValue(2000, 1);
  yield delayedValue(1000, 2);
  yield delayedValue(500, 3);
  yield delayedValue(250, 4);
  yield delayedValue(125, 5);
  yield delayedValue(50, 6);
  console.log("All done!");
}

async function main() {
  for await (const value of generate()) {
    console.log("value", value);
  }
}

main().catch((e) => console.error(e));
```

AsyncGenerator.prototype.next()

The **`next()`** method of `AsyncGenerator` instances returns the next value in the sequence.

Syntax

```
next()
next(value)
```

Parameters

`value` Optional

An optional value used to modify the internal state of the generator. A value passed to the `next()` method will be received by `yield`

Return value

A `Promise` which when resolved returns an `Object` with two properties:

`done`

A boolean value:

- `true` if the generator is past the end of its control flow. In this case `value` specifies the *return value* of the generator (which may be undefined).
- `false` if the generator is able to produce more values.

`value`

Any JavaScript value yielded or returned by the generator.

Examples

Using next()

The following example shows a generator and the object that the `next` method returns:

```
// An async task. Pretend it's doing something more useful
// in practice.
function delayedValue(time, value) {
  return new Promise((resolve, reject) => {
    setTimeout(() => resolve(value), time);
  });
}

async function* createAsyncGenerator() {
  yield delayedValue(500, 1);
  yield delayedValue(500, 2);
  yield delayedValue(500, 3);
}

const asyncGen = createAsyncGenerator();
asyncGen.next().then((res) => console.log(res)); // { value: 1, done: false }
asyncGen.next().then((res) => console.log(res)); // { value: 2, done: false }
```

```
asyncGen.next().then((res) => console.log(res)); // { value: 3, done: false }
asyncGen.next().then((res) => console.log(res)); // { value: undefined, done: true }
```

Sending values to the generator

In this example, `next` is called with a value.

> **Note:** The first call does not log anything, because the generator was not yielding anything initially.

```
// An async task. Pretend it's doing something more useful
// in practice.
function sleep(time) {
  return new Promise((resolve, reject) => {
    setTimeout(resolve, time);
  });
}

async function* createAsyncGenerator() {
  while (true) {
    await sleep(500);
    const value = yield;
    console.log(value);
  }
}

async function main() {
  const asyncGen = createAsyncGenerator();
  // No log at this step: the first value sent through `next` is lost
  console.log(await asyncGen.next(1)); // { value: undefined, done: false }
  // Logs 2: the value sent through `next`
  console.log(await asyncGen.next(2)); // { value: undefined, done: false }
}

main();
```

See also

- `async function*`

AsyncGenerator.prototype.return()

The **`return()`** method of `AsyncGenerator` instances acts as if a `return` statement is inserted in the generator's body at the current suspended position, which finishes the generator and allows the generator to perform any cleanup tasks when combined with a `try...finally` block.

Syntax

```
asyncGeneratorInstance.return()
asyncGeneratorInstance.return(value)
```

Parameters

`value` Optional

The value to return.

Return value

A `Promise` which resolves with an `Object` with two properties:

`done`

A boolean value:

- `true` if the generator function's control flow has reached the end.
- `false` if the generator function's control flow hasn't reached the end and can produce more values. This can only happen if the `return` is captured in a `try...finally` and there are more `yield` expressions in the `finally` block.

`value`

The value that is given as an argument, or, if the `yield` expression is wrapped in a `try...finally`, the value yielded/returned from the `finally` block.

Description

The `return()` method, when called, can be seen as if a `return value;` statement is inserted in the generator's body at the current suspended position, where `value` is the value passed to the `return()` method. Therefore, in a typical flow, calling `return(value)` will return `{ done: true, value: value }`. However, if the `yield` expression is wrapped in a `try...finally` block, the control flow doesn't exit the function body, but proceeds to the `finally` block instead. In this case, the value returned may be different, and `done` may even be `false`, if there are more `yield` expressions within the `finally` block.

Examples

Using return()

The following example shows an async generator and the `return` method.

```
// An async task. Pretend it's doing something more useful
// in practice.
function delayedValue(time, value) {
  return new Promise((resolve, reject) => {
    setTimeout(() => resolve(value), time);
  });
}

async function* createAsyncGenerator() {
  yield delayedValue(500, 1);
  yield delayedValue(500, 2);
  yield delayedValue(500, 3);
}

const asyncGen = createAsyncGenerator();
asyncGen.next().then((res) => console.log(res)); // { value: 1, done: false }
asyncGen.return("foo").then((res) => console.log(res)); // { value: "foo", done: true }
asyncGen.next().then((res) => console.log(res)); // { value: undefined, done: true }
```

Using return() once a generator is complete

If no `value` argument is passed into the `return()` method, the promise will resolve as if the next() method has been called. In this example the generator has completed, so the value returned is `undefined`.

`return()` can still be called after the generator is in a "completed" state, however the generator will stay in this state.

```
async function* createAsyncGenerator() {
  yield Promise.resolve(1);
  yield await Promise.resolve(2);
  yield 3;
}
const asyncGen = createAsyncGenerator();
asyncGen.next().then((res) => console.log(res)); // { value: 1, done: false }
asyncGen.next().then((res) => console.log(res)); // { value: 2, done: false }
asyncGen.next().then((res) => console.log(res)); // { value: 3, done: false }
// value is returned undefined, as no value is passed and generator is 'done'
asyncGen.return().then((res) => console.log(res)); // { value: undefined, done: true }
// we can still return a value once the generator is complete
asyncGen.return(1).then((res) => console.log(res)); // { value: 1, done: true }
```

See also

- `async function*`
- Iterators and generators guide

AsyncGenerator.prototype.throw()

The **`throw()`** method of `AsyncGenerator` instances acts as if a `throw` statement is inserted in the generator's body at the current suspended position, which informs the generator of an error condition and allows it to handle the error, or perform cleanup and close itself.

Syntax

```
asyncGeneratorInstance.throw(exception)
```

Parameters

`exception`

The exception to throw. For debugging purposes, it is useful to make it an `instanceof` `Error`.

Return value

If the thrown error is not caught, it will return a `Promise` which rejects with the exception passed in.

If the exception is caught by a `try...catch` and the generator resumes to yield more values, it will return a `Promise` which resolves with an `Object` with two properties:

`done`

A boolean value:

- `true` if the generator function's control flow has reached the end.
- `false` if the generator function is able to produce more values.

`value`

The value yielded from the next `yield` expression.

Examples

Using throw()

The following example shows a generator and an error that is thrown using the `throw` method. An error can be caught by a `try...catch` block as usual.

```
// An async task. Pretend it's doing something more useful
// in practice.
function sleep(time) {
  return new Promise((resolve, reject) => {
    setTimeout(resolve, time);
  });
}

async function* createAsyncGenerator() {
  while (true) {
    try {
      await sleep(500);
      yield 42;
    } catch (e) {
      console.error(e);
    }
  }
}

const asyncGen = createAsyncGenerator();
asyncGen.next(1).then((res) => console.log(res)); // { value: 42, done: false }
asyncGen
  .throw(new Error("Something went wrong")) // Error: Something went wrong
  .then((res) => console.log(res)); // { value: 42, done: false }
```

See also

AsyncGeneratorFunction

The **`AsyncGeneratorFunction`** object provides methods for async generator functions. In JavaScript, every async generator function is actually an `AsyncGeneratorFunction` object.

Note that `AsyncGeneratorFunction` is *not* a global object. It can be obtained with the following code:

```
const AsyncGeneratorFunction = async function* () {}.constructor;
```

`AsyncGeneratorFunction` is a subclass of `Function`.

Try it

```
const AsyncGeneratorFunction = async function* () {}.constructor;

const foo = new AsyncGeneratorFunction(`
  yield await Promise.resolve('a');
  yield await Promise.resolve('b');
  yield await Promise.resolve('c');
`);

let str = "";

async function generate() {
  for await (const val of foo()) {
    str += val;
  }
  console.log(str);
}

generate();
// Expected output: "abc"
```

Constructor

`AsyncGeneratorFunction()`

Creates a new `AsyncGeneratorFunction` object.

Instance properties

Also inherits instance properties from its parent `Function`.

These properties are defined on `AsyncGeneratorFunction.prototype` and shared by all `AsyncGeneratorFunction` instances.

`AsyncGeneratorFunction.prototype.constructor`

The constructor function that created the instance object. For `AsyncGeneratorFunction` instances, the initial value is the `AsyncGeneratorFunction` constructor.

`AsyncGeneratorFunction.prototype.prototype`

All async generator functions share the same `prototype` property, which is `AsyncGenerator.prototype`. Each async generator function created with the `async function*` syntax or the `AsyncGeneratorFunction()` constructor also has its own `prototype` property, whose prototype is

`AsyncGeneratorFunction.prototype.prototype`. When the async generator function is called, its `prototype` property becomes the prototype of the returned async generator object.

`AsyncGeneratorFunction.prototype[Symbol.toStringTag]`

The initial value of the `[Symbol.toStringTag]` property is the string `"AsyncGeneratorFunction"`. This property is used in `Object.prototype.toString()`.

These properties are own properties of each `AsyncGeneratorFunction` instance.

`prototype`

Used when the function is used as a constructor with the `new` operator. It will become the new object's prototype.

Instance methods

Inherits instance methods from its parent `Function`.

AsyncGeneratorFunction() constructor

> **Warning:** The arguments passed to this constructor are dynamically parsed and executed as JavaScript. APIs like this are known as injection sinks, and are potentially a vector for cross-site-scripting (XSS) attacks.
>
> You can mitigate this risk by always passing `TrustedScript` objects instead of strings and enforcing trusted types.
>
> See Security considerations in the `Function()` constructor reference for more information.

The **`AsyncGeneratorFunction()`** constructor creates `AsyncGeneratorFunction` objects.

Note that `AsyncGeneratorFunction` is not a global object. It could be obtained by evaluating the following code.

```
const AsyncGeneratorFunction = async function* () {}.constructor;
```

The `AsyncGeneratorFunction()` constructor is not intended to be used directly, and all caveats mentioned in the `Function()` description apply to `AsyncGeneratorFunction()`.

Syntax

```
new AsyncGeneratorFunction(functionBody)
new AsyncGeneratorFunction(arg1, functionBody)
new AsyncGeneratorFunction(arg1, arg2, functionBody)
new AsyncGeneratorFunction(arg1, arg2, /* …, */ argN, functionBody)

AsyncGeneratorFunction(functionBody)
AsyncGeneratorFunction(arg1, functionBody)
AsyncGeneratorFunction(arg1, arg2, functionBody)
AsyncGeneratorFunction(arg1, arg2, /* …, */ argN, functionBody)
```

> **Note:** `AsyncGeneratorFunction()` can be called with or without `new`. Both create a new `AsyncGeneratorFunction` instance.

Parameters

See `Function()`.

Examples

Note that these examples omit the use of trusted types for brevity. For code showing the recommended approach, see Using `TrustedScript` in `eval()`.

Using the constructor

The following example uses the `AsyncGeneratorFunction` constructor to create an async generator function.

```
const AsyncGeneratorFunction = async function* () {}.constructor;
const createAsyncGenerator = new AsyncGeneratorFunction("a", "yield a * 2");
const asyncGen = createAsyncGenerator(10);
asyncGen.next().then((res) => console.log(res.value)); // 20
```

- Functions

AsyncGeneratorFunction.prototype.prototype

The **`prototype`** property of `AsyncGeneratorFunction.prototype` is shared by all async generator functions. Its value is `AsyncGenerator.prototype`. Each async generator function created with the `async function*` syntax or the `AsyncGeneratorFunction()` constructor also has its own `prototype` property, whose prototype is `AsyncGeneratorFunction.prototype.prototype`. When the async generator function is called, its `prototype` property becomes the prototype of the returned async generator object.

Value

The same object as `AsyncGenerator.prototype`. `AsyncGeneratorFunction.prototype.prototype` is the technically more accurate name, but `AsyncGenerator.prototype` appeals to the intuition that it's the prototype of async generator objects.

Property attributes of `AsyncGeneratorFunction.prototype.prototype`	
Writable	no
Enumerable	no
Configurable	yes

The `prototype` property of each `AsyncGeneratorFunction` instance is an empty object with no properties, whose prototype is `AsyncGeneratorFunction.prototype.prototype`. It has the following property attributes:

Property attributes of `AsyncGeneratorFunction.prototype.prototype`	
Writable	yes
Enumerable	no
Configurable	no

Description

An async generator function instance has two `prototype` properties. The first one is its own `prototype` property. The second one is the `prototype` property on its prototype, which is `AsyncGeneratorFunction.prototype`. (Remember that every async generator function is an instance of `AsyncGeneratorFunction`, so it has `AsyncGeneratorFunction.prototype` as its prototype.)

```
async function* genFunc() {}
const AsyncGeneratorFunctionPrototype = Object.getPrototypeOf(genFunc);
console.log(Object.hasOwn(genFunc, "prototype")); // true
console.log(Object.hasOwn(AsyncGeneratorFunctionPrototype, "prototype")); // true
```

When an async generator function is called, the async generator function's `prototype` property becomes the prototype of the returned async generator object.

```
const gen = genFunc();
const proto = Object.getPrototypeOf;
console.log(proto(gen) === genFunc.prototype); // true
console.log(proto(proto(gen)) === AsyncGeneratorFunctionPrototype.prototype); // true
```

The following diagram illustrates the prototype chain of an async generator function and its instances. Each hollow arrow indicates an inheritance relationship (i.e., a prototype link), and each solid arrow indicates a property relationship. Note that there's no way to access `genFunc` from `gen` — they only have an `instanceof` relationship.

- `GeneratorFunction`
- Inheritance and the prototype chain
- Iterators and generators

AsyncIterator

An **`AsyncIterator`** object is an object that conforms to the async iterator protocol by providing a `next()` method that returns a promise fulfilling to an iterator result object. The `AsyncIterator.prototype` object is a hidden global object that all built-in async iterators inherit from. It provides a `[Symbol.asyncIterator]()` method that returns the async iterator object itself, making the async iterator also async iterable.

Note that `AsyncIterator` is *not* a global object, although it will be in the future with the async iterator helpers proposal. The `AsyncIterator.prototype` object shared by all built-in async iterators can be obtained with the following code:

```
const AsyncIteratorPrototype = Object.getPrototypeOf(
  Object.getPrototypeOf(Object.getPrototypeOf((async function* () {})())),
);
```

Description

Currently, the only built-in JavaScript async iterator is the `AsyncGenerator` object returned by async generator functions. There are some other built-in async iterators in web API, such as the one of a `ReadableStream`.

Each of these async iterators have a distinct prototype object, which defines the `next()` method used by the particular async iterator. All of these prototype objects inherit from `AsyncIterator.prototype`, which provides a `[Symbol.asyncIterator]()` method that returns the async iterator object itself, making the async iterator also async iterable.

> **Note:** `AsyncIterator.prototype` does not implement `[Symbol.iterator]()`, so async iterators are not sync iterable by default.

Instance methods

`AsyncIterator.prototype[Symbol.asyncDispose]()`

Calls and awaits the `return()` method of `this`, if it exists. This implements the *async disposable protocol* and allows it to be disposed when used with `await using`.

`AsyncIterator.prototype[Symbol.asyncIterator]()`

Returns the async iterator object itself. This allows async iterator objects to also be async iterable.

Examples

Using an async iterator as an async iterable

All built-in async iterators are also async iterable, so you can use them in a `for await...of` loop:

```
const asyncIterator = (async function* () {
  yield 1;
  yield 2;
  yield 3;
})();
(async () => {
  for await (const value of asyncIterator) {
    console.log(value);
  }
})();
// Logs: 1, 2, 3
```

See also

- `async function*`
- Iteration protocols

AsyncIterator.prototype[Symbol.asyncDispose]()

The **`[Symbol.asyncDispose]()`** method of `AsyncIterator` instances implements the *async disposable protocol* and allows it to be disposed when used with `await using`. It calls and awaits the `return()` method of `this`, if it exists.

Syntax

```
asyncIterator[Symbol.asyncDispose]()
```

Parameters

None.

Return value

None (`undefined`).

Examples

Declaring an async iterator with <code>await using</code>

The `Symbol.asyncDispose` method is intended to be automatically called in an `await using` declaration. This is useful if you have an async iterator that you manually iterate over by calling its `next()` method; if you iterate it with `for await...of` or something similar, then error handling and cleanup is done automatically.

```
async function* generateNumbers() {
  try {
    yield 1;
    yield 2;
    yield 3;
  } finally {
    console.log("Cleaning up");
  }
}
```

```
async function doSomething() {
  await using numbers = generateNumbers();
  const res1 = await numbers.next();
  // Not iterating the rest of the numbers
  // Before the function exits, the async iterator is disposed
  // Logs "Cleaning up"
}

doSomething();
```

See also

- Polyfill of `AsyncIterator.prototype[Symbol.asyncDispose]` in `core-js`
- JavaScript resource management
- `Symbol.asyncDispose`
- `await using`

AsyncIterator.prototype[Symbol.asyncIterator]()

The **`[Symbol.asyncIterator]()`** method of `AsyncIterator` instances implements the async iterable protocol and allows built-in async iterators to be consumed by most syntaxes expecting async iterables, such as `for await...of` loops. It returns the value of `this`, which is the async iterator object itself.

Syntax

```
asyncIterator[Symbol.asyncIterator]()
```

Parameters

None.

Return value

The value of `this`, which is the async iterator object itself.

Examples

Iteration using for await...of loop

Note that you seldom need to call this method directly. The existence of the `[Symbol.asyncIterator]()` method makes all built-in async iterators async iterable, and iterating syntaxes like the `for await...of` loop automatically calls this method to obtain the async iterator to loop over.

```
const asyncIterator = (async function* () {
  yield 1;
  yield 2;
  yield 3;
})();
(async () => {
  for await (const value of asyncIterator) {
    console.log(value);
  }
})();
// Logs: 1, 2, 3
```

See also

- `for await...of`

Atomics

The **`Atomics`** namespace object contains static methods for carrying out atomic operations. They are used with `SharedArrayBuffer` and `ArrayBuffer` objects.

Description

Unlike most global objects, `Atomics` is not a constructor. You cannot use it with the `new` operator or invoke the `Atomics` object as a function. All properties and methods of `Atomics` are static (just like the `Math` object).

Atomic operations

When memory is shared, multiple threads can read and write the same data in memory. Atomic operations make sure that predictable values are written and read, that operations are finished before the next operation starts and that operations are not interrupted.

Wait and notify

The `wait()` and `notify()` methods are modeled on Linux futexes ("fast user-space mutex") and provide ways for waiting until a certain condition becomes true and are typically used as blocking constructs.

Static properties

`Atomics[Symbol.toStringTag]`

> The initial value of the `[Symbol.toStringTag]` property is the string `"Atomics"`. This property is used in `Object.prototype.toString()`.

Static methods

`Atomics.add()`

Adds the provided value to the existing value at the specified index of the array. Returns the old value at that index.

`Atomics.and()`

Computes a bitwise AND on the value at the specified index of the array with the provided value. Returns the old value at that index.

`Atomics.compareExchange()`

Stores a value at the specified index of the array, if it equals a value. Returns the old value.

`Atomics.exchange()`

Stores a value at the specified index of the array. Returns the old value.

`Atomics.isLockFree()`

An optimization primitive that can be used to determine whether to use locks or atomic operations. Returns `true` if an atomic operation on arrays of the given element size will be implemented using a hardware atomic operation (as opposed to a lock). Experts only.

`Atomics.load()`

Returns the value at the specified index of the array.

`Atomics.notify()`

Notifies agents that are waiting on the specified index of the array. Returns the number of agents that were notified.

`Atomics.or()`

Computes a bitwise OR on the value at the specified index of the array with the provided value. Returns the old value at that index.

`Atomics.pause()`

Provides a micro-wait primitive that hints to the CPU that the caller is spinning while waiting on access to a shared resource. This allows the system to reduce the resources allocated to the core (such as power) or thread, without yielding the current thread.

`Atomics.store()`

Stores a value at the specified index of the array. Returns the value.

`Atomics.sub()`

Subtracts a value at the specified index of the array. Returns the old value at that index.

`Atomics.wait()`

Verifies that the specified index of the array still contains a value and sleeps awaiting or times out. Returns either `"ok"`, `"not-equal"`, or `"timed-out"`. If waiting is not allowed in the calling agent then it throws an exception. (Most browsers will not allow `wait()` on the browser's main thread.)

`Atomics.waitAsync()`

Waits asynchronously (i.e., without blocking, unlike `Atomics.wait`) on a shared memory location and returns an object representing the result of the operation.

`Atomics.xor()`

Computes a bitwise XOR on the value at the specified index of the array with the provided value. Returns the old value at that index.

Examples

Note that these examples cannot be run directly from the console or an arbitrary web page, because `SharedArrayBuffer` is not defined unless its security requirements are met.

Using Atomics

```
const sab = new SharedArrayBuffer(1024);
const ta = new Uint8Array(sab);

ta[0]; // 0
ta[0] = 5; // 5

Atomics.add(ta, 0, 12); // 5
Atomics.load(ta, 0); // 17

Atomics.and(ta, 0, 1); // 17
Atomics.load(ta, 0); // 1

Atomics.compareExchange(ta, 0, 5, 12); // 1
Atomics.load(ta, 0); // 1

Atomics.exchange(ta, 0, 12); // 1
Atomics.load(ta, 0); // 12
```

```
Atomics.isLockFree(1); // true
Atomics.isLockFree(2); // true
Atomics.isLockFree(3); // false
Atomics.isLockFree(4); // true

Atomics.or(ta, 0, 1); // 12
Atomics.load(ta, 0); // 13

Atomics.store(ta, 0, 12); // 12

Atomics.sub(ta, 0, 2); // 12
Atomics.load(ta, 0); // 10

Atomics.xor(ta, 0, 1); // 10
Atomics.load(ta, 0); // 11
```

Waiting and notifying

Given a shared `Int32Array`:

```
const sab = new SharedArrayBuffer(1024);
const int32 = new Int32Array(sab);
```

A reading thread is sleeping and waiting on location 0 because the provided value matches what is stored at the provided index. The reading thread will not move on until the writing thread has called `Atomics.notify()` on position 0 of the provided typed array. Note that if, after being woken up, the value of location 0 has not been changed by the writing thread, the reading thread will **not** go back to sleep, but will continue on.

```
Atomics.wait(int32, 0, 0);
console.log(int32[0]); // 123
```

A writing thread stores a new value and notifies the waiting thread once it has written:

```
console.log(int32[0]); // 0;
Atomics.store(int32, 0, 123);
Atomics.notify(int32, 0, 1);
```

Atomics.add()

The **`Atomics.add()`** static method adds a given value at a given position in the array, and returns the old value at that position. This atomic operation guarantees that no other write happens until the modified value is written back.

Syntax

```
Atomics.add(typedArray, index, value)
```

Parameters

`typedArray`

: An integer typed array. One of `Int8Array`, `Uint8Array`, `Int16Array`, `Uint16Array`, `Int32Array`, `Uint32Array`, `BigInt64Array`, or `BigUint64Array`.

`index`

: The position in the `typedArray` to add a `value` to.

`value`

: The number to add.

Return value

The old value at the given position (`typedArray[index]`).

Exceptions

`TypeError`

: Thrown if `typedArray` is not one of the allowed integer types.

`RangeError`

: Thrown if `index` is out of bounds in the `typedArray`.

Examples

Note that these examples cannot be run directly from the console or an arbitrary web page, because `SharedArrayBuffer` is not defined unless its security requirements are met.

Using Atomics.add()

```
// Create a SharedArrayBuffer with a size in bytes
const sab = new SharedArrayBuffer(1024);
// Create a view and set the value of the 0 index
const ta = new Uint8Array(sab);
ta[0] = 7;

// 7 + 12 = 19
console.log(Atomics.add(ta, 0, 12)); // 7, the old value
console.log(Atomics.load(ta, 0)); // 19, the new/current value
```

See also

- `Atomics`
- `Atomics.sub()`

Atomics.and()

The **`Atomics.and()`** static method computes a bitwise AND with a given value at a given position in the array, and returns the old value at that position. This atomic operation guarantees that no other write happens until the modified value is written back.

Syntax

```
Atomics.and(typedArray, index, value)
```

Parameters

`typedArray`

An integer typed array. One of `Int8Array`, `Uint8Array`, `Int16Array`, `Uint16Array`, `Int32Array`, `Uint32Array`, `BigInt64Array`, or `BigUint64Array`.

`index`

The position in the `typedArray` to compute the bitwise AND.

`value`

The number to compute the bitwise AND with.

Return value

The old value at the given position (`typedArray[index]`).

Exceptions

`TypeError`

Thrown if `typedArray` is not one of the allowed integer types.

`RangeError`

Thrown if `index` is out of bounds in the `typedArray`.

Description

The bitwise AND operation only yields 1, if both `a` and `b` are 1. The truth table for the AND operation is:

a	b	a & b
0	0	0
0	1	0
1	0	0
1	1	1

For example, a bitwise AND of `5 & 1` results in `0001` which is 1 in decimal.

```
5  0101
1  0001
   ----
1  0001
```

Examples

Note that these examples cannot be run directly from the console or an arbitrary web page, because `SharedArrayBuffer` is not defined unless its security requirements are met.

Using Atomics.and()

```
// Create a SharedArrayBuffer with a size in bytes
const sab = new SharedArrayBuffer(1024);
// Create a view and set the value of the 0 index
const ta = new Uint8Array(sab);
ta[0] = 7;

// 7 (0111) AND 10 (1010) = 2 (0010)
console.log(Atomics.and(ta, 0, 10)); // 7, the old value
console.log(Atomics.load(ta, 0)); // 2, the new/current value
```

See also

- `Atomics`
- `Atomics.or()`
- `Atomics.xor()`

Atomics.compareExchange()

The **`Atomics.compareExchange()`** static method exchanges a given replacement value at a given position in the array, if a given expected value equals the old value. It returns the old value at that position whether it was equal to the expected value or not. This atomic operation guarantees that no other write happens until the modified value is written back.

Syntax

```
Atomics.compareExchange(typedArray, index, expectedValue, replacementValue)
```

Parameters

`typedArray`

An integer typed array. One of `Int8Array`, `Uint8Array`, `Int16Array`, `Uint16Array`, `Int32Array`, `Uint32Array`, `BigInt64Array`, or `BigUint64Array`.

`index`

The position in the `typedArray` to exchange a `replacementValue`.

`expectedValue`

The value to check for equality.

`replacementValue`

The number to exchange.

Return value

The old value at the given position (`typedArray[index]`). If the return value is equal to `expectedValue`, the exchange was successful; otherwise, the exchange failed.

Exceptions

`TypeError`

Thrown if `typedArray` is not one of the allowed integer types.

`RangeError`

Thrown if `index` is out of bounds in the `typedArray`.

Examples

Note that these examples cannot be run directly from the console or an arbitrary web page, because `SharedArrayBuffer` is not defined unless its security requirements are met.

Using Atomics.compareExchange()

```
// Create a SharedArrayBuffer with a size in bytes
const sab = new SharedArrayBuffer(1024);
// Create a view and set the value of the 0 index
const ta = new Uint8Array(sab);
ta[0] = 7;

console.log(Atomics.compareExchange(ta, 0, 7, 12)); // 7, the old value
console.log(Atomics.load(ta, 0)); // 12, the new/current value
```

Checking the return value

Compare-and-swap guarantees that the new value is calculated based on up-to-date information; if the value had been updated by another thread in the meantime, the write would fail. Therefore, you should check the return value of `compareExchange()` to check if it has failed, and retry if necessary.

Here is one example of an atomic adder (same functionality as `Atomics.add()`), adapted from the linked Wikipedia article:

```
function add(mem, index, a) {
  let done = false;
```

```
  while (!done) {
    const value = Atomics.load(mem, index);
    done = Atomics.compareExchange(mem, index, value, value + a) === value;
  }
  return value + a;
}
```

It first reads the value at the given index, then tries to update it with the new value. It keeps retrying until it successfully updates the value.

See also

- `Atomics`
- `Atomics.exchange()`

Atomics.exchange()

The **`Atomics.exchange()`** static method exchanges a given value at a given position in the array, and returns the old value at that position. This atomic operation guarantees that no other write happens between the read of the old value and the write of the new value.

Syntax

```
Atomics.exchange(typedArray, index, value)
```

Parameters

`typedArray`

: An integer typed array. One of `Int8Array`, `Uint8Array`, `Int16Array`, `Uint16Array`, `Int32Array`, `Uint32Array`, `BigInt64Array`, or `BigUint64Array`.

`index`

: The position in the `typedArray` to exchange a `value`.

`value`

: The number to exchange.

Return value

The old value at the given position (`typedArray[index]`).

Exceptions

`TypeError`

: Thrown if `typedArray` is not one of the allowed integer types.

`RangeError`

: Thrown if `index` is out of bounds in the `typedArray`.

Examples

Note that these examples cannot be run directly from the console or an arbitrary web page, because `SharedArrayBuffer` is not defined unless its security requirements are met.

Using Atomics.exchange()

```
// Create a SharedArrayBuffer with a size in bytes
const sab = new SharedArrayBuffer(1024);
// Create a view and set the value of the 0 index
const ta = new Uint8Array(sab);
ta[0] = 7;

console.log(Atomics.exchange(ta, 0, 12)); // 7, the old value
console.log(Atomics.load(ta, 0)); // 12, the new/current value
```

See also

- `Atomics`
- `Atomics.compareExchange()`
- `Atomics.store()`

Atomics.isLockFree()

The **`Atomics.isLockFree()`** static method is used to determine whether the `Atomics` methods use locks or atomic hardware operations when applied to typed arrays with the given element byte size. It is intended as an optimization primitive, so that high-performance algorithms can determine whether to use locks or atomic operations in critical sections. If an atomic primitive is not lock-free, it is often more efficient for an algorithm to provide its own locking.

Try it

```
console.log(Atomics.isLockFree(3));
// 3 is not one of the BYTES_PER_ELEMENT values
// Expected output: false
```

```
console.log(Atomics.isLockFree(4));
// 4 is one of the BYTES_PER_ELEMENT values
// Expected output: true
```

Syntax

```
Atomics.isLockFree(size)
```

Parameters

`size`

The size in bytes to check.

Return value

A `true` or `false` value indicating whether the operation is lock free.

- Always `true` if `size` is 4, because all known platforms support 4-byte atomic operations.
- Always `false` if the given size is not one of the `BYTES_PER_ELEMENT` property of integer TypedArray types.

Examples

Using Atomics.isLockFree()

```
Atomics.isLockFree(1); // true (platform-dependent)
Atomics.isLockFree(2); // true (platform-dependent)
Atomics.isLockFree(3); // false
Atomics.isLockFree(4); // true
Atomics.isLockFree(5); // false
Atomics.isLockFree(6); // false
Atomics.isLockFree(7); // false
Atomics.isLockFree(8); // true (platform-dependent)
```

See also

- `Atomics`

Atomics.load()

The **`Atomics.load()`** static method returns a value at a given position in the array. This atomic operation guarantees that the read is tear-free, and that all atomic reads are sequentially consistent.

Syntax

```
Atomics.load(typedArray, index)
```

Parameters

`typedArray`

An integer typed array. One of `Int8Array`, `Uint8Array`, `Int16Array`, `Uint16Array`, `Int32Array`, `Uint32Array`, `BigInt64Array`, or `BigUint64Array`.

`index`

The position in the `typedArray` to load from.

Return value

The value at the given position (`typedArray[index]`).

Exceptions

`TypeError`

Thrown if `typedArray` is not one of the allowed integer types.

`RangeError`

Thrown if `index` is out of bounds in the `typedArray`.

Examples

Note that these examples cannot be run directly from the console or an arbitrary web page, because `SharedArrayBuffer` is not defined unless its security requirements are met.

Using Atomics.load()

```
// Create a SharedArrayBuffer with a size in bytes
const sab = new SharedArrayBuffer(1024);
// Create a view and set the value of the 0 index
const ta = new Uint8Array(sab);
ta[0] = 7;
```

```
Atomics.add(ta, 0, 12); // Add 12 to index 0
console.log(Atomics.load(ta, 0)); // 19, the new/current value
```

See also

- `Atomics`
- `Atomics.store()`

Atomics.notify()

The **`Atomics.notify()`** static method notifies up some agents that are sleeping in the wait queue.

> **Note:** This operation only works with an `Int32Array` or `BigInt64Array` that views a `SharedArrayBuffer`. It will return `0` on non-shared `ArrayBuffer` objects.

Syntax

```
Atomics.notify(typedArray, index, count)
```

Parameters

`typedArray`

: An `Int32Array` or `BigInt64Array` that views a `SharedArrayBuffer`.

`index`

: The position in the `typedArray` to wake up on.

`count` Optional

: The number of sleeping agents to notify. Defaults to `Infinity`.

Return value

Returns the number of woken up agents, or `0` if `typedArray` is a view on a non-shared `ArrayBuffer`.

Exceptions

`TypeError`

: Thrown if `typedArray` is not an `Int32Array` or `BigInt64Array`.

`RangeError`

: Thrown if `index` is out of bounds in the `typedArray`.

Examples

Note that these examples cannot be run directly from the console or an arbitrary web page, because `SharedArrayBuffer` is not defined unless its security requirements are met.

Using Atomics.notify()

Given a shared `Int32Array`:

```
const sab = new SharedArrayBuffer(1024);
const int32 = new Int32Array(sab);
```

A reading thread is sleeping and waiting on location 0 because the provided `value` matches what is stored at the provided `index`. The reading thread will not move on until the writing thread has called `Atomics.notify()` on position 0 of the provided `typedArray`. Note that if, after being woken up, the value of location 0 has not been changed by the writing thread, the reading thread will **not** go back to sleep, but will continue on.

```
Atomics.wait(int32, 0, 0);
console.log(int32[0]); // 123
```

A writing thread stores a new value and notifies the waiting thread once it has written:

```
console.log(int32[0]); // 0;
Atomics.store(int32, 0, 123);
Atomics.notify(int32, 0, 1);
```

See also

- `Atomics`
- `Atomics.wait()`
- `Atomics.waitAsync()`

Atomics.or()

The **`Atomics.or()`** static method computes a bitwise OR with a given value at a given position in the array, and returns the old value at that position. This atomic operation guarantees that no other write happens until the modified value is written back.

Syntax

```
Atomics.or(typedArray, index, value)
```

Parameters

`typedArray`

An integer typed array. One of `Int8Array`, `Uint8Array`, `Int16Array`, `Uint16Array`, `Int32Array`, `Uint32Array`, `BigInt64Array`, or `BigUint64Array`.

`index`

The position in the `typedArray` to compute the bitwise OR.

`value`

The number to compute the bitwise OR with.

Return value

The old value at the given position (`typedArray[index]`).

Exceptions

`TypeError`

Thrown if `typedArray` is not one of the allowed integer types.

`RangeError`

Thrown if `index` is out of bounds in the `typedArray`.

Description

The bitwise OR operation yields 1, if either `a` or `b` is 1. The truth table for the OR operation is:

a	b	a | b
0	0	0
0	1	1
1	0	1
1	1	1

For example, a bitwise OR of `5 | 1` results in `0101` which is 5 in decimal.

```
5  0101
1  0001
   ----
5  0101
```

Examples

Note that these examples cannot be run directly from the console or an arbitrary web page, because `SharedArrayBuffer` is not defined unless its security requirements are met.

Using Atomics.or()

```
// Create a SharedArrayBuffer with a size in bytes
const sab = new SharedArrayBuffer(1024);
// Create a view and set the value of the 0 index
const ta = new Uint8Array(sab);
ta[0] = 7;

// 7 (0111) OR 10 (1010) = 15 (1111)
console.log(Atomics.or(ta, 0, 10)); // 7, the old value
console.log(Atomics.load(ta, 0)); // 15, the new/current value
```

See also

- `Atomics`
- `Atomics.and()`
- `Atomics.xor()`

Atomics.pause()

The **`Atomics.pause()`** static method provides a micro-wait primitive that hints to the CPU that the caller is spinning while waiting on access to a shared resource. This allows the system to reduce the resources allocated to the core (such as power) or thread, without yielding the current thread.

`pause()` has no observable behavior other than timing. The exact behavior is dependent on the CPU architecture and the operating system. For example, in Intel x86, it may be a `pause` instruction as per Intel's optimization manual. It could be a no-op in certain platforms.

Syntax

```
Atomics.pause()
```

Parameters

None.

Return value

None (`undefined`).

Examples

Note that these examples cannot be run directly from the console or an arbitrary web page, because `SharedArrayBuffer` is not defined unless its security requirements are met.

Using Atomics.pause()

Calling `Atomics.wait()` or `Atomics.waitAsync()` in order to wait for access to shared memory causes the thread to be scheduled out of the core and then back in again after the wait. This is efficient during times of high contention, where access to the shared memory could take some time. When contention is low, then it is often more efficient to poll on the lock without yielding the thread: this approach is known as busy waiting or spinlocking. The `pause()` method allows you to spinlock more efficiently while waiting, by providing a hint to the CPU about what the thread is doing, and hence its low need for resources.

To cater for both conditions, a common approach is to first spinlock in the hope that contention is low, and then wait if the lock is not gained after a short time. If we acquired the lock via spinlocking already, then the `wait()` call will be a no-op.

The example below shows how this approach can be used with `Atomics.pause()` and `Atomics.wait()`.

> **Warning:** Using spinlocking on the main thread is not recommended, as it will freeze the entire page. In general, unless designed very carefully, spinlocks may not actually be more performant than a regular wait.

```
// Imagine another thread also has access to this shared memory
const sab = new SharedArrayBuffer(1024);
const i32 = new Int32Array(sab);

// Fast path: spin the CPU for a short while
let spin = 0;
do {
  if (Atomics.compareExchange(i32, 0, 0, 1) === 0) {
    break;
  }
  Atomics.pause();
  spin++;
} while (spin < 10);

// Slow path: wait for the lock
// This can only be called in a worker thread,
// because the main thread cannot be blocked
Atomics.wait(i32, 0, 1);
```

See also

- `Atomics`
- `Atomics.wait()`
- `Atomics.waitAsync()`

Atomics.store()

The **`Atomics.store()`** static method stores a given value at a given position in the array and returns that value. This atomic operation guarantees that the write is tear-free, and that all atomic writes are sequentially consistent.

Note that unlike many other `Atomic` methods, `store()` returns the new value instead of the old value. To get the old value, use `Atomics.exchange()` instead.

Syntax

```
Atomics.store(typedArray, index, value)
```

Parameters

`typedArray`

An integer typed array. One of `Int8Array`, `Uint8Array`, `Int16Array`, `Uint16Array`, `Int32Array`, `Uint32Array`, `BigInt64Array`, or `BigUint64Array`.

`index`

The position in the `typedArray` to store a `value` in.

`value`

The number to store.

Return value

The value that has been stored.

Exceptions

`TypeError`

Thrown if `typedArray` is not one of the allowed integer types.

`RangeError`

Thrown if `index` is out of bounds in the `typedArray`.

Examples

Note that these examples cannot be run directly from the console or an arbitrary web page, because `SharedArrayBuffer` is not defined unless its security requirements are met.

Using Atomics.store()

```
// Create a SharedArrayBuffer with a size in bytes
const sab = new SharedArrayBuffer(1024);
const ta = new Uint8Array(sab);

console.log(Atomics.store(ta, 0, 12)); // 12, the new/current value
console.log(Atomics.load(ta, 0)); // 12, the new/current value
```

See also

- `Atomics`
- `Atomics.load()`
- `Atomics.exchange()`

Atomics.sub()

The **`Atomics.sub()`** static method subtracts a given value at a given position in the array, and returns the old value at that position. This atomic operation guarantees that no other write happens until the modified value is written back.

Syntax

```
Atomics.sub(typedArray, index, value)
```

Parameters

`typedArray`

An integer typed array. One of `Int8Array`, `Uint8Array`, `Int16Array`, `Uint16Array`, `Int32Array`, `Uint32Array`, `BigInt64Array`, or `BigUint64Array`.

`index`

The position in the `typedArray` to subtract a `value` from.

`value`

The number to subtract.

Return value

The old value at the given position (`typedArray[index]`).

Exceptions

`TypeError`

Thrown if `typedArray` is not one of the allowed integer types.

`RangeError`

Thrown if `index` is out of bounds in the `typedArray`.

Examples

Note that these examples cannot be run directly from the console or an arbitrary web page, because `SharedArrayBuffer` is not defined unless its security requirements are met.

Using Atomics.sub()

```
// Create a SharedArrayBuffer with a size in bytes
const sab = new SharedArrayBuffer(1024);
```

```
// Create a view and set the value of the 0 index
const ta = new Uint8Array(sab);
ta[0] = 48;

// 48 - 12 = 36
console.log(Atomics.sub(ta, 0, 12)); // 48, the old value
console.log(Atomics.load(ta, 0)); // 36, the new/current value
```

See also

- `Atomics`
- `Atomics.add()`

Atomics.wait()

The **`Atomics.wait()`** static method verifies that a shared memory location contains a given value and if so sleeps, awaiting a wake-up notification or a timeout. It returns a string which is `"not-equal"` if the memory location does not match the given value, `"ok"` if woken by `Atomics.notify()`, or `"timed-out"` if the timeout expires.

`Atomics.wait()` and `Atomics.notify()` are used together to enable thread synchronization based on a value in shared memory. A thread can proceed immediately if the synchronization value has changed, or it can wait for notification from another thread when it reaches the synchronization point.

This method only works with an `Int32Array` or `BigInt64Array` that views a `SharedArrayBuffer`. It is blocking and cannot be used in the main thread. For a non-blocking, asynchronous version of this method, see `Atomics.waitAsync()`.

Syntax

```
Atomics.wait(typedArray, index, value)
Atomics.wait(typedArray, index, value, timeout)
```

Parameters

`typedArray`

An `Int32Array` or `BigInt64Array` that views a `SharedArrayBuffer`.

`index`

The position in the `typedArray` to wait on.

`value`

The expected value to test.

`timeout` Optional

Time to wait in milliseconds. `NaN` (and values that get converted to `NaN`, such as `undefined`) becomes `Infinity`. Negative values become `0`.

Return value

A string which is either `"not-equal"`, `"ok"`, or `"timed-out"`.

- `"not-equal"` is returned immediately if the initial `value` does not equal what is stored at `index`.
- `"ok"` is returned if woken up by a call to `Atomics.notify()`, **regardless of whether the expected value has changed**.
- `"timed-out"` is returned if a sleeping wait exceeds the specified `timeout` without being woken up by `Atomics.notify()`.

Exceptions

`TypeError`

Thrown in one of the following cases:

- If `typedArray` is not an `Int32Array` or `BigInt64Array` that views a `SharedArrayBuffer`.
- If the current thread cannot be blocked (for example, because it's the main thread).

`RangeError`

Thrown if `index` is out of bounds in the `typedArray`.

Examples

Note that these examples cannot be run directly from the console or an arbitrary web page, because `SharedArrayBuffer` is not defined unless its security requirements are met.

Using Atomics.wait()

Given a shared `Int32Array`:

```
// Create a SharedArrayBuffer with a size in bytes
const sab = new SharedArrayBuffer(1024);
const int32 = new Int32Array(sab);
```

A reading thread is sleeping and waiting on location 0 because the provided `value` matches what is stored at the provided `index`. The reading thread will not move on until the writing thread has called `Atomics.notify()` on position 0 of the provided `typedArray`. Note that if, after being woken up, the value of location 0 has not been changed by the writing thread, the reading thread will **not** go back to sleep, but will continue on.

```
Atomics.wait(int32, 0, 0);
console.log(int32[0]); // 123
```

A writing thread stores a new value and notifies the waiting thread once it has written:

```
console.log(int32[0]); // 0;
Atomics.store(int32, 0, 123);
Atomics.notify(int32, 0, 1);
```

See also

- `Atomics`
- `Atomics.waitAsync()`
- `Atomics.notify()`

Atomics.waitAsync()

The **`Atomics.waitAsync()`** static method verifies that a shared memory location contains a given value, immediately returning an object with the `value` property containing the string `"not-equal"` if the memory location does not match the given value, or `"timed-out"` if the timeout was set to zero. Otherwise the method returns an object where the `value` property is a `Promise` that fulfills with either `"ok"` when `Atomics.notify()` is called, or `"timed-out"` if the timeout expires.

`Atomics.waitAsync()` and `Atomics.notify()` are used together to enable thread synchronization based on a value in shared memory. A thread can proceed immediately if the synchronization value has changed, or it can wait for notification from another thread when it reaches the synchronization point.

This method only works with an `Int32Array` or `BigInt64Array` that views a `SharedArrayBuffer`. It is non-blocking and, unlike `Atomics.wait()`, can be used on the main thread. Because it does not block the whole thread, you still need to be careful not to access the shared memory before the promise settles.

Syntax

```
Atomics.waitAsync(typedArray, index, value)
Atomics.waitAsync(typedArray, index, value, timeout)
```

Parameters

`typedArray`

: An `Int32Array` or `BigInt64Array` that views a `SharedArrayBuffer`.

`index`

: The position in the `typedArray` to wait on.

`value`

: The expected value to test.

`timeout` Optional

: Time to wait in milliseconds. `NaN` (and values that get converted to `NaN`, such as `undefined`) becomes `Infinity`. Negative values become `0`.

Return value

An `Object` with the following properties:

`async`

: A boolean indicating whether the `value` property is a `Promise` or not.

`value`

: If `async` is `false`, it will be a string which is either `"not-equal"` or `"timed-out"` (only when the `timeout` parameter is `0`). If `async` is `true`, it will be a `Promise` which is fulfilled with a string value, either `"ok"` or `"timed-out"`. The promise is never rejected.

Exceptions

`TypeError`

: Thrown if `typedArray` is not an `Int32Array` or `BigInt64Array` that views a `SharedArrayBuffer`.

`RangeError`

: Thrown if `index` is out of bounds in the `typedArray`.

Examples

Note that these examples cannot be run directly from the console or an arbitrary web page, because `SharedArrayBuffer` is not defined unless its security requirements are met.

Using Atomics.waitAsync()

Given a shared `Int32Array`:

```
// Create a SharedArrayBuffer with a size in bytes
const sab = new SharedArrayBuffer(1024);
const int32 = new Int32Array(sab);
```

A reading thread is sleeping and waiting on location 0 which is expected to be 0. The `result.value` will be a promise.

```
const result = Atomics.waitAsync(int32, 0, 0, 1000);
// { async: true, value: Promise {<pending>} }
```

In the reading thread or in another thread, the memory location 0 is called and the promise can be resolved with `"ok"`.

```
Atomics.notify(int32, 0);
// { async: true, value: Promise {<fulfilled>: 'ok'} }
```

If it isn't resolving to `"ok"`, the value in the shared memory location wasn't the expected (the `value` would be `"not-equal"` instead of a promise) or the timeout was reached (the promise will resolve to `"time-out"`).

See also

- `Atomics`
- `Atomics.wait()`
- `Atomics.notify()`

Atomics.xor()

The **`Atomics.xor()`** static method computes a bitwise XOR with a given value at a given position in the array, and returns the old value at that position. This atomic operation guarantees that no other write happens until the modified value is written back.

Syntax

```
Atomics.xor(typedArray, index, value)
```

Parameters

`typedArray`

: An integer typed array. One of `Int8Array`, `Uint8Array`, `Int16Array`, `Uint16Array`, `Int32Array`, `Uint32Array`, `BigInt64Array`, or `BigUint64Array`.

`index`

: The position in the `typedArray` to compute the bitwise XOR.

`value`

: The number to compute the bitwise XOR with.

Return value

The old value at the given position (`typedArray[index]`).

Exceptions

`TypeError`

: Thrown if `typedArray` is not one of the allowed integer types.

`RangeError`

: Thrown if `index` is out of bounds in the `typedArray`.

Description

The bitwise XOR operation yields 1, if `a` and `b` are different. The truth table for the XOR operation is:

a	b	a ^ b
0	0	0
0	1	1
1	0	1
1	1	0

For example, a bitwise XOR of `5 ^ 1` results in `0100` which is 4 in decimal.

```
5  0101
1  0001
   ----
4  0100
```

Examples

Note that these examples cannot be run directly from the console or an arbitrary web page, because `SharedArrayBuffer` is not defined unless its security requirements are met.

Using Atomics.xor()

```
// Create a SharedArrayBuffer with a size in bytes
const sab = new SharedArrayBuffer(1024);
// Create a view and set the value of the 0 index
const ta = new Uint8Array(sab);
ta[0] = 7;

// 7 (0111) XOR 2 (0010) = 5 (0101)
console.log(Atomics.xor(ta, 0, 2)); // 7, the old value
console.log(Atomics.load(ta, 0)); // 5, the new/current value
```

BigInt

`BigInt` values represent integer values which are too high or too low to be represented by the `number` primitive.

Description

A **BigInt value**, also sometimes just called a **BigInt**, is a `bigint` primitive, created by appending `n` to the end of an integer literal, or by calling the `BigInt()` function (without the `new` operator) and giving it an integer value or string value.

```
const previouslyMaxSafeInteger = 9007199254740991n;

const alsoHuge = BigInt(9007199254740991);
// 9007199254740991n

const hugeString = BigInt("9007199254740991");
// 9007199254740991n

const hugeHex = BigInt("0x1fffffffffffff");
// 9007199254740991n

const hugeOctal = BigInt("0o377777777777777777");
// 9007199254740991n

const hugeBin = BigInt(
  "0b11111111111111111111111111111111111111111111111111111",
);
// 9007199254740991n
```

BigInt values are similar to Number values in some ways, but also differ in a few key matters: A BigInt value cannot be used with methods in the built-in `Math` object and cannot be mixed with a Number value in operations; they must be coerced to the same type. Be careful coercing values back and forth, however, as the precision of a BigInt value may be lost when it is coerced to a Number value.

Type information

When tested against `typeof`, a BigInt value (`bigint` primitive) will give `"bigint"`:

```
typeof 1n === "bigint"; // true
typeof BigInt("1") === "bigint"; // true
```

A BigInt value can also be wrapped in an `Object`:

```
typeof Object(1n) === "object"; // true
```

Operators

Most operators support BigInts, however most do not permit operands to be of mixed types — both operands must be BigInt or neither:

- Arithmetic operators: `+`, `-`, `*`, `/`, `%`, `**`
- Bitwise operators: `>>`, `<<`, `&`, `|`, `^`, `~`
- Unary negation (`-`)
- Increment/decrement: `++`, `--`

The boolean-returning operators allow mixing numbers and BigInts as operands:

- Relational operators and equality operators: `>`, `<`, `>=`, `<=`, `==`, `!=`, `===`, `!==`
- Logical operators only rely on the truthiness of operands

A couple of operators do not support BigInt at all:

- Unary plus (`+`) cannot be supported due to conflicting usage in asm.js, so it has been left out in order to not break asm.js.
- Unsigned right shift (`>>>`) is the only bitwise operator that's unsupported, as every BigInt value is signed.

Special cases:

- Addition (+) involving a string and a BigInt returns a string.
- Division (/) truncates fractional components towards zero, since BigInt is unable to represent fractional quantities.

```
const previousMaxSafe = BigInt(Number.MAX_SAFE_INTEGER); // 9007199254740991n
const maxPlusOne = previousMaxSafe + 1n; // 9007199254740992n
const theFuture = previousMaxSafe + 2n; // 9007199254740993n, this works now!
const prod = previousMaxSafe * 2n; // 18014398509481982n
const diff = prod - 10n; // 18014398509481972n
const mod = prod % 10n; // 2n
const bigN = 2n ** 54n; // 18014398509481984n
bigN * -1n; // -18014398509481984n
const expected = 4n / 2n; // 2n
const truncated = 5n / 2n; // 2n, not 2.5n
```

Comparisons

A BigInt value is not strictly equal to a Number value, but it *is* loosely so:

```
0n === 0; // false
0n == 0; // true
```

A Number value and a BigInt value may be compared as usual:

```
1n < 2; // true
2n > 1; // true
2 > 2; // false
2n > 2; // false
2n >= 2; // true
```

BigInt values and Number values may be mixed in arrays and sorted:

```
const mixed = [4n, 6, -12n, 10, 4, 0, 0n];
// [4n, 6, -12n, 10, 4, 0, 0n]

mixed.sort(); // default sorting behavior
// [ -12n, 0, 0n, 10, 4n, 4, 6 ]

mixed.sort((a, b) => a - b);
// won't work since subtraction will not work with mixed types
// TypeError: can't convert BigInt value to Number value

// sort with an appropriate numeric comparator
mixed.sort((a, b) => (a < b ? -1 : a > b ? 1 : 0));
// [ -12n, 0, 0n, 4n, 4, 6, 10 ]
```

Note that comparisons with `Object`-wrapped BigInt values act as with other objects, only indicating equality when the same object instance is compared:

```
Object(0n) === 0n; // false
Object(0n) === Object(0n); // false

const o = Object(0n);
o === o; // true
```

Because coercing between Number values and BigInt values can lead to loss of precision, the following are recommended:

- Only use a BigInt value when values greater than 2^{53} are reasonably expected.
- Don't coerce between BigInt values and Number values.

Conditionals

A BigInt value follows the same conversion rules as Numbers when:

- it is converted to a `Boolean`: via the `Boolean` function;
- when used with logical operators `||`, `&&`, and `!`; or
- within a conditional test like an `if` statement.

Namely, only `0n` is falsy; everything else is truthy.

```
if (0n) {
  console.log("Hello from the if!");
} else {
  console.log("Hello from the else!");
}
// "Hello from the else!"

0n || 12n; // 12n
0n && 12n; // 0n
Boolean(0n); // false
Boolean(12n); // true
```

```
!12n; // false
!0n; // true
```

Cryptography

The operations supported on BigInt values are not constant-time and are thus open to timing attacks. JavaScript BigInts therefore could be dangerous for use in cryptography without mitigating factors. As a very generic example, an attacker could measure the time difference between `101n ** 65537n` and `17n ** 9999n`, and deduce the magnitude of secrets, such as private keys, based on the time elapsed. If you still have to use BigInts, take a look at the Timing attack FAQ for general advice regarding the issue.

Use within JSON

Using `JSON.stringify()` with any BigInt value will raise a `TypeError`, as BigInt values aren't serialized in JSON by default. However, `JSON.stringify()` specifically leaves a backdoor for BigInt values: it would try to call the BigInt's `toJSON()` method. (It doesn't do so for any other primitive values.) Therefore, you can implement your own `toJSON()` method (which is one of the few cases where patching built-in objects is not explicitly discouraged):

```
BigInt.prototype.toJSON = function () {
  return { $bigint: this.toString() };
};
```

Instead of throwing, `JSON.stringify()` now produces a string like this:

```
console.log(JSON.stringify({ a: 1n }));
// {"a":{"$bigint":"1"}}
```

If you do not wish to patch `BigInt.prototype`, you can use the `replacer` parameter of `JSON.stringify` to serialize BigInt values:

```
const replacer = (key, value) =>
  typeof value === "bigint" ? { $bigint: value.toString() } : value;

const data = {
  number: 1,
  big: 18014398509481982n,
};
const stringified = JSON.stringify(data, replacer);

console.log(stringified);
// {"number":1,"big":{"$bigint":"18014398509481982"}}
```

You can then use the `reviver` parameter of `JSON.parse` to handle them:

```
const reviver = (key, value) =>
  value !== null &&
  typeof value === "object" &&
  "$bigint" in value &&
  typeof value.$bigint === "string"
    ? BigInt(value.$bigint)
    : value;

const payload = '{"number":1,"big":{"$bigint":"18014398509481982"}}';
const parsed = JSON.parse(payload, reviver);

console.log(parsed);
// { number: 1, big: 18014398509481982n }
```

> **Note:** While it's possible to make the replacer of `JSON.stringify()` generic and properly serialize BigInt values for all objects as shown above, the reviver of `JSON.parse()` has to be used with caution, because the serialization is *irreversible*: it's not possible to distinguish between an object that happens to have a property called `$bigint` and an actual BigInt.
>
> In addition, the example above creates an entire object during replacing and reviving, which may have performance or storage implications for larger objects containing many BigInts. If you know the shape of the payload, it may be better to just serialize them as strings and revive them based on the property key's name instead.

In fact, JSON allows number literals that are arbitrarily long; they just cannot be parsed to full precision in JavaScript. If you are communicating with another program in a language that supports longer integers (such as 64-bit integers), and you want to transmit the BigInt as a JSON number instead of a JSON string, see Lossless number serialization.

BigInt coercion

Many built-in operations that expect BigInts first coerce their arguments to BigInts. The operation can be summarized as follows:

- BigInts are returned as-is.
- `undefined` and `null` throw a `TypeError`.
- `true` turns into `1n`; `false` turns into `0n`.
- Strings are converted by parsing them as if they contain an integer literal. Any parsing failure results in a `SyntaxError`. The syntax is a subset of string numeric literals, where decimal points or exponent indicators are not allowed.
- Numbers throw a `TypeError` to prevent unintended implicit coercion causing loss of precision.
- Symbols throw a `TypeError`.

- Objects are first converted to a primitive by calling their `[Symbol.toPrimitive]()` (with `"number"` as hint), `valueOf()`, and `toString()` methods, in that order. The resulting primitive is then converted to a BigInt.

The best way to achieve nearly the same effect in JavaScript is through the `BigInt()` function: `BigInt(x)` uses the same algorithm to convert `x`, except that Numbers don't throw a `TypeError`, but are converted to BigInts if they are integers.

Note that built-in operations expecting BigInts often truncate the BigInt to a fixed width after coercion. This includes `BigInt.asIntN()`, `BigInt.asUintN()`, and methods of `BigInt64Array` and `BigUint64Array`.

Constructor

`BigInt()`

Returns primitive values of type BigInt. Throws an error when called with `new`.

Static methods

`BigInt.asIntN()`

Truncates a `BigInt` value to the given number of least significant bits and returns that value as a signed integer.

`BigInt.asUintN()`

Truncates a `BigInt` value to the given number of least significant bits and returns that value as an unsigned integer.

Instance properties

These properties are defined on `BigInt.prototype` and shared by all `BigInt` instances.

`BigInt.prototype.constructor`

The constructor function that created the instance object. For `BigInt` instances, the initial value is the `BigInt` constructor.

`BigInt.prototype[Symbol.toStringTag]`

The initial value of the `[Symbol.toStringTag]` property is the string `"BigInt"`. This property is used in `Object.prototype.toString()`. However, because `BigInt` also has its own `toString()` method, this property is not used unless you call `Object.prototype.toString.call()` with a BigInt as `thisArg`.

Instance methods

`BigInt.prototype.toLocaleString()`

Returns a string with a language-sensitive representation of this BigInt value. Overrides the `Object.prototype.toLocaleString()` method.

`BigInt.prototype.toString()`

Returns a string representing this BigInt value in the specified radix (base). Overrides the `Object.prototype.toString()` method.

`BigInt.prototype.valueOf()`

Returns this BigInt value. Overrides the `Object.prototype.valueOf()` method.

Examples

Calculating Primes

```
function isPrime(n) {
  if (n < 2n) {
    return false;
  }
  if (n % 2n === 0n) {
    return n === 2n;
  }
  for (let factor = 3n; factor * factor <= n; factor += 2n) {
    if (n % factor === 0n) {
      return false;
    }
  }
  return true;
}

// Takes a BigInt value as an argument, returns nth prime number as a BigInt value
function nthPrime(nth) {
  let maybePrime = 2n;
  let prime = 0n;

  while (nth >= 0n) {
    if (isPrime(maybePrime)) {
      nth--;
      prime = maybePrime;
    }
    maybePrime++;
  }

  return prime;
}
```

```
nthPrime(20n);
// 73n
```

> **Note:** The `isPrime()` implementation is for demonstration only. For a real-world application, you would want to use a heavily memoized algorithm such as the Sieve of Eratosthenes to avoid repeated calculations.

- `Number.MAX_SAFE_INTEGER`

BigInt.asIntN()

The **`BigInt.asIntN()`** static method truncates a `BigInt` value to the given number of least significant bits and returns that value as a signed integer.

Try it

```
const I64_CEIL = 2n ** 63n;

console.log(BigInt.asIntN(64, I64_CEIL - 1n));
// 9223372036854775807n (2n ** 64n - 1n, the maximum non-wrapping value)
console.log(BigInt.asIntN(64, I64_CEIL));
// -9223372036854775808n (wraps to min value)
console.log(BigInt.asIntN(64, I64_CEIL + 1n));
// -9223372036854775807n (min value + 1n)
console.log(BigInt.asIntN(64, I64_CEIL * 2n));
// 0n (wrapped around to zero)
console.log(BigInt.asIntN(64, -I64_CEIL * -42n));
// 0n (also wraps on negative multiples)
```

Syntax

```
BigInt.asIntN(bits, bigint)
```

Parameters

`bits`

The number of bits available for the returned BigInt. Should be an integer between 0 and 2^{53} - 1, inclusive.

`bigint`

The BigInt value to truncate to fit into the supplied bits.

Return value

A BigInt containing the bit representation of `bigint` truncated to `bits` bits, interpreted as a signed integer.

Exceptions

`RangeError`

Thrown if `bits` is negative or greater than 2^{53} - 1.

Description

The `BigInt.asIntN` method truncates a `BigInt` value to the given number of bits, and interprets the result as a signed integer. For example, for `BigInt.asIntN(3, 25n)`, the value `25n` is truncated to `1n`:

```
25n = 00011001 (base 2)
          ^=== Use only the three remaining bits
===>       001 (base 2) = 1n
```

If the leading bit of the remaining number is `1`, the result is negative. For example, `BigInt.asIntN(4, 25n)` yields `-7n`, because `1001` is the encoding of `-7` under two's complement:

```
25n = 00011001 (base 2)
         ^==== Use only the four remaining bits
===>      1001 (base 2) = -7n
```

> **Note:** `BigInt` values are always encoded as two's complement in binary.

Unlike similar language APIs such as `Number.prototype.toExponential()`, `asIntN` is a static property of `BigInt`, so you always use it as `BigInt.asIntN()`, rather than as a method of a BigInt value. Exposing `asIntN()` as a "standard library function" allows interop with asm.js.

Examples

Staying in 64-bit ranges

The `BigInt.asIntN()` method can be useful to stay in the range of 64-bit arithmetic.

```
const max = 2n ** (64n - 1n) - 1n;

BigInt.asIntN(64, max); // 9223372036854775807n

BigInt.asIntN(64, max + 1n); // -9223372036854775808n
// negative because the 64th bit of 2^63 is 1
```

See also

- `BigInt`
- `BigInt.asUintN()`

BigInt.asUintN()

The **`BigInt.asUintN()`** static method truncates a `BigInt` value to the given number of least significant bits and returns that value as an unsigned integer.

Try it

```
const U64_CEIL = 2n ** 64n;

console.log(BigInt.asUintN(64, U64_CEIL - 1n));
// 18446744073709551615n (2n ** 64n - 1n, the maximum non-wrapping value)
console.log(BigInt.asUintN(64, U64_CEIL));
// 0n (wraps to zero)
console.log(BigInt.asUintN(64, U64_CEIL + 1n));
// 1n
console.log(BigInt.asUintN(64, U64_CEIL * 2n));
// 0n (wraps on multiples)
console.log(BigInt.asUintN(64, U64_CEIL * -42n));
// 0n (also wraps on negative multiples)
```

Syntax

```
BigInt.asUintN(bits, bigint)
```

Parameters

`bits`

The number of bits available for the returned BigInt. Should be an integer between 0 and 2^{53} - 1, inclusive.

`bigint`

The BigInt value to truncate to fit into the supplied bits.

Return value

A BigInt containing the bit representation of `bigint` truncated to `bits` bits, interpreted as an unsigned integer.

Exceptions

`RangeError`

Thrown if `bits` is negative or greater than 2^{53} - 1.

Description

The `BigInt.asUintN` method truncates a `BigInt` value to the given number of bits, and interprets the result as an unsigned integer. Unsigned integers have no sign bits and are always non-negative. For example, for `BigInt.asUintN(4, 25n)`, the value `25n` is truncated to `9n`:

```
25n = 00011001 (base 2)
         ^==== Use only the four remaining bits
===>      1001 (base 2) = 9n
```

> **Note:** `BigInt` values are always encoded as two's complement in binary.

Unlike similar language APIs such as `Number.prototype.toExponential()`, `asUintN` is a static property of `BigInt`, so you always use it as `BigInt.asUintN()`, rather than as a method of a BigInt value. Exposing `asUintN()` as a "standard library function" allows interop with asm.js.

Examples

Staying in 64-bit ranges

The `BigInt.asUintN()` method can be useful to stay in the range of 64-bit arithmetic.

```
const max = 2n ** 64n - 1n;
```

```
BigInt.asUintN(64, max); // 18446744073709551615n

BigInt.asUintN(64, max + 1n); // 0n
// zero because of overflow: the lowest 64 bits are all zeros
```

See also

- `BigInt`
- `BigInt.asIntN()`

BigInt() constructor

The **`BigInt()`** function returns primitive values of type BigInt.

Syntax

```
BigInt(value)
```

> **Note:** `BigInt()` can only be called without `new`. Attempting to construct it with `new` throws a `TypeError`.

Parameters

`value`

The value to be converted to a BigInt value. It may be a string, an integer, a boolean, or another `BigInt`.

Return value

A `BigInt` value. Number values must be integers and are converted to BigInts. The boolean value `true` becomes `1n`, and `false` becomes `0n`. Strings are parsed as if they are source text for integer literals, which means they can have leading and trailing whitespaces and can be prefixed with `0b`, `0o`, or `0x`.

Exceptions

`RangeError`

Thrown if the parameter is a non-integral number.

`TypeError`

Thrown in one of the following cases:

- The parameter cannot be converted to a primitive.
- After conversion to a primitive, the result is `undefined`, `null`, or `Symbol`.

`SyntaxError`

Thrown if the parameter is a string that cannot be parsed as a `BigInt`.

Examples

Using BigInt() to convert a number to a BigInt

`BigInt()` is the only case where a number can be converted to a BigInt without throwing, because it's very explicit. However, only integers are allowed.

```
BigInt(123); // 123n
BigInt(123.3); // RangeError: The number 123.3 cannot be converted to a BigInt because it is not an integer
```

Using string values

```
BigInt("123"); // 123n
BigInt("0b10101"); // 21n, which is 10101 in binary
BigInt("0o123"); // 83n, which is 123 in octal
BigInt("0x123"); // 291n, which is 123 in hexadecimal
BigInt("  123  "); // 123n, leading and trailing whitespaces are allowed
```

BigInt.prototype.toLocaleString()

The **`toLocaleString()`** method of `BigInt` values returns a string with a language-sensitive representation of this BigInt. In implementations with `Intl.NumberFormat` API support, this method delegates to `Intl.NumberFormat`.

Every time `toLocaleString` is called, it has to perform a search in a big database of localization strings, which is potentially inefficient. When the method is called many times with the same arguments, it is better to create an `Intl.NumberFormat` object and use its `format()` method, because a `NumberFormat` object remembers the arguments passed to it and may decide to cache a slice of the database, so future `format` calls can search for localization strings within a more constrained context.

Try it

```
const bigint = 123456789123456789n;
```

```
// German uses period for thousands
console.log(bigint.toLocaleString("de-DE"));
// Expected output: "123.456.789.123.456.789"

// Request a currency format
console.log(
  bigint.toLocaleString("de-DE", { style: "currency", currency: "EUR" }),
);
// Expected output: "123.456.789.123.456.789,00 €"
```

Syntax

```
toLocaleString()
toLocaleString(locales)
toLocaleString(locales, options)
```

Parameters

The `locales` and `options` parameters customize the behavior of the function and let applications specify the language whose formatting conventions should be used.

In implementations that support the `Intl.NumberFormat` API, these parameters correspond exactly to the `Intl.NumberFormat()` constructor's parameters. Implementations without `Intl.NumberFormat` support are asked to ignore both parameters, making the locale used and the form of the string returned entirely implementation-dependent.

`locales` Optional

> A string with a BCP 47 language tag, or an array of such strings. Corresponds to the `locales` parameter of the `Intl.NumberFormat()` constructor.
>
> In implementations without `Intl.NumberFormat` support, this parameter is ignored and the host's locale is usually used.

`options` Optional

> An object adjusting the output format. Corresponds to the `options` parameter of the `Intl.NumberFormat()` constructor.
>
> In implementations without `Intl.NumberFormat` support, this parameter is ignored.

See the `Intl.NumberFormat()` constructor for details on these parameters and how to use them.

Return value

A string representing the given BigInt according to language-specific conventions.

In implementations with `Intl.NumberFormat`, this is equivalent to `new Intl.NumberFormat(locales, options).format(number)`.

> **Note:** Most of the time, the formatting returned by `toLocaleString()` is consistent. However, the output may vary between implementations, even within the same locale — output variations are by design and allowed by the specification. It may also not be what you expect. For example, the string may use non-breaking spaces or be surrounded by bidirectional control characters. You should not compare the results of `toLocaleString()` to hardcoded constants.

Examples

Using toLocaleString()

Basic use of this method without specifying a `locale` returns a formatted string in the default locale and with default options.

```
const bigint = 3500n;

console.log(bigint.toLocaleString());
// "3,500" if in U.S. English locale
```

Checking for support for locales and options parameters

The `locales` and `options` parameters may not be supported in all implementations, because support for the internationalization API is optional, and some systems may not have the necessary data. For implementations without internationalization support, `toLocaleString()` always uses the system's locale, which may not be what you want. Because any implementation that supports the `locales` and `options` parameters must support the `Intl` API, you can check the existence of the latter for support:

```
function toLocaleStringSupportsLocales() {
  return (
    typeof Intl === "object" &&
    !!Intl &&
    typeof Intl.NumberFormat === "function"
  );
}
```

Using locales

This example shows some of the variations in localized number formats. In order to get the format of the language used in the user interface of your application, make sure to specify that language (and possibly some fallback languages) using the `locales` argument:

```
const bigint = 123456789123456789n;

// German uses period for thousands
```

```
console.log(bigint.toLocaleString("de-DE"));
// 123.456.789.123.456.789

// Arabic in most Arabic speaking countries uses Eastern Arabic digits
console.log(bigint.toLocaleString("ar-EG"));
// ١٢٣,٤٥٦,٧٨٩,١٢٣,٤٥٦,٧٨٩

// India uses thousands/lakh/crore separators
console.log(bigint.toLocaleString("en-IN"));
// 1,23,45,67,89,12,34,56,789

// the nu extension key requests a numbering system, e.g. Chinese decimal
console.log(bigint.toLocaleString("zh-Hans-CN-u-nu-hanidec"));
// 一二三,四五六,七八九,一二三,四五六,七八九

// when requesting a language that may not be supported, such as
// Balinese, include a fallback language, in this case Indonesian
console.log(bigint.toLocaleString(["ban", "id"]));
// 123.456.789.123.456.789
```

Using options

The results provided by `toLocaleString()` can be customized using the `options` parameter:

```
const bigint = 123456789123456789n;

// request a currency format
console.log(
  bigint.toLocaleString("de-DE", { style: "currency", currency: "EUR" }),
);
// 123.456.789.123.456.789,00 €

// the Japanese yen doesn't use a minor unit
console.log(
  bigint.toLocaleString("ja-JP", { style: "currency", currency: "JPY" }),
);
// ￥123,456,789,123,456,789

// limit to three significant digits
console.log(bigint.toLocaleString("en-IN", { maximumSignificantDigits: 3 }));
// 1,23,00,00,00,00,00,00,000
```

See also

- `Intl.NumberFormat`
- `BigInt.prototype.toString()`

BigInt.prototype.toString()

The **`toString()`** method of `BigInt` values returns a string representing the specified `BigInt` value. The trailing "n" is not part of the string.

Try it

```
console.log(1024n.toString());
// Expected output: "1024"

console.log(1024n.toString(2));
// Expected output: "10000000000"

console.log(1024n.toString(16));
// Expected output: "400"
```

Syntax

```
toString()
toString(radix)
```

Parameters

`radix` Optional

An integer in the range 2 through 36 specifying the base to use for representing the BigInt value. Defaults to 10.

Return value

A string representing the specified `BigInt` value.

Exceptions

`RangeError`

Thrown if `radix` is less than 2 or greater than 36.

Description

The `BigInt` object overrides the `toString` method of `Object`; it does not inherit `Object.prototype.toString()`. For `BigInt` values, the `toString()` method returns a string representation of the value in the specified radix.

For radixes above 10, the letters of the alphabet indicate digits greater than 9. For example, for hexadecimal numbers (base 16) `a` through `f` are used.

If the specified BigInt value is negative, the sign is preserved. This is the case even if the radix is 2; the string returned is the positive binary representation of the BigInt value preceded by a `-` sign, **not** the two's complement of the BigInt value.

The `toString()` method requires its `this` value to be a `BigInt` primitive or wrapper object. It throws a `TypeError` for other `this` values without attempting to coerce them to BigInt values.

Because `BigInt` doesn't have a `[Symbol.toPrimitive]()` method, JavaScript calls the `toString()` method automatically when a `BigInt` *object* is used in a context expecting a string, such as in a template literal. However, BigInt *primitive* values do not consult the `toString()` method to be coerced to strings — rather, they are directly converted using the same algorithm as the initial `toString()` implementation.

```
BigInt.prototype.toString = () => "Overridden";
console.log(`${1n}`); // "1"
console.log(`${Object(1n)}`); // "Overridden"
```

Examples

Using toString()

```
17n.toString(); // "17"
66n.toString(2); // "1000010"
254n.toString(16); // "fe"
(-10n).toString(2); // "-1010"
(-0xffn).toString(2); // "-11111111"
```

Negative-zero BigInt

There is no negative-zero `BigInt` as there are no negative zeros in integers. `-0.0` is an IEEE floating-point concept that only appears in the JavaScript `Number` type.

```
(-0n).toString(); // "0"
BigInt(-0).toString(); // "0"
```

See also

- `BigInt.prototype.toLocaleString()`
- `BigInt.prototype.valueOf()`
- `Number.prototype.toString()`

BigInt.prototype.valueOf()

The **`valueOf()`** method of `BigInt` values returns the wrapped primitive value of a `BigInt` object.

Try it

```
console.log(typeof Object(1n));
// Expected output: "object"

console.log(typeof Object(1n).valueOf());
// Expected output: "bigint"
```

Syntax

```
valueOf()
```

Parameters

None.

Return value

A BigInt representing the primitive value of the specified `BigInt` object.

Examples

Using <code>valueOf</code>

```
typeof Object(1n); // object
typeof Object(1n).valueOf(); // bigint
```

See also

- `BigInt.prototype.toString()`

BigInt64Array

The **`BigInt64Array`** typed array represents an array of 64-bit signed integers in the platform byte order. If control over byte order is needed, use `DataView` instead. The contents are initialized to `0n` unless initialization data is explicitly provided. Once established, you can reference elements in the array using the object's methods, or

using standard array index syntax (that is, using bracket notation).

`BigInt64Array` is a subclass of the hidden `TypedArray` class.

Try it

```
const buffer = new ArrayBuffer(24);
const bigint64 = new BigInt64Array(buffer);
bigint64[0] = 5886014448488689n;
bigint64[1] = 1881938909131133n;
bigint64[2] = 1898875537769492n;

bigint64[0] = 6118793953620967n;
console.log(bigint64);
// Expected Output: BigInt64Array [6118793953620967n, 1881938909131133n, 1898875537769492n]

console.log(bigint64[2]);
// Expected Output: 1898875537769492n

console.log("Array length:", bigint64.length);
// Expected Output: Array length: 3

console.log("Array byte length:", bigint64.byteLength);
// Expected Output: Array byte length: 24

console.log("Array byte offset:", bigint64.byteOffset);
// Expected Output: Array byte offset: 0

bigint64.set([100n, 200n], 1);
console.log(bigint64);
// Expected Output: BigInt64Array [6118793953620967n, 100n, 200n]
```

Constructor

`BigInt64Array()`

Creates a new `BigInt64Array` object.

Static properties

Also inherits static properties from its parent `TypedArray`.

`BigInt64Array.BYTES_PER_ELEMENT`

Returns a number value of the element size. `8` in the case of `BigInt64Array`.

Static methods

Inherits static methods from its parent `TypedArray`.

Instance properties

Also inherits instance properties from its parent `TypedArray`.

These properties are defined on `BigInt64Array.prototype` and shared by all `BigInt64Array` instances.

`BigInt64Array.prototype.BYTES_PER_ELEMENT`

Returns a number value of the element size. `8` in the case of a `BigInt64Array`.

`BigInt64Array.prototype.constructor`

The constructor function that created the instance object. For `BigInt64Array` instances, the initial value is the `BigInt64Array` constructor.

Instance methods

Inherits instance methods from its parent `TypedArray`.

Examples

Different ways to create a BigInt64Array

```
// From a length
const bigint64 = new BigInt64Array(2);
bigint64[0] = 42n;
console.log(bigint64[0]); // 42n
console.log(bigint64.length); // 2
console.log(bigint64.BYTES_PER_ELEMENT); // 8

// From an array
const x = new BigInt64Array([21n, 31n]);
console.log(x[1]); // 31n

// From another TypedArray
const y = new BigInt64Array(x);
```

```
console.log(y[0]); // 21n

// From an ArrayBuffer
const buffer = new ArrayBuffer(64);
const z = new BigInt64Array(buffer, 8, 4);
console.log(z.byteOffset); // 8

// From an iterable
const iterable = (function* () {
  yield* [1n, 2n, 3n];
})();
const bigint64FromIterable = new BigInt64Array(iterable);
console.log(bigint64FromIterable);
// BigInt64Array [1n, 2n, 3n]
```

BigInt64Array() constructor

The **`BigInt64Array()`** constructor creates `BigInt64Array` objects. The contents are initialized to `0n` unless initialization data is explicitly provided.

Syntax

```
new BigInt64Array()
new BigInt64Array(length)
new BigInt64Array(typedArray)
new BigInt64Array(object)

new BigInt64Array(buffer)
new BigInt64Array(buffer, byteOffset)
new BigInt64Array(buffer, byteOffset, length)
```

> **Note:** `BigInt64Array()` can only be constructed with `new`. Attempting to call it without `new` throws a `TypeError`.

Parameters

See `TypedArray`.

Exceptions

See `TypedArray`.

Examples

Different ways to create a BigInt64Array

```
// From a length
const bigint64 = new BigInt64Array(2);
bigint64[0] = 42n;
console.log(bigint64[0]); // 42n
console.log(bigint64.length); // 2
console.log(bigint64.BYTES_PER_ELEMENT); // 8

// From an array
const x = new BigInt64Array([21n, 31n]);
console.log(x[1]); // 31n

// From another TypedArray
const y = new BigInt64Array(x);
console.log(y[0]); // 21n

// From an ArrayBuffer
const buffer = new ArrayBuffer(64);
const z = new BigInt64Array(buffer, 8, 4);
console.log(z.byteOffset); // 8

// From an iterable
const iterable = (function* () {
  yield* [1n, 2n, 3n];
})();
const bigint64FromIterable = new BigInt64Array(iterable);
console.log(bigint64FromIterable);
// BigInt64Array [1n, 2n, 3n]
```

BigUint64Array

The **`BigUint64Array`** typed array represents an array of 64-bit unsigned integers in the platform byte order. If control over byte order is needed, use `DataView` instead. The contents are initialized to `0n` unless initialization data is explicitly provided. Once established, you can reference elements in the array using the object's methods, or using standard array index syntax (that is, using bracket notation).

`BigUint64Array` is a subclass of the hidden `TypedArray` class.

Constructor

`BigUint64Array()`

Creates a new `BigUint64Array` object.

Static properties

Also inherits static properties from its parent `TypedArray`.

`BigUint64Array.BYTES_PER_ELEMENT`

Returns a number value of the element size. `8` in the case of `BigUint64Array`.

Static methods

Inherits static methods from its parent `TypedArray`.

Instance properties

Also inherits instance properties from its parent `TypedArray`.

These properties are defined on `BigUint64Array.prototype` and shared by all `BigUint64Array` instances.

`BigUint64Array.prototype.BYTES_PER_ELEMENT`

Returns a number value of the element size. `8` in the case of a `BigUint64Array`.

`BigUint64Array.prototype.constructor`

The constructor function that created the instance object. For `BigUint64Array` instances, the initial value is the `BigUint64Array` constructor.

Instance methods

Inherits instance methods from its parent `TypedArray`.

Examples

Different ways to create a BigUint64Array

```
// From a length
const biguint64 = new BigUint64Array(2);
biguint64[0] = 42n;
console.log(biguint64[0]); // 42n
console.log(biguint64.length); // 2
console.log(biguint64.BYTES_PER_ELEMENT); // 8

// From an array
const x = new BigUint64Array([21n, 31n]);
console.log(x[1]); // 31n

// From another TypedArray
const y = new BigUint64Array(x);
console.log(y[0]); // 21n

// From an ArrayBuffer
const buffer = new ArrayBuffer(64);
const z = new BigUint64Array(buffer, 8, 4);
console.log(z.byteOffset); // 8

// From an iterable
const iterable = (function* () {
  yield* [1n, 2n, 3n];
})();
const biguint64FromIterable = new BigUint64Array(iterable);
console.log(biguint64FromIterable);
// BigUint64Array [1n, 2n, 3n]
```

BigUint64Array() constructor

The **`BigUint64Array()`** constructor creates `BigUint64Array` objects. The contents are initialized to `0n` unless initialization data is explicitly provided.

Syntax

```
new BigUint64Array()
new BigUint64Array(length)
new BigUint64Array(typedArray)
new BigUint64Array(object)

new BigUint64Array(buffer)
new BigUint64Array(buffer, byteOffset)
new BigUint64Array(buffer, byteOffset, length)
```

> **Note:** `BigUint64Array()` can only be constructed with `new`. Attempting to call it without `new` throws a `TypeError`.

Parameters

See `TypedArray`.

Exceptions

See `TypedArray`.

Examples

Different ways to create a BigUint64Array

```
// From a length
const biguint64 = new BigUint64Array(2);
biguint64[0] = 42n;
console.log(biguint64[0]); // 42n
console.log(biguint64.length); // 2
console.log(biguint64.BYTES_PER_ELEMENT); // 8

// From an array
const x = new BigUint64Array([21n, 31n]);
console.log(x[1]); // 31n

// From another TypedArray
const y = new BigUint64Array(x);
console.log(y[0]); // 21n

// From an ArrayBuffer
const buffer = new ArrayBuffer(64);
const z = new BigUint64Array(buffer, 8, 4);
console.log(z.byteOffset); // 8

// From an iterable
const iterable = (function* () {
  yield* [1n, 2n, 3n];
})();
const biguint64FromIterable = new BigUint64Array(iterable);
console.log(biguint64FromIterable);
// BigUint64Array [1n, 2n, 3n]
```

Boolean

`Boolean` values can be one of two values: `true` or `false`, representing the truth value of a logical proposition.

Description

Boolean values are typically produced by relational operators, equality operators, and logical NOT (`!`). They can also be produced by functions that represent conditions, such as `Array.isArray()`. Note that binary logical operators such as `&&` and `||` return the values of the operands, which may or may not be boolean values.

Boolean values are typically used in conditional testing, such as the condition for `if...else` and `while` statements, the conditional operator (`? :`), or the predicate return value of `Array.prototype.filter()`.

You would rarely need to explicitly convert something to a boolean value, as JavaScript does this automatically in boolean contexts, so you can use any value as if it's a boolean, based on its truthiness. You are also encouraged to use `if (condition)` and `if (!condition)` instead of `if (condition === true)` or `if (condition === false)`

in your own code so you can take advantage of this convention. However, making sure that values representing conditions are always booleans can help clarify the intent of your code.

```
// Do this:
// This always returns a boolean value
const isObject = (obj) => !!obj && typeof obj === "object";

// Or this:
const isObject = (obj) => Boolean(obj) && typeof obj === "object";

// Or this:
const isObject = (obj) => obj !== null && typeof obj === "object";

// Instead of this:
// This may return falsy values that are not equal to false
const isObject = (obj) => obj && typeof obj === "object";
```

Boolean primitives and Boolean objects

For converting non-boolean values to boolean, use `Boolean` as a function or use the double NOT operator. Do not use the `Boolean()` constructor with `new`.

```
const good = Boolean(expression);
const good2 = !!expression;
```

```
const bad = new Boolean(expression); // don't use this!
```

This is because *all* objects, including a `Boolean` object whose wrapped value is `false`, are truthy and evaluate to `true` in places such as conditional statements. (See also the boolean coercion section below.)

```
if (new Boolean(true)) {
  console.log("This log is printed.");
}

if (new Boolean(false)) {
  console.log("This log is ALSO printed.");
}

const myFalse = new Boolean(false); // myFalse is a Boolean object (not the primitive value false)
const g = Boolean(myFalse); // g is true
const myString = new String("Hello"); // myString is a String object
const s = Boolean(myString); // s is true
```

> **Warning:** You should rarely find yourself using `Boolean` as a constructor.

Boolean coercion

Many built-in operations that expect booleans first coerce their arguments to booleans. The operation can be summarized as follows:

- Booleans are returned as-is.
- `undefined` turns into `false`.
- `null` turns into `false`.
- `0`, `-0`, and `NaN` turn into `false`; other numbers turn into `true`.
- `0n` turns into `false`; other BigInts turn into `true`.
- The empty string `""` turns into `false`; other strings turn into `true`.
- Symbols turn into `true`.
- All objects become `true`.

> **Note:** A legacy behavior makes `document.all` return `false` when used as a boolean, despite it being an object. This property is legacy and non-standard and should not be used.

> **Note:** Unlike other type conversions like string coercion or number coercion, boolean coercion does not attempt to convert objects to primitives by calling user methods.

In other words, there are only a handful of values that get coerced to `false` — these are called falsy values. All other values are called truthy values. A value's truthiness is important when used with logical operators, conditional statements, or any boolean context.

There are two ways to achieve the same effect in JavaScript.

- Double NOT: `!!x` negates `x` twice, which converts `x` to a boolean using the same algorithm as above.
- The `Boolean()` function: `Boolean(x)` uses the same algorithm as above to convert `x`.

Note that truthiness is not the same as being loosely equal to `true` or `false`.

```
if ([]) {
  console.log("[] is truthy");
}
```

```
if ([] == false) {
  console.log("[] == false");
}
// [] is truthy
// [] == false
```

`[]` is truthy, but it's also loosely equal to `false`. It's truthy, because all objects are truthy. However, when comparing with `false`, which is a primitive, `[]` is also converted to a primitive, which is `""` via `Array.prototype.toString()`. Comparing strings and booleans results in both being converted to numbers, and they both become `0`, so `[] == false` is `true`. In general, falsiness and `== false` differ in the following cases:

- `NaN`, `undefined`, and `null` are falsy but not loosely equal to `false`.
- `"0"` (and other string literals that are not `""` but get coerced to 0) is truthy but loosely equal to `false`.
- Objects are always truthy, but their primitive representation may be loosely equal to `false`.

Truthy values are even more unlikely to be loosely equal to `true`. All values are either truthy or falsy, but most values are loosely equal to neither `true` nor `false`.

Constructor

`Boolean()`

Creates `Boolean` objects. When called as a function, it returns primitive values of type Boolean.

Instance properties

These properties are defined on `Boolean.prototype` and shared by all `Boolean` instances.

`Boolean.prototype.constructor`

The constructor function that created the instance object. For `Boolean` instances, the initial value is the `Boolean` constructor.

Instance methods

`Boolean.prototype.toString()`

Returns a string of either `true` or `false` depending upon the value of the object. Overrides the `Object.prototype.toString()` method.

`Boolean.prototype.valueOf()`

Returns the primitive value of the `Boolean` object. Overrides the `Object.prototype.valueOf()` method.

Examples

Creating false values

```
const bNoParam = Boolean();
const bZero = Boolean(0);
const bNull = Boolean(null);
const bEmptyString = Boolean("");
const bfalse = Boolean(false);
```

Creating true values

```
const btrue = Boolean(true);
const btrueString = Boolean("true");
const bfalseString = Boolean("false");
const bSuLin = Boolean("Su Lin");
const bArrayProto = Boolean([]);
const bObjProto = Boolean({});
```

See also

- Boolean
- Boolean primitives
- Boolean data type on Wikipedia

Boolean() constructor

The **`Boolean()`** constructor creates `Boolean` objects. When called as a function, it returns primitive values of type Boolean.

Try it

```
const flag = new Boolean();
console.log(typeof flag);
// Expected output: object
console.log(flag === false);
// Expected output: false

const flag2 = Boolean();
console.log(typeof flag2);
// Expected output: boolean
console.log(flag2 === false);
// Expected output: true
```

Syntax

```
new Boolean(value)
Boolean(value)
```

> **Note:** `Boolean()` can be called with or without `new`, but with different effects. See Return value.

Parameters

`value`

The initial value of the `Boolean` object.

Return value

When `Boolean()` is called as a function (without `new`), it returns `value` coerced to a boolean primitive.

When `Boolean()` is called as a constructor (with `new`), it coerces `value` to a boolean primitive and returns a wrapping `Boolean` object, which is **not** a primitive.

> **Warning:** You should rarely find yourself using `Boolean` as a constructor.

Description

The value passed as the first parameter is converted to a boolean value. If the value is omitted or is `0`, `-0`, `0n`, `null`, `false`, `NaN`, `undefined`, or the empty string (`""`), then the object has an initial value of `false`. All other values, including any object, an empty array (`[]`), or the string `"false"`, create an object with an initial value of `true`.

> **Note:** When the non-standard property `document.all` is used as an argument for this constructor, the result is a `Boolean` object with the value `false`. This property is legacy and non-standard and should not be used.

Examples

Creating Boolean objects with an initial value of false

```
const bZero = new Boolean(0);
const bNull = new Boolean(null);
const bEmptyString = new Boolean("");
const bfalse = new Boolean(false);

typeof bfalse; // "object"
Boolean(bfalse); // true
```

Note how converting a `Boolean` object to a primitive with `Boolean()` always yields `true`, even if the object holds a value of `false`. You are therefore always advised to avoid constructing `Boolean` wrapper objects.

If you need to take the primitive value out from the wrapper object, instead of using the `Boolean()` function, use the object's `valueOf()` method instead.

```
const bfalse = new Boolean(false);

bfalse.valueOf(); // false
```

Creating <code>Boolean</code> objects with an initial value of <code>true</code>

```
const btrue = new Boolean(true);
const btrueString = new Boolean("true");
const bfalseString = new Boolean("false");
const bSuLin = new Boolean("Su Lin");
const bArrayProto = new Boolean([]);
const bObjProto = new Boolean({});
```

See also

- Boolean

Boolean.prototype.toString()

The **`toString()`** method of `Boolean` values returns a string representing the specified boolean value.

Try it

```
const flag1 = new Boolean(true);

console.log(flag1.toString());
// Expected output: "true"

const flag2 = new Boolean(1);
```

```
console.log(flag2.toString());
// Expected output: "true"
```

Syntax

```
toString()
```

Parameters

None.

Return value

A string representing the specified boolean value.

Description

The `Boolean` object overrides the `toString` method of `Object`; it does not inherit `Object.prototype.toString()`. For `Boolean` values, the `toString` method returns a string representation of the boolean value, which is either `"true"` or `"false"`.

The `toString()` method requires its `this` value to be a `Boolean` primitive or wrapper object. It throws a `TypeError` for other `this` values without attempting to coerce them to boolean values.

Because `Boolean` doesn't have a `[Symbol.toPrimitive]()` method, JavaScript calls the `toString()` method automatically when a `Boolean` *object* is used in a context expecting a string, such as in a template literal. However, boolean *primitive* values do not consult the `toString()` method to be coerced to strings — rather, they are directly converted using the same algorithm as the initial `toString()` implementation.

```
Boolean.prototype.toString = () => "Overridden";
console.log(`${true}`); // "true"
console.log(`${new Boolean(true)}`); // "Overridden"
```

Examples

Using toString()

```
const flag = new Boolean(true);
console.log(flag.toString()); // "true"
console.log(false.toString()); // "false"
```

See also

- `Object.prototype.toString()`

Boolean.prototype.valueOf()

The **`valueOf()`** method of `Boolean` values returns the primitive value of a `Boolean` object.

Try it

```
const x = new Boolean();

console.log(x.valueOf());
// Expected output: false

const y = new Boolean("Mozilla");

console.log(y.valueOf());
// Expected output: true
```

Syntax

```
valueOf()
```

Parameters

None.

Return value

The primitive value of the given `Boolean` object.

Description

The `valueOf()` method of `Boolean` returns the primitive value of a `Boolean` object or literal `Boolean` as a Boolean data type.

This method is usually called internally by JavaScript and not explicitly in code.

Examples

Using <code>valueOf()</code>

```
const x = new Boolean();
const myVar = x.valueOf(); // assigns false to myVar
```

See also

- `Object.prototype.valueOf()`

DataView

The **`DataView`** view provides a low-level interface for reading and writing multiple number types in a binary `ArrayBuffer`, without having to care about the platform's endianness.

Description

Endianness

Multi-byte number formats are represented in memory differently depending on machine architecture — see Endianness for an explanation. `DataView` accessors provide explicit control of how data is accessed, regardless of the executing computer's endianness. For example, WebAssembly memory is always little-endian, so you should use `DataView` instead of typed arrays to read and write multi-byte values. See `WebAssembly.Memory` for an example.

```
const littleEndian = (() => {
  const buffer = new ArrayBuffer(2);
  new DataView(buffer).setInt16(0, 256, true /* littleEndian */);
  // Int16Array uses the platform's endianness.
  return new Int16Array(buffer)[0] === 256;
})();
console.log(littleEndian); // true or false
```

> **Note:** `DataView` defaults to big-endian read and write, but most platforms use little-endian.

Constructor

`DataView()`

Creates a new `DataView` object.

Instance properties

These properties are defined on `DataView.prototype` and shared by all `DataView` instances.

`DataView.prototype.buffer`

Returns the `ArrayBuffer` referenced by the `DataView`.

`DataView.prototype.byteLength`

Returns the length (in bytes) of the `DataView`.

`DataView.prototype.byteOffset`

Returns the offset (in bytes) of the `DataView` from the start of its `ArrayBuffer`.

`DataView.prototype.constructor`

The constructor function that created the instance object. For `DataView` instances, the initial value is the `DataView` constructor.

`DataView.prototype[Symbol.toStringTag]`

The initial value of the `[Symbol.toStringTag]` property is the string `"DataView"`. This property is used in `Object.prototype.toString()`.

Instance methods

`DataView.prototype.getBigInt64()`

Reads 8 bytes starting at the specified byte offset of this `DataView` and interprets them as a 64-bit signed integer.

`DataView.prototype.getBigUint64()`

Reads 8 bytes starting at the specified byte offset of this `DataView` and interprets them as a 64-bit unsigned integer.

`DataView.prototype.getFloat16()`

Reads 2 bytes starting at the specified byte offset of this `DataView` and interprets them as a 16-bit floating point number.

`DataView.prototype.getFloat32()`

Reads 4 bytes starting at the specified byte offset of this `DataView` and interprets them as a 32-bit floating point number.

`DataView.prototype.getFloat64()`

Reads 8 bytes starting at the specified byte offset of this `DataView` and interprets them as a 64-bit floating point number.

`DataView.prototype.getInt16()`

Reads 2 bytes starting at the specified byte offset of this `DataView` and interprets them as a 16-bit signed integer.

`DataView.prototype.getInt32()`

Reads 4 bytes starting at the specified byte offset of this `DataView` and interprets them as a 32-bit signed integer.

`DataView.prototype.getInt8()`

Reads 1 byte at the specified byte offset of this `DataView` and interprets it as an 8-bit signed integer.

`DataView.prototype.getUint16()`

Reads 2 bytes starting at the specified byte offset of this `DataView` and interprets them as a 16-bit unsigned integer.

`DataView.prototype.getUint32()`

Reads 4 bytes starting at the specified byte offset of this `DataView` and interprets them as a 32-bit unsigned integer.

`DataView.prototype.getUint8()`

Reads 1 byte at the specified byte offset of this `DataView` and interprets it as an 8-bit unsigned integer.

`DataView.prototype.setBigInt64()`

Takes a BigInt and stores it as a 64-bit signed integer in the 8 bytes starting at the specified byte offset of this `DataView`.

`DataView.prototype.setBigUint64()`

Takes a BigInt and stores it as a 64-bit unsigned integer in the 8 bytes starting at the specified byte offset of this `DataView`.

`DataView.prototype.setFloat16()`

Takes a number and stores it as a 16-bit float in the 2 bytes starting at the specified byte offset of this `DataView`.

`DataView.prototype.setFloat32()`

Takes a number and stores it as a 32-bit float in the 4 bytes starting at the specified byte offset of this `DataView`.

`DataView.prototype.setFloat64()`

Takes a number and stores it as a 64-bit float in the 8 bytes starting at the specified byte offset of this `DataView`.

`DataView.prototype.setInt16()`

Takes a number and stores it as a 16-bit signed integer in the 2 bytes at the specified byte offset of this `DataView`.

`DataView.prototype.setInt32()`

Takes a number and stores it as a 32-bit signed integer in the 4 bytes at the specified byte offset of this `DataView`.

`DataView.prototype.setInt8()`

Takes a number and stores it as an 8-bit signed integer in the byte at the specified byte offset of this `DataView`.

`DataView.prototype.setUint16()`

Takes a number and stores it as a 16-bit unsigned integer in the 2 bytes at the specified byte offset of this `DataView`.

`DataView.prototype.setUint32()`

Takes a number and stores it as a 32-bit unsigned integer in the 4 bytes at the specified byte offset of this `DataView`.

`DataView.prototype.setUint8()`

Takes a number and stores it as an 8-bit unsigned integer in the byte at the specified byte offset of this `DataView`.

Examples

Using DataView

```
const buffer = new ArrayBuffer(16);
const view = new DataView(buffer, 0);

view.setInt16(1, 42);
view.getInt16(1); // 42
```

See also

- Polyfill of `DataView` in `core-js`
- `ArrayBuffer`
- `SharedArrayBuffer`

DataView.prototype.buffer

The **`buffer`** accessor property of `DataView` instances returns the `ArrayBuffer` or `SharedArrayBuffer` referenced by this view at construction time.

Try it

```
// Create an ArrayBuffer
const buffer = new ArrayBuffer(123);

// Create a view
const view = new DataView(buffer);

console.log(view.buffer.byteLength);
// Expected output: 123
```

Description

The `buffer` property is an accessor property whose set accessor function is `undefined`, meaning that you can only read this property. The value is established when the `DataView` is constructed and cannot be changed.

Examples

Using the buffer property

```
const buffer = new ArrayBuffer(8);
const dataview = new DataView(buffer);
dataview.buffer; // ArrayBuffer { byteLength: 8 }
```

See also

- `DataView`
- `ArrayBuffer`
- `SharedArrayBuffer`

DataView.prototype.byteLength

The **`byteLength`** accessor property of `DataView` instances returns the length (in bytes) of this view.

Try it

```
// Create an ArrayBuffer with a size in bytes
const buffer = new ArrayBuffer(16);

const view1 = new DataView(buffer);
const view2 = new DataView(buffer, 12, 4); // From byte 12 for the next 4 bytes

console.log(view1.byteLength + view2.byteLength); // 16 + 4
// Expected output: 20
```

Description

The `byteLength` property is an accessor property whose set accessor function is `undefined`, meaning that you can only read this property. If the `DataView` is length-tracking, then its length depends on the length of the underlying buffer, and may change if the buffer is resized. Otherwise, the value is established when the `DataView` is constructed and cannot be changed. Whether length-tracking or not, the `byteLength` becomes 0 if the underlying buffer is resized such that the viewed range is no longer valid.

Examples

Using the byteLength property

```
const buffer = new ArrayBuffer(8);
const dataview = new DataView(buffer);
dataview.byteLength; // 8 (matches the byteLength of the buffer)

const dataview2 = new DataView(buffer, 1, 5);
dataview2.byteLength; // 5 (as specified when constructing the DataView)

const dataview3 = new DataView(buffer, 2);
dataview3.byteLength; // 6 (due to the offset of the constructed DataView)

const buffer2 = new ArrayBuffer(16, { maxByteLength: 32 });
const dataviewLengthTracking = new DataView(buffer2, 4);
dataviewLengthTracking.byteLength; // 12 (16 - 4)
buffer2.resize(20);
dataviewLengthTracking.byteLength; // 16 (20 - 4)
buffer2.resize(3);
dataviewLengthTracking.byteLength; // 0 (viewed range is no longer valid)
```

See also

- JavaScript typed arrays guide
- `DataView`
- `ArrayBuffer`
- `SharedArrayBuffer`

DataView.prototype.byteOffset

The **`byteOffset`** accessor property of `DataView` instances returns the offset (in bytes) of this view from the start of its `ArrayBuffer` or `SharedArrayBuffer`.

Try it

```
// Create an ArrayBuffer with a size in bytes
const buffer = new ArrayBuffer(16);

const view = new DataView(buffer, 12, 4); // From byte 12 for the next 4 bytes

console.log(view.byteOffset);
// Expected output: 12
```

Description

The `byteOffset` property is an accessor property whose set accessor function is `undefined`, meaning that you can only read this property. The value is established when the `DataView` is constructed and cannot be changed. However, the `byteOffset` becomes 0 if the underlying buffer is resized such that the viewed range is no longer valid.

Examples

Using the byteOffset property

```
const buffer = new ArrayBuffer(8);
const dataview = new DataView(buffer);
dataview.byteOffset; // 0 (no offset specified)

const dataview2 = new DataView(buffer, 3);
dataview2.byteOffset; // 3 (as specified when constructing the DataView)

const buffer2 = new ArrayBuffer(16, { maxByteLength: 32 });
const dataviewLengthTracking = new DataView(buffer2, 4);
dataviewLengthTracking.byteOffset; // 4
buffer2.resize(3);
dataviewLengthTracking.byteOffset; // 0 (viewed range is no longer valid)
```

DataView() constructor

The **`DataView()`** constructor creates `DataView` objects.

Try it

```
// Create an ArrayBuffer with a size in bytes
const buffer = new ArrayBuffer(16);

// Create a couple of views
const view1 = new DataView(buffer);
const view2 = new DataView(buffer, 12, 4); // From byte 12 for the next 4 bytes
view1.setInt8(12, 42); // Put 42 in slot 12

console.log(view2.getInt8(0));
// Expected output: 42
```

Syntax

```
new DataView(buffer)
new DataView(buffer, byteOffset)
new DataView(buffer, byteOffset, byteLength)
```

> **Note:** `DataView()` can only be constructed with `new`. Attempting to call it without `new` throws a `TypeError`.

Parameters

`buffer`

An existing `ArrayBuffer` or `SharedArrayBuffer` to use as the storage backing the new `DataView` object.

`byteOffset` Optional

The offset, in bytes, to the first byte in the above buffer for the new view to reference. If unspecified, the buffer view starts with the first byte.

`byteLength` Optional

The number of elements in the byte array. If unspecified, the view's length will match the buffer's length.

Return value

A new `DataView` object representing the specified data buffer.

Exceptions

`RangeError`

Thrown if the `byteOffset` or `byteLength` parameter values result in the view extending past the end of the buffer. In other words, `byteOffset + byteLength > buffer.byteLength`.

Examples

Using DataView

```
const buffer = new ArrayBuffer(16);
const view = new DataView(buffer, 0);

view.setInt16(1, 42);
view.getInt16(1); // 42
```

See also

- Polyfill of `DataView` in `core-js`
- `DataView`

DataView.prototype.getBigInt64()

The **`getBigInt64()`** method of `DataView` instances reads 8 bytes starting at the specified byte offset of this `DataView` and interprets them as a 64-bit signed integer. There is no alignment constraint; multi-byte values may be fetched from any offset within bounds.

Try it

```
// Create an ArrayBuffer with a size in bytes
const buffer = new ArrayBuffer(16);

// Highest possible BigInt value that fits in a signed 64-bit integer
const max = 2n ** (64n - 1n) - 1n;

const view = new DataView(buffer);
view.setBigInt64(1, max);

console.log(view.getBigInt64(1));
// Expected output: 92233720368547758O7n
```

Syntax

```
getBigInt64(byteOffset)
getBigInt64(byteOffset, littleEndian)
```

Parameters

`byteOffset`

The offset, in bytes, from the start of the view to read the data from.

`littleEndian` Optional

Indicates whether the data is stored in little- or big-endian format. If `false` or `undefined`, a big-endian value is read.

Return value

A `BigInt` from -2^{63} to $2^{63}-1$, inclusive.

Exceptions

`RangeError`

Thrown if the `byteOffset` is set such that it would read beyond the end of the view.

Examples

Using getBigInt64()

```
const { buffer } = new Uint8Array([0, 1, 2, 3, 4, 5, 6, 7, 8, 9]);
const dataview = new DataView(buffer);
console.log(dataview.getBigInt64(1)); // 72623859790382856n
```

See also

DataView.prototype.getBigUint64()

The **`getBigUint64()`** method of `DataView` instances reads 8 bytes starting at the specified byte offset of this `DataView` and interprets them as a 64-bit unsigned integer. There is no alignment constraint; multi-byte values may be fetched from any offset within bounds.

Try it

```
// Create an ArrayBuffer with a size in bytes
const buffer = new ArrayBuffer(16);

// Highest possible BigInt value that fits in an unsigned 64-bit integer
const max = 2n ** 64n - 1n;

const view = new DataView(buffer);
view.setBigUint64(1, max);

console.log(view.getBigUint64(1));
// Expected output: 18446744073709551615n
```

Syntax

```
getBigUint64(byteOffset)
getBigUint64(byteOffset, littleEndian)
```

Parameters

`byteOffset`

The offset, in bytes, from the start of the view to read the data from.

`littleEndian` Optional

Indicates whether the data is stored in little- or big-endian format. If `false` or `undefined`, a big-endian value is read.

Return value

A `BigInt` from 0 to 2^{64}-1, inclusive.

Exceptions

`RangeError`

Thrown if the `byteOffset` is set such that it would read beyond the end of the view.

Examples

Using getBigUint64()

```
const { buffer } = new Uint8Array([0, 1, 2, 3, 4, 5, 6, 7, 8, 9]);
const dataview = new DataView(buffer);
console.log(dataview.getBigUint64(1)); // 72623859790382856n
```

See also

DataView.prototype.getFloat16()

The **`getFloat16()`** method of `DataView` instances reads 2 bytes starting at the specified byte offset of this `DataView` and interprets them as a 16-bit floating point number. There is no alignment constraint; multi-byte values may be fetched from any offset within bounds.

Try it

```
// Create an ArrayBuffer with a size in bytes
const buffer = new ArrayBuffer(16);

const view = new DataView(buffer);
view.setFloat16(1, Math.PI);

console.log(view.getFloat16(1));
// Expected output: 3.140625
```

Syntax

```
getFloat16(byteOffset)
getFloat16(byteOffset, littleEndian)
```

Parameters

`byteOffset`

The offset, in bytes, from the start of the view to read the data from.

`littleEndian` Optional

Indicates whether the data is stored in little- or big-endian format. If `false` or `undefined`, a big-endian value is read.

Return value

A floating point number from `-65504` to `65504`.

Exceptions

`RangeError`

Thrown if the `byteOffset` is set such that it would read beyond the end of the view.

Examples

Using getFloat16()

```
const { buffer } = new Uint8Array([0, 1, 2, 3, 4, 5, 6, 7, 8, 9]);
const dataview = new DataView(buffer);
console.log(dataview.getFloat16(1)); // 0.00091537799835205078
```

See also

DataView.prototype.getFloat32()

The **`getFloat32()`** method of `DataView` instances reads 4 bytes starting at the specified byte offset of this `DataView` and interprets them as a 32-bit floating point number. There is no alignment constraint; multi-byte values may be fetched from any offset within bounds.

Try it

```
// Create an ArrayBuffer with a size in bytes
const buffer = new ArrayBuffer(16);

const view = new DataView(buffer);
view.setFloat32(1, Math.PI);

console.log(view.getFloat32(1));
// Expected output: 3.1415927410125732
```

Syntax

```
getFloat32(byteOffset)
getFloat32(byteOffset, littleEndian)
```

Parameters

`byteOffset`

The offset, in bytes, from the start of the view to read the data from.

`littleEndian` Optional

Indicates whether the data is stored in little- or big-endian format. If `false` or `undefined`, a big-endian value is read.

Return value

A floating point number from `-3.4e38` to `3.4e38`.

Exceptions

`RangeError`

Thrown if the `byteOffset` is set such that it would read beyond the end of the view.

Examples

Using getFloat32()

```
const { buffer } = new Uint8Array([0, 1, 2, 3, 4, 5, 6, 7, 8, 9]);
const dataview = new DataView(buffer);
```

```
console.log(dataview.getFloat32(1)); // 2.387939260590663e-38
```

DataView.prototype.getFloat64()

The **`getFloat64()`** method of `DataView` instances reads 8 bytes starting at the specified byte offset of this `DataView` and interprets them as a 64-bit floating point number. There is no alignment constraint; multi-byte values may be fetched from any offset within bounds.

Try it

```
// Create an ArrayBuffer with a size in bytes
const buffer = new ArrayBuffer(16);

const view = new DataView(buffer);
view.setFloat64(1, Math.PI);

console.log(view.getFloat64(1));
// Expected output: 3.141592653589793
```

Syntax

```
getFloat64(byteOffset)
getFloat64(byteOffset, littleEndian)
```

Parameters

`byteOffset`

The offset, in bytes, from the start of the view to read the data from.

`littleEndian` Optional

Indicates whether the data is stored in little- or big-endian format. If `false` or `undefined`, a big-endian value is read.

Return value

Any number value.

Exceptions

`RangeError`

Thrown if the `byteOffset` is set such that it would read beyond the end of the view.

Examples

Using getFloat64()

```
const { buffer } = new Uint8Array([0, 1, 2, 3, 4, 5, 6, 7, 8, 9]);
const dataview = new DataView(buffer);
console.log(dataview.getFloat64(1)); // 8.20788039913184e-304
```

See also

DataView.prototype.getInt16()

The **`getInt16()`** method of `DataView` instances reads 2 bytes starting at the specified byte offset of this `DataView` and interprets them as a 16-bit signed integer. There is no alignment constraint; multi-byte values may be fetched from any offset within bounds.

Try it

```
// Create an ArrayBuffer with a size in bytes
const buffer = new ArrayBuffer(16);

const view = new DataView(buffer);
view.setInt16(1, 32767); // Max signed 16-bit integer

console.log(view.getInt16(1));
// Expected output: 32767
```

Syntax

```
getInt16(byteOffset)
getInt16(byteOffset, littleEndian)
```

Parameters

`byteOffset`

The offset, in bytes, from the start of the view to read the data from.

`littleEndian` Optional

Indicates whether the data is stored in little- or big-endian format. If `false` or `undefined`, a big-endian value is read.

Return value

An integer from -32768 to 32767, inclusive.

Exceptions

`RangeError`

Thrown if the `byteOffset` is set such that it would read beyond the end of the view.

Examples

Using getInt16()

```
const { buffer } = new Uint8Array([0, 1, 2, 3, 4, 5, 6, 7, 8, 9]);
const dataview = new DataView(buffer);
console.log(dataview.getInt16(1)); // 258
```

See also

DataView.prototype.getInt32()

The **`getInt32()`** method of `DataView` instances reads 4 bytes starting at the specified byte offset of this `DataView` and interprets them as a 32-bit signed integer. There is no alignment constraint; multi-byte values may be fetched from any offset within bounds.

Try it

```
// Create an ArrayBuffer with a size in bytes
const buffer = new ArrayBuffer(16);

const view = new DataView(buffer);
view.setInt32(1, 2147483647); // Max signed 32-bit integer

console.log(view.getInt32(1));
// Expected output: 2147483647
```

Syntax

```
getInt32(byteOffset)
getInt32(byteOffset, littleEndian)
```

Parameters

`byteOffset`

The offset, in bytes, from the start of the view to read the data from.

`littleEndian` Optional

Indicates whether the data is stored in little- or big-endian format. If `false` or `undefined`, a big-endian value is read.

Return value

An integer from -2147483648 to 2147483647, inclusive.

Exceptions

`RangeError`

Thrown if the `byteOffset` is set such that it would read beyond the end of the view.

Examples

Using getInt32()

```
const { buffer } = new Uint8Array([0, 1, 2, 3, 4, 5, 6, 7, 8, 9]);
const dataview = new DataView(buffer);
console.log(dataview.getInt32(1)); // 16909060
```

See also

- JavaScript typed arrays guide
- `DataView`
- `ArrayBuffer`

DataView.prototype.getInt8()

The **`getInt8()`** method of `DataView` instances reads 1 byte at the specified byte offset of this `DataView` and interprets it as an 8-bit signed integer.

Try it

```
// Create an ArrayBuffer with a size in bytes
const buffer = new ArrayBuffer(16);

const view = new DataView(buffer);
view.setInt8(1, 127); // Max signed 8-bit integer

console.log(view.getInt8(1));
// Expected output: 127
```

Syntax

```
getInt8(byteOffset)
```

Parameters

`byteOffset`

The offset, in bytes, from the start of the view to read the data from.

Return value

An integer from -128 to 127, inclusive.

Exceptions

`RangeError`

Thrown if the `byteOffset` is set such that it would read beyond the end of the view.

Examples

Using getInt8()

```
const { buffer } = new Uint8Array([0, 1, 2, 3, 4, 5, 6, 7, 8, 9]);
const dataview = new DataView(buffer);
console.log(dataview.getInt8(1)); // 1
```

DataView.prototype.getUint16()

The **`getUint16()`** method of `DataView` instances reads 2 bytes starting at the specified byte offset of this `DataView` and interprets them as a 16-bit unsigned integer. There is no alignment constraint; multi-byte values may be fetched from any offset within bounds.

Try it

```
// Create an ArrayBuffer with a size in bytes
const buffer = new ArrayBuffer(16);

const view = new DataView(buffer);
view.setUint16(1, 65535); // Max unsigned 16-bit integer

console.log(view.getUint16(1));
// Expected output: 65535
```

Syntax

```
getUint16(byteOffset)
getUint16(byteOffset, littleEndian)
```

Parameters

`byteOffset`

The offset, in bytes, from the start of the view to read the data from.

`littleEndian` Optional

Indicates whether the data is stored in little- or big-endian format. If `false` or `undefined`, a big-endian value is read.

Return value

An integer from 0 to 65535, inclusive.

Exceptions

`RangeError`

Thrown if the `byteOffset` is set such that it would read beyond the end of the view.

Examples

Using getUint16()

```
const { buffer } = new Uint8Array([0, 1, 2, 3, 4, 5, 6, 7, 8, 9]);
const dataview = new DataView(buffer);
console.log(dataview.getUint16(1)); // 258
```

See also

DataView.prototype.getUint32()

The **`getUint32()`** method of `DataView` instances reads 4 bytes starting at the specified byte offset of this `DataView` and interprets them as a 32-bit unsigned integer. There is no alignment constraint; multi-byte values may be fetched from any offset within bounds.

Try it

```
// Create an ArrayBuffer with a size in bytes
const buffer = new ArrayBuffer(16);

const view = new DataView(buffer);
view.setUint32(1, 4294967295); // Max unsigned 32-bit integer

console.log(view.getUint32(1));
// Expected output: 4294967295
```

Syntax

```
getUint32(byteOffset)
getUint32(byteOffset, littleEndian)
```

Parameters

`byteOffset`

The offset, in bytes, from the start of the view to read the data from.

`littleEndian` Optional

Indicates whether the data is stored in little- or big-endian format. If `false` or `undefined`, a big-endian value is read.

Return value

An integer from 0 to 4294967295, inclusive.

Exceptions

`RangeError`

Thrown if the `byteOffset` is set such that it would read beyond the end of the view.

Examples

Using getUint32()

```
const { buffer } = new Uint8Array([0, 1, 2, 3, 4, 5, 6, 7, 8, 9]);
const dataview = new DataView(buffer);
console.log(dataview.getUint32(1)); // 16909060
```

See also

DataView.prototype.getUint8()

The **`getUint8()`** method of `DataView` instances reads 1 byte at the specified byte offset of this `DataView` and interprets it as an 8-bit unsigned integer.

Try it

```
// Create an ArrayBuffer with a size in bytes
const buffer = new ArrayBuffer(16);

const view = new DataView(buffer);
view.setUint8(1, 255); // Max unsigned 8-bit integer

console.log(view.getUint8(1));
// Expected output: 255
```

Syntax

```
getUint8(byteOffset)
```

Parameters

`byteOffset`

The offset, in bytes, from the start of the view to read the data from.

Return value

An integer from 0 to 255, inclusive.

Exceptions

`RangeError`

Thrown if the `byteOffset` is set such that it would read beyond the end of the view.

Examples

Using getUint8()

```
const { buffer } = new Uint8Array([0, 1, 2, 3, 4, 5, 6, 7, 8, 9]);
const dataview = new DataView(buffer);
console.log(dataview.getUint8(1)); // 1
```

See also

- JavaScript typed arrays guide
- `DataView`
- `ArrayBuffer`

DataView.prototype.setBigInt64()

The **`setBigInt64()`** method of `DataView` instances takes a BigInt and stores it as a 64-bit signed integer in the 8 bytes starting at the specified byte offset of this `DataView`. There is no alignment constraint; multi-byte values may be stored at any offset within bounds.

Try it

```
// Create an ArrayBuffer with a size in bytes
const buffer = new ArrayBuffer(16);

// Highest possible BigInt value that fits in a signed 64-bit integer
const max = 2n ** (64n - 1n) - 1n;

const view = new DataView(buffer);
view.setBigInt64(1, max);

console.log(view.getBigInt64(1));
// Expected output: 9223372036854775807n
```

Syntax

```
setBigInt64(byteOffset, value)
setBigInt64(byteOffset, value, littleEndian)
```

Parameters

`byteOffset`

The offset, in bytes, from the start of the view to store the data in.

`value`

The value to set as a `BigInt`. For how the value is encoded in bytes, see Value encoding and normalization.

`littleEndian` Optional

Indicates whether the data is stored in little- or big-endian format. If `false` or `undefined`, a big-endian value is written.

Return value

`undefined`.

Exceptions

`RangeError`

Thrown if the `byteOffset` is set such that it would store beyond the end of the view.

Examples

Using setBigInt64()

```
const buffer = new ArrayBuffer(10);
const dataview = new DataView(buffer);
dataview.setBigInt64(0, 3n);
dataview.getBigInt64(1); // 768n
```

See also

- JavaScript typed arrays guide
- `DataView`
- `ArrayBuffer`
- `BigInt64Array`

DataView.prototype.setBigUint64()

The **`setBigUint64()`** method of `DataView` instances takes a BigInt and stores it as a 64-bit unsigned integer in the 8 bytes starting at the specified byte offset of this `DataView`. There is no alignment constraint; multi-byte values may be stored at any offset within bounds.

Try it

```
// Create an ArrayBuffer with a size in bytes
const buffer = new ArrayBuffer(16);

// Highest possible BigInt value that fits in an unsigned 64-bit integer
const max = 2n ** 64n - 1n;

const view = new DataView(buffer);
view.setBigUint64(1, max);

console.log(view.getBigUint64(1));
// Expected output: 18446744073709551615n
```

Syntax

```
setBigUint64(byteOffset, value)
setBigUint64(byteOffset, value, littleEndian)
```

Parameters

`byteOffset`

The offset, in bytes, from the start of the view to store the data in.

`value`

The value to set as a `BigInt`. For how the value is encoded in bytes, see Value encoding and normalization.

`littleEndian` Optional

Indicates whether the data is stored in little- or big-endian format. If `false` or `undefined`, a big-endian value is written.

Return value

`undefined`.

Exceptions

`RangeError`

Thrown if the `byteOffset` is set such that it would store beyond the end of the view.

Examples

Using setBigUint64()

```
const buffer = new ArrayBuffer(10);
const dataview = new DataView(buffer);
dataview.setBigUint64(0, 3n);
dataview.getBigUint64(1); // 768n
```

DataView.prototype.setFloat16()

The **`setFloat16()`** method of `DataView` instances takes a number and stores it as a 16-bit floating point number in the 2 bytes starting at the specified byte offset of this `DataView`. There is no alignment constraint; multi-byte values may be stored at any offset within bounds.

Try it

```
// Create an ArrayBuffer with a size in bytes
const buffer = new ArrayBuffer(16);

const view = new DataView(buffer);
view.setFloat16(1, Math.PI);

console.log(view.getFloat16(1));
// Expected output: 3.140625
```

Syntax

```
setFloat16(byteOffset, value)
setFloat16(byteOffset, value, littleEndian)
```

Parameters

`byteOffset`

Thrown if the `byteOffset` is set such that it would store beyond the end of the view.

`value`

The value to set. For how the value is encoded in bytes, see Value encoding and normalization.

`littleEndian` Optional

Indicates whether the data is stored in little- or big-endian format. If `false` or `undefined`, a big-endian value is written.

Return value

`undefined`.

Exceptions

`RangeError`

Thrown if the `byteOffset` is set such that it would store beyond the end of the view.

Examples

Using setFloat16()

```
const buffer = new ArrayBuffer(10);
const dataview = new DataView(buffer);
dataview.setFloat16(0, 3);
dataview.getFloat16(1); // 0
```

DataView.prototype.setFloat32()

The **`setFloat32()`** method of `DataView` instances takes a number and stores it as a 32-bit floating point number in the 4 bytes starting at the specified byte offset of this `DataView`. There is no alignment constraint; multi-byte values may be stored at any offset within bounds.

Try it

```
// Create an ArrayBuffer with a size in bytes
const buffer = new ArrayBuffer(16);

const view = new DataView(buffer);
view.setFloat32(1, Math.PI);

console.log(view.getFloat32(1));
// Expected output: 3.1415927410125732
```

Syntax

```
setFloat32(byteOffset, value)
setFloat32(byteOffset, value, littleEndian)
```

Parameters

`byteOffset`

The offset, in bytes, from the start of the view to store the data in.

`value`

The value to set. For how the value is encoded in bytes, see Value encoding and normalization.

`littleEndian` Optional

Indicates whether the data is stored in little- or big-endian format. If `false` or `undefined`, a big-endian value is written.

Return value

`undefined`.

Exceptions

`RangeError`

Thrown if the `byteOffset` is set such that it would store beyond the end of the view.

Examples

Using setFloat32()

```
const buffer = new ArrayBuffer(10);
const dataview = new DataView(buffer);
dataview.setFloat32(0, 3);
dataview.getFloat32(1); // 2
```

DataView.prototype.setFloat64()

The **`setFloat64()`** method of `DataView` instances takes a number and stores it as a 64-bit floating point number in the 8 bytes starting at the specified byte offset of this `DataView`. There is no alignment constraint; multi-byte values may be stored at any offset within bounds.

Try it

```
// Create an ArrayBuffer with a size in bytes
const buffer = new ArrayBuffer(16);

const view = new DataView(buffer);
view.setFloat64(1, Math.PI);

console.log(view.getFloat64(1));
// Expected output: 3.141592653589793
```

Syntax

```
setFloat64(byteOffset, value)
setFloat64(byteOffset, value, littleEndian)
```

Parameters

`byteOffset`

The offset, in bytes, from the start of the view to store the data in.

`value`

The value to set. For how the value is encoded in bytes, see Value encoding and normalization.

`littleEndian` Optional

Indicates whether the data is stored in little- or big-endian format. If `false` or `undefined`, a big-endian value is written.

Return value

`undefined`.

Exceptions

`RangeError`

Thrown if the `byteOffset` is set such that it would store beyond the end of the view.

Examples

Using setFloat64()

```
const buffer = new ArrayBuffer(10);
const dataview = new DataView(buffer);
dataview.setFloat64(0, 3);
dataview.getFloat64(1); // 3.785766995733679e-270
```

DataView.prototype.setInt16()

The **`setInt16()`** method of `DataView` instances takes a number and stores it as a 16-bit signed integer in the 2 bytes starting at the specified byte offset of this `DataView`. There is no alignment constraint; multi-byte values may be stored at any offset within bounds.

Try it

```
// Create an ArrayBuffer with a size in bytes
const buffer = new ArrayBuffer(16);

const view = new DataView(buffer);
view.setInt16(1, 32767); // Max signed 16-bit integer

console.log(view.getInt16(1));
// Expected output: 32767
```

Syntax

```
setInt16(byteOffset, value)
setInt16(byteOffset, value, littleEndian)
```

Parameters

`byteOffset`

The offset, in bytes, from the start of the view to store the data in.

`value`

The value to set. For how the value is encoded in bytes, see Value encoding and normalization.

`littleEndian` Optional

Indicates whether the data is stored in little- or big-endian format. If `false` or `undefined`, a big-endian value is written.

Return value

`undefined`.

Exceptions

`RangeError`

Thrown if the `byteOffset` is set such that it would store beyond the end of the view.

Examples

Using setInt16()

```
const buffer = new ArrayBuffer(10);
const dataview = new DataView(buffer);
dataview.setInt16(0, 3);
dataview.getInt16(1); // 768
```

DataView.prototype.setInt32()

The **`setInt32()`** method of `DataView` instances takes a number and stores it as a 32-bit signed integer in the 4 bytes starting at the specified byte offset of this `DataView`. There is no alignment constraint; multi-byte values may be stored at any offset within bounds.

Try it

```
// Create an ArrayBuffer with a size in bytes
const buffer = new ArrayBuffer(16);

const view = new DataView(buffer);
view.setInt32(1, 2147483647); // Max signed 32-bit integer

console.log(view.getInt32(1));
// Expected output: 2147483647
```

Syntax

```
setInt32(byteOffset, value)
setInt32(byteOffset, value, littleEndian)
```

Parameters

`byteOffset`

The offset, in bytes, from the start of the view to store the data in.

`value`

The value to set. For how the value is encoded in bytes, see Value encoding and normalization.

`littleEndian` Optional

Indicates whether the data is stored in little- or big-endian format. If `false` or `undefined`, a big-endian value is written.

Return value

`undefined`.

Exceptions

`RangeError`

Thrown if the `byteOffset` is set such that it would store beyond the end of the view.

Examples

Using setInt32()

```
const buffer = new ArrayBuffer(10);
const dataview = new DataView(buffer);
dataview.setInt32(0, 3);
dataview.getInt32(1); // 768
```

DataView.prototype.setInt8()

The **`setInt8()`** method of `DataView` instances takes a number and stores it as an 8-bit signed integer in the byte at the specified byte offset of this `DataView`.

Try it

```
// Create an ArrayBuffer with a size in bytes
const buffer = new ArrayBuffer(16);

const view = new DataView(buffer);
```

```
view.setInt8(1, 127); // Max signed 8-bit integer

console.log(view.getInt8(1));
// Expected output: 127
```

Syntax

```
setInt8(byteOffset, value)
```

Parameters

`byteOffset`

The offset, in bytes, from the start of the view to store the data in.

`value`

The value to set. For how the value is encoded in bytes, see Value encoding and normalization.

Return value

`undefined`.

Exceptions

`RangeError`

Thrown if the `byteOffset` is set such that it would store beyond the end of the view.

Examples

Using setInt8()

```
const buffer = new ArrayBuffer(10);
const dataview = new DataView(buffer);
dataview.setInt8(0, 3);
dataview.getInt8(0); // 3
```

DataView.prototype.setUint16()

The **`setUint16()`** method of `DataView` instances takes a number and stores it as a 16-bit unsigned integer in the 2 bytes starting at the specified byte offset of this `DataView`. There is no alignment constraint; multi-byte values may be stored at any offset within bounds.

Try it

```
// Create an ArrayBuffer with a size in bytes
const buffer = new ArrayBuffer(16);

const view = new DataView(buffer);
view.setUint16(1, 65535); // Max unsigned 16-bit integer

console.log(view.getUint16(1));
// Expected output: 65535
```

Syntax

```
setUint16(byteOffset, value)
setUint16(byteOffset, value, littleEndian)
```

Parameters

`byteOffset`

The offset, in bytes, from the start of the view to store the data in.

`value`

The value to set. For how the value is encoded in bytes, see Value encoding and normalization.

`littleEndian` Optional

Indicates whether the data is stored in little- or big-endian format. If `false` or `undefined`, a big-endian value is written.

Return value

`undefined`.

Exceptions

`RangeError`

Thrown if the `byteOffset` is set such that it would store beyond the end of the view.

Examples

Using setUint16()

```
const buffer = new ArrayBuffer(10);
const dataview = new DataView(buffer);
dataview.setUint16(0, 3);
dataview.getUint16(1); // 768
```

DataView.prototype.setUint32()

The **`setUint32()`** method of `DataView` instances takes a number and stores it as a 32-bit unsigned integer in the 4 bytes starting at the specified byte offset of this `DataView`. There is no alignment constraint; multi-byte values may be stored at any offset within bounds.

Try it

```
// Create an ArrayBuffer with a size in bytes
const buffer = new ArrayBuffer(16);

const view = new DataView(buffer);
view.setUint32(1, 4294967295); // Max unsigned 32-bit integer

console.log(view.getUint32(1));
// Expected output: 4294967295
```

Syntax

```
setUint32(byteOffset, value)
setUint32(byteOffset, value, littleEndian)
```

Parameters

`byteOffset`

The offset, in bytes, from the start of the view to store the data in.

`value`

The value to set. For how the value is encoded in bytes, see Value encoding and normalization.

`littleEndian` Optional

Indicates whether the data is stored in little- or big-endian format. If `false` or `undefined`, a big-endian value is written.

Return value

`undefined`.

Exceptions

`RangeError`

Thrown if the `byteOffset` is set such that it would store beyond the end of the view.

Examples

Using setUint32()

```
const buffer = new ArrayBuffer(10);
const dataview = new DataView(buffer);
dataview.setUint32(0, 3);
dataview.getUint32(1); // 768
```

DataView.prototype.setUint8()

The **`setUint8()`** method of `DataView` instances takes a number and stores it as an 8-bit unsigned integer in the byte at the specified byte offset of this `DataView`.

Try it

```
// Create an ArrayBuffer with a size in bytes
const buffer = new ArrayBuffer(16);

const view = new DataView(buffer);
view.setUint8(1, 255); // Max unsigned 8-bit integer

console.log(view.getUint8(1));
// Expected output: 255
```

Syntax

```
setUint8(byteOffset, value)
```

Parameters

`byteOffset`

The offset, in bytes, from the start of the view to store the data in.

`value`

The value to set. For how the value is encoded in bytes, see Value encoding and normalization.

Return value

`undefined`.

Exceptions

`RangeError`

Thrown if the `byteOffset` is set such that it would store beyond the end of the view.

Examples

Using setUint8()

```
const buffer = new ArrayBuffer(10);
const dataview = new DataView(buffer);
dataview.setUint8(0, 3);
dataview.getUint8(0); // 3
```

Date

JavaScript **`Date`** objects represent a single moment in time in a platform-independent format. `Date` objects encapsulate an integral number that represents milliseconds since the midnight at the beginning of January 1, 1970, UTC (the *epoch*).

> **Note:** With the introduction of the `Temporal` API, the `Date` object is considered a legacy feature. Consider using `Temporal` for new code and migrate existing code over to it if possible (check the browser compatibility. We will be writing a usage guide soon!

Description

The epoch, timestamps, and invalid date

A JavaScript date is fundamentally specified as the time in milliseconds that has elapsed since the epoch, which is defined as the midnight at the beginning of January 1, 1970, UTC (equivalent to the UNIX epoch). This timestamp is *timezone-agnostic* and uniquely defines an instant in history.

> **Note:** While the time value at the heart of a Date object is UTC, the basic methods to fetch the date and time or its components all work in the local (i.e., host system) time zone and offset.

The maximum timestamp representable by a `Date` object is slightly smaller than the maximum safe integer (`Number.MAX_SAFE_INTEGER`, which is 9,007,199,254,740,991). A `Date` object can represent a maximum of ±8,640,000,000,000,000 milliseconds, or ±100,000,000 (one hundred million) days, relative to the epoch. This is the range from April 20, 271821 BC to September 13, 275760 AD. Any attempt to represent a time outside this range results in the `Date` object holding a timestamp value of `NaN`, which is an "Invalid Date".

```
console.log(new Date(8.64e15).toString()); // "Sat Sep 13 275760 00:00:00 GMT+0000 (Coordinated Universal Time)"
console.log(new Date(8.64e15 + 1).toString()); // "Invalid Date"
```

There are various methods that allow you to interact with the timestamp stored in the date:

- You can interact with the timestamp value directly using the `getTime()` and `setTime()` methods.
- The `valueOf()` and `[Symbol.toPrimitive]()` (when passed `"number"`) methods — which are automatically called in number coercion — return the timestamp, causing `Date` objects to behave like their timestamps when used in number contexts.
- All static methods (`Date.now()`, `Date.parse()`, and `Date.UTC()`) return timestamps instead of `Date` objects.
- The `Date()` constructor can be called with a timestamp as the only argument.

Date components and time zones

A date is represented internally as a single number, the *timestamp*. When interacting with it, the timestamp needs to be interpreted as a structured date-and-time representation. There are always two ways to interpret a timestamp: as a local time or as a Coordinated Universal Time (UTC), the global standard time defined by the World Time Standard. The local timezone is not stored in the date object, but is determined by the host environment (user's device).

> **Note:** UTC should not be confused with the Greenwich Mean Time (GMT), because they are not always equal — this is explained in more detail in the linked Wikipedia page.

For example, the timestamp 0 represents a unique instant in history, but it can be interpreted in two ways:

- As a UTC time, it is midnight at the beginning of January 1, 1970, UTC,
- As a local time in New York (UTC-5), it is 19:00:00 on December 31, 1969.

The `getTimezoneOffset()` method returns the difference between UTC and the local time in minutes. Note that the timezone offset does not only depend on the current timezone, but also on the time represented by the `Date` object, because of daylight saving time and historical changes. In essence, the timezone offset is the offset from UTC time, at the time represented by the `Date` object and at the location of the host environment.

There are two groups of `Date` methods: one group gets and sets various date components by interpreting the timestamp as a local time, while the other uses UTC.

Component	Local		UTC	
	Get	Set	Get	Set
Year	`getFullYear()`	`setFullYear()`	`getUTCFullYear()`	`setUTCFullYear()`
Month	`getMonth()`	`setMonth()`	`getUTCMonth()`	`setUTCMonth()`
Date (of month)	`getDate()`	`setDate()`	`getUTCDate()`	`setUTCDate()`
Hours	`getHours()`	`setHours()`	`getUTCHours()`	`setUTCHours()`
Minutes	`getMinutes()`	`setMinutes()`	`getUTCMinutes()`	`setUTCMinutes()`
Seconds	`getSeconds()`	`setSeconds()`	`getUTCSeconds()`	`setUTCSeconds()`
Milliseconds	`getMilliseconds()`	`setMilliseconds()`	`getUTCMilliseconds()`	`setUTCMilliseconds()`
Day (of week)	`getDay()`	N/A	`getUTCDay()`	N/A

The `Date()` constructor can be called with two or more arguments, in which case they are interpreted as the year, month, day, hour, minute, second, and millisecond, respectively, in local time. `Date.UTC()` works similarly, but it interprets the components as UTC time and also accepts a single argument representing the year.

> **Note:** Some methods, including the `Date()` constructor, `Date.UTC()`, and the deprecated `getYear()`/`setYear()` methods, interpret a two-digit year as a year in the 1900s. For example, `new Date(99, 5, 24)` is interpreted as June 24, 1999, not June 24, 99. See Interpretation of two-digit years for more information.

When a segment overflows or underflows its expected range, it usually "carries over to" or "borrows from" the higher segment. For example, if the month is set to 12 (months are zero-based, so December is 11), it becomes the January of the next year. If the day of month is set to 0, it becomes the last day of the previous month. This also applies to dates specified with the date time string format.

When attempting to set the local time to a time falling within an offset transition (usually daylight saving time), the exact time is derived using the same behavior as `Temporal`'s `disambiguation: "compatible"` option. That is, if the local time corresponds to two instants, the earlier one is chosen; if the local time does not exist (there is a gap), we go forward by the gap duration.

```
// Assume America/New_York local time zone
// 2024-03-10 02:30 is within the spring-forward transition and does not exist
// 01:59 (UTC-5) jumps to 03:00 (UTC-4), so 02:30 moves forward by one hour
console.log(new Date(2024, 2, 10, 2, 30).toString());
// Sun Mar 10 2024 03:30:00 GMT-0400 (Eastern Daylight Time)

// 2024-11-03 01:30 is within the fall-back transition and exists twice
// 01:59 (UTC-4) jumps to 01:00 (UTC-5), so the earlier 01:30 (UTC-4) is chosen
console.log(new Date(2024, 10, 3, 1, 30).toString());
// Sun Nov 03 2024 01:30:00 GMT-0400 (Eastern Daylight Time)
```

Date time string format

There are many ways to format a date as a string. The JavaScript specification only specifies one format to be universally supported: the *date time string format*, a simplification of the ISO 8601 calendar date extended format. The format is as follows:

```
YYYY-MM-DDTHH:mm:ss.sssZ
```

- `YYYY` is the year, with four digits (`0000` to `9999`), or as an *expanded year* of `+` or `-` followed by six digits. The sign is required for expanded years. `-000000` is explicitly disallowed as a valid year.
- `MM` is the month, with two digits (`01` to `12`). Defaults to `01`.
- `DD` is the day of the month, with two digits (`01` to `31`). Defaults to `01`.
- `T` is a literal character, which indicates the beginning of the *time* part of the string. The `T` is required when specifying the time part.
- `HH` is the hour, with two digits (`00` to `23`). As a special case, `24:00:00` is allowed, and is interpreted as midnight at the beginning of the next day. Defaults to `00`.
- `mm` is the minute, with two digits (`00` to `59`). Defaults to `00`.
- `ss` is the second, with two digits (`00` to `59`). Defaults to `00`.
- `sss` is the millisecond, with three digits (`000` to `999`). Defaults to `000`.
- `Z` is the timezone offset, which can either be the literal character `Z` (indicating UTC), or `+` or `-` followed by `HH:mm`, the offset in hours and minutes from UTC.

Various components can be omitted, so the following are all valid:

- Date-only form: `YYYY`, `YYYY-MM`, `YYYY-MM-DD`
- Date-time form: one of the above date-only forms, followed by `T`, followed by `HH:mm`, `HH:mm:ss`, or `HH:mm:ss.sss`. Each combination can be followed by a time zone offset.

For example, `"2011-10-10"` (*date-only* form), `"2011-10-10T14:48:00"` (*date-time* form), or `"2011-10-10T14:48:00.000+09:00"` (*date-time* form with milliseconds and time zone) are all valid date time strings.

When the time zone offset is absent, **date-only forms are interpreted as a UTC time and date-time forms are interpreted as a local time.** The interpretation as a UTC time is due to a historical spec error that was not consistent with ISO 8601 but could not be changed due to web compatibility. See Broken Parser – A Web Reality Issue.

`Date.parse()` and the `Date()` constructor both accept strings in the date time string format as input. Furthermore, implementations are allowed to support other date formats when the input fails to match this format.

The `toISOString()` method returns a string representation of the date in the date time string format, with the time zone offset always set to `Z` (UTC).

> **Note:** You are encouraged to make sure your input conforms to the date time string format above for maximum compatibility, because support for other formats is not guaranteed. However, there are some formats that are supported in all major implementations — like RFC 2822 format — in which case their usage can be acceptable. Always conduct cross-browser tests to ensure your code works in all target browsers. A library can help if many different formats are to be accommodated.

Non-standard strings can be parsed in any way as desired by the implementation, including the time zone — most implementations use the local time zone by default. Implementations are not required to return invalid date for out-of-bounds date components, although they usually do. A string may have in-bounds date components (with the bounds defined above), but does not represent a date in reality (for example, "February 30"). Implementations behave inconsistently in this case. The `Date.parse()` page offers more examples about these non-standard cases.

Other ways to format a date

- `toISOString()` returns a string in the format `1970-01-01T00:00:00.000Z` (the date time string format introduced above, which is simplified ISO 8601). `toJSON()` calls `toISOString()` and returns the result.
- `toString()` returns a string in the format `Thu Jan 01 1970 00:00:00 GMT+0000 (Coordinated Universal Time)`, while `toDateString()` and `toTimeString()` return the date and time parts of the string, respectively. `[Symbol.toPrimitive]()` (when passed `"string"` or `"default"`) calls `toString()` and returns the result.
- `toUTCString()` returns a string in the format `Thu, 01 Jan 1970 00:00:00 GMT` (generalized RFC 7231).
- `toLocaleDateString()`, `toLocaleTimeString()`, and `toLocaleString()` use locale-specific date and time formats, usually provided by the `Intl` API.

See the Formats of `toString` method return values section for examples.

Constructor

`Date()`

When called as a constructor, returns a new `Date` object. When called as a function, returns a string representation of the current date and time.

Static methods

`Date.now()`

Returns the numeric value corresponding to the current time—the number of milliseconds since January 1, 1970 00:00:00 UTC, with leap seconds ignored.

`Date.parse()`

Parses a string representation of a date and returns the number of milliseconds since January 1, 1970 00:00:00 UTC, with leap seconds ignored.

`Date.UTC()`

Accepts the same parameters as the longest form of the constructor (i.e., 2 to 7) and returns the number of milliseconds since January 1, 1970 00:00:00 UTC, with leap seconds ignored.

Instance properties

These properties are defined on `Date.prototype` and shared by all `Date` instances.

`Date.prototype.constructor`

The constructor function that created the instance object. For `Date` instances, the initial value is the `Date` constructor.

Instance methods

`Date.prototype.getDate()`

Returns the day of the month (`1` – `31`) for the specified date according to local time.

`Date.prototype.getDay()`

Returns the day of the week (`0` – `6`) for the specified date according to local time.

`Date.prototype.getFullYear()`

Returns the year (4 digits for 4-digit years) of the specified date according to local time.

`Date.prototype.getHours()`

Returns the hour (`0` – `23`) in the specified date according to local time.

`Date.prototype.getMilliseconds()`

Returns the milliseconds (`0` – `999`) in the specified date according to local time.

`Date.prototype.getMinutes()`

Returns the minutes (`0` – `59`) in the specified date according to local time.

`Date.prototype.getMonth()`

Returns the month (`0` – `11`) in the specified date according to local time.

`Date.prototype.getSeconds()`

Returns the seconds (`0` – `59`) in the specified date according to local time.

`Date.prototype.getTime()`

Returns the numeric value of the specified date as the number of milliseconds since January 1, 1970 00:00:00 UTC. (Negative values are returned for prior times.)

`Date.prototype.getTimezoneOffset()`

Returns the time-zone offset in minutes for the current locale.

`Date.prototype.getUTCDate()`

Returns the day (date) of the month (`1` – `31`) in the specified date according to universal time.

`Date.prototype.getUTCDay()`

Returns the day of the week (`0` – `6`) in the specified date according to universal time.

`Date.prototype.getUTCFullYear()`

Returns the year (4 digits for 4-digit years) in the specified date according to universal time.

`Date.prototype.getUTCHours()`

Returns the hours (`0` – `23`) in the specified date according to universal time.

`Date.prototype.getUTCMilliseconds()`

Returns the milliseconds (`0` – `999`) in the specified date according to universal time.

`Date.prototype.getUTCMinutes()`

Returns the minutes (`0` – `59`) in the specified date according to universal time.

`Date.prototype.getUTCMonth()`

Returns the month (`0` – `11`) in the specified date according to universal time.

`Date.prototype.getUTCSeconds()`

Returns the seconds (`0` – `59`) in the specified date according to universal time.

`Date.prototype.getYear()`

Returns the year (usually 2–3 digits) in the specified date according to local time. Use `getFullYear()` instead.

`Date.prototype.setDate()`

Sets the day of the month for a specified date according to local time.

`Date.prototype.setFullYear()`

Sets the full year (e.g., 4 digits for 4-digit years) for a specified date according to local time.

`Date.prototype.setHours()`

Sets the hours for a specified date according to local time.

`Date.prototype.setMilliseconds()`

Sets the milliseconds for a specified date according to local time.

`Date.prototype.setMinutes()`

Sets the minutes for a specified date according to local time.

`Date.prototype.setMonth()`

Sets the month for a specified date according to local time.

`Date.prototype.setSeconds()`

Sets the seconds for a specified date according to local time.

`Date.prototype.setTime()`

Sets the `Date` object to the time represented by the number of milliseconds since January 1, 1970 00:00:00 UTC. Use negative numbers for times prior.

`Date.prototype.setUTCDate()`

Sets the day of the month for a specified date according to universal time.

`Date.prototype.setUTCFullYear()`

Sets the full year (e.g., 4 digits for 4-digit years) for a specified date according to universal time.

`Date.prototype.setUTCHours()`

Sets the hour for a specified date according to universal time.

`Date.prototype.setUTCMilliseconds()`

Sets the milliseconds for a specified date according to universal time.

`Date.prototype.setUTCMinutes()`

Sets the minutes for a specified date according to universal time.

`Date.prototype.setUTCMonth()`

Sets the month for a specified date according to universal time.

`Date.prototype.setUTCSeconds()`

Sets the seconds for a specified date according to universal time.

`Date.prototype.setYear()`

Sets the year (usually 2–3 digits) for a specified date according to local time. Use `setFullYear()` instead.

`Date.prototype.toDateString()`

Returns the "date" portion of the `Date` as a human-readable string like `'Thu Apr 12 2018'`.

`Date.prototype.toISOString()`

Converts a date to a string following the ISO 8601 Extended Format.

`Date.prototype.toJSON()`

Returns a string representing the `Date` using `toISOString()`. Intended to be implicitly called by `JSON.stringify()`.

`Date.prototype.toLocaleDateString()`

Returns a string with a locality sensitive representation of the date portion of this date based on system settings.

`Date.prototype.toLocaleString()`

Returns a string with a locality-sensitive representation of this date. Overrides the `Object.prototype.toLocaleString()` method.

`Date.prototype.toLocaleTimeString()`

Returns a string with a locality-sensitive representation of the time portion of this date, based on system settings.

`Date.prototype.toString()`

Returns a string representing the specified `Date` object. Overrides the `Object.prototype.toString()` method.

`Date.prototype.toTemporalInstant()`

Returns a new `Temporal.Instant` object with the same `epochMilliseconds` value as this date's timestamp.

`Date.prototype.toTimeString()`

Returns the "time" portion of the `Date` as a human-readable string.

`Date.prototype.toUTCString()`

Converts a date to a string using the UTC timezone.

`Date.prototype.valueOf()`

Returns the primitive value of a `Date` object. Overrides the `Object.prototype.valueOf()` method.

`Date.prototype[Symbol.toPrimitive]()`

Converts this `Date` object to a primitive value.

Examples

Several ways to create a Date object

The following examples show several ways to create JavaScript dates:

> **Note:** Creating a date from a string has a lot of behavior inconsistencies. See date time string format for caveats on using different formats.

```
const today = new Date();
const birthday = new Date("December 17, 1995 03:24:00"); // DISCOURAGED: may not work in all runtimes
const birthday2 = new Date("1995-12-17T03:24:00"); // This is standardized and will work reliably
const birthday3 = new Date(1995, 11, 17); // the month is 0-indexed
const birthday4 = new Date(1995, 11, 17, 3, 24, 0);
const birthday5 = new Date(628021800000); // passing epoch timestamp
```

Formats of toString method return values

```
const date = new Date("2020-05-12T23:50:21.817Z");
date.toString(); // Tue May 12 2020 18:50:21 GMT-0500 (Central Daylight Time)
date.toDateString(); // Tue May 12 2020
date.toTimeString(); // 18:50:21 GMT-0500 (Central Daylight Time)
date[Symbol.toPrimitive]("string"); // Tue May 12 2020 18:50:21 GMT-0500 (Central Daylight Time)

date.toISOString(); // 2020-05-12T23:50:21.817Z
date.toJSON(); // 2020-05-12T23:50:21.817Z

date.toUTCString(); // Tue, 12 May 2020 23:50:21 GMT

date.toLocaleString(); // 5/12/2020, 6:50:21 PM
date.toLocaleDateString(); // 5/12/2020
date.toLocaleTimeString(); // 6:50:21 PM
```

To get Date, Month and Year or Time

```
const date = new Date("2000-01-17T16:45:30");
const [month, day, year] = [
  date.getMonth(),
  date.getDate(),
  date.getFullYear(),
];
// [0, 17, 2000] as month are 0-indexed
const [hour, minutes, seconds] = [
  date.getHours(),
  date.getMinutes(),
  date.getSeconds(),
];
// [16, 45, 30]
```

Interpretation of two-digit years

`new Date()` exhibits legacy undesirable, inconsistent behavior with two-digit year values; specifically, when a `new Date()` call is given a two-digit year value, that year value does not get treated as a literal year and used as-is but instead gets interpreted as a relative offset — in some cases as an offset from the year `1900`, but in other cases, as an offset from the year `2000`.

```
let date = new Date(98, 1); // Sun Feb 01 1998 00:00:00 GMT+0000 (GMT)
date = new Date(22, 1); // Wed Feb 01 1922 00:00:00 GMT+0000 (GMT)
date = new Date("2/1/22"); // Tue Feb 01 2022 00:00:00 GMT+0000 (GMT)

// Legacy method; always interprets two-digit year values as relative to 1900
date.setYear(98);
date.toString(); // Sun Feb 01 1998 00:00:00 GMT+0000 (GMT)
date.setYear(22);
date.toString(); // Wed Feb 01 1922 00:00:00 GMT+0000 (GMT)
```

So, to create and get dates between the years `0` and `99`, instead use the preferred `setFullYear()` and `getFullYear()` methods:.

```
// Preferred method; never interprets any value as being a relative offset,
// but instead uses the year value as-is
date.setFullYear(98);
date.getFullYear(); // 98 (not 1998)
date.setFullYear(22);
date.getFullYear(); // 22 (not 1922, not 2022)
```

Calculating elapsed time

The following examples show how to determine the elapsed time between two JavaScript dates in milliseconds.

Due to the differing lengths of days (due to daylight saving changeover), months, and years, expressing elapsed time in units greater than hours, minutes, and seconds requires addressing a number of issues, and should be thoroughly researched before being attempted.

```
// Using Date objects
const start = Date.now();

// The event to time goes here:
doSomethingForALongTime();
const end = Date.now();
const elapsed = end - start; // elapsed time in milliseconds
```

```
// Using built-in methods
const start = new Date();

// The event to time goes here:
doSomethingForALongTime();
const end = new Date();
const elapsed = end.getTime() - start.getTime(); // elapsed time in milliseconds
```

```
// To test a function and get back its return
function printElapsedTime(testFn) {
  const startTime = Date.now();
  const result = testFn();
  const endTime = Date.now();

  console.log(`Elapsed time: ${String(endTime - startTime)} milliseconds`);
  return result;
}

const yourFunctionReturn = printElapsedTime(yourFunction);
```

> **Note:** In browsers that support the Performance API's high-resolution time feature, `Performance.now()` can provide more reliable and precise measurements of elapsed time than `Date.now()`.

Get the number of seconds since the ECMAScript Epoch

```
const seconds = Math.floor(Date.now() / 1000);
```

In this case, it's important to return only an integer—so a simple division won't do. It's also important to only return actually elapsed seconds. (That's why this code uses `Math.floor()`, and *not* `Math.round()`.)

See also

- `Date()`

Date() constructor

The **`Date()`** constructor creates `Date` objects. When called as a function, it returns a string representing the current time.

Try it

```
const date1 = new Date("December 17, 1995 03:24:00");
// Sun Dec 17 1995 03:24:00 GMT...

const date2 = new Date("1995-12-17T03:24:00");
// Sun Dec 17 1995 03:24:00 GMT...

console.log(date1.getTime() === date2.getTime());
// Expected output: true
```

Syntax

```
new Date()
new Date(value)
new Date(dateString)
new Date(dateObject)

new Date(year, monthIndex)
new Date(year, monthIndex, day)
```

```
new Date(year, monthIndex, day, hours)
new Date(year, monthIndex, day, hours, minutes)
new Date(year, monthIndex, day, hours, minutes, seconds)
new Date(year, monthIndex, day, hours, minutes, seconds, milliseconds)

Date()
```

> **Note:** `Date()` can be called with or without `new`, but with different effects. See Return value.

Parameters

There are five basic forms for the `Date()` constructor:

No parameters

When no parameters are provided, the newly-created `Date` object represents the current date and time as of the time of instantiation. The returned date's timestamp is the same as the number returned by `Date.now()`.

Time value or timestamp number

`value`

An integer value representing the timestamp (the number of milliseconds since midnight at the beginning of January 1, 1970, UTC — a.k.a. the epoch).

Date string

`dateString`

A string value representing a date, parsed and interpreted using the same algorithm implemented by `Date.parse()`. See date time string format for caveats on using different formats.

Date object

`dateObject`

An existing `Date` object. This effectively makes a copy of the existing `Date` object with the same date and time. This is equivalent to `new Date(dateObject.valueOf())`, except the `valueOf()` method is not called.

When one parameter is passed to the `Date()` constructor, `Date` instances are specially treated. All other values are converted to primitives. If the result is a string, it will be parsed as a date string. Otherwise, the resulting primitive is further coerced to a number and treated as a timestamp.

Individual date and time component values

Given at least a year and month, this form of `Date()` returns a `Date` object whose component values (year, month, day, hour, minute, second, and millisecond) all come from the following parameters. Any missing fields are given the lowest possible value (`1` for `day` and `0` for every other component). The parameter values are all evaluated against the local time zone, rather than UTC. `Date.UTC()` accepts similar parameters but interprets the components as UTC and returns a timestamp.

If any parameter overflows its defined bounds, it "carries over". For example, if a `monthIndex` greater than `11` is passed in, those months will cause the year to increment; if a `minutes` greater than `59` is passed in, `hours` will increment accordingly, etc. Therefore, `new Date(1990, 12, 1)` will return January 1st, 1991; `new Date(2020, 5, 19, 25, 65)` will return 2:05 A.M. June 20th, 2020.

Similarly, if any parameter underflows, it "borrows" from the higher positions. For example, `new Date(2020, 5, 0)` will return May 31st, 2020.

`year`

Integer value representing the year. Values from `0` to `99` map to the years `1900` to `1999`. All other values are the actual year. See the example.

`monthIndex`

Integer value representing the month, beginning with `0` for January to `11` for December.

`day` Optional

Integer value representing the day of the month. Defaults to `1`.

`hours` Optional

Integer value between `0` and `23` representing the hour of the day. Defaults to `0`.

`minutes` Optional

Integer value representing the minute segment of a time. Defaults to `0`.

`seconds` Optional

Integer value representing the second segment of a time. Defaults to `0`.

`milliseconds` Optional

Integer value representing the millisecond segment of a time. Defaults to `0`.

Return value

Calling `new Date()` (the `Date()` constructor) returns a `Date` object. If called with an invalid date string, or if the date to be constructed will have a timestamp less than `-8,640,000,000,000,000` or greater than `8,640,000,000,000,000` milliseconds, it returns an invalid date (a `Date` object whose `toString()` method returns `"Invalid Date"` and `valueOf()` method returns `NaN`).

Calling the `Date()` function (without the `new` keyword) returns a string representation of the current date and time, exactly as `new Date().toString()` does. Any arguments given in a `Date()` function call (without the `new` keyword) are ignored; regardless of whether it's called with an invalid date string — or even called with any arbitrary object or other primitive as an argument — it always returns a string representation of the current date and time.

Description

Reduced time precision

To offer protection against timing attacks and fingerprinting, the precision of `new Date()` may be reduced depending on browser settings.

When a timestamp, date string, date object, or date component values are supplied to the constructor, the browser does not apply timer rounding to the supplied time.

When called without arguments, the constructor obtains the current time in the same way as `Date.now()`. It inherits the precision of that clock reading without introducing additional inaccuracy.

Examples

Several ways to create a Date object

The following examples show several ways to create JavaScript dates:

```
const today = new Date();
const birthday = new Date("December 17, 1995 03:24:00"); // DISCOURAGED: may not work in all runtimes
const birthday = new Date("1995-12-17T03:24:00"); // This is standardized and will work reliably
const birthday = new Date(1995, 11, 17); // the month is 0-indexed
const birthday = new Date(1995, 11, 17, 3, 24, 0);
const birthday = new Date(628021800000); // passing epoch timestamp
```

Passing a non-Date, non-string, non-number value

If the `Date()` constructor is called with one parameter which is not a `Date` instance, it will be coerced to a primitive and then checked whether it's a string. For example, `new Date(undefined)` is different from `new Date()`:

```
console.log(new Date(undefined)); // Invalid Date
```

This is because `undefined` is already a primitive but not a string, so it will be coerced to a number, which is `NaN` and therefore not a valid timestamp. On the other hand, `null` will be coerced to `0`.

```
console.log(new Date(null)); // 1970-01-01T00:00:00.000Z
```

Arrays would be coerced to a string via `Array.prototype.toString()`, which joins the elements with commas. However, the resulting string for any array with more than one element is not a valid ISO 8601 date string, so its parsing behavior would be implementation-defined. **Do not pass arrays to the `Date()` constructor.**

```
console.log(new Date(["2020-06-19", "17:13"]));
// 2020-06-19T17:13:00.000Z in Chrome, since it recognizes "2020-06-19,17:13"
// "Invalid Date" in Firefox
```

See also

- `Date`

Date.prototype.getDate()

The **`getDate()`** method of `Date` instances returns the day of the month for this date according to local time.

Try it

```
const birthday = new Date("August 19, 1975 23:15:30");
const date = birthday.getDate();

console.log(date);
// Expected output: 19
```

Syntax

```
getDate()
```

Parameters

None.

Return value

An integer, between 1 and 31, representing the day of the month for the given date according to local time. Returns `NaN` if the date is invalid.

Examples

Using getDate()

The `day` variable has value `25`, based on the value of the `Date` object `xmas95`.

```
const xmas95 = new Date("1995-12-25T23:15:30");
const day = xmas95.getDate();

console.log(day); // 25
```

See also

- `Date.prototype.getUTCDate()`
- `Date.prototype.getUTCDay()`
- `Date.prototype.setDate()`

Date.prototype.getDay()

The **`getDay()`** method of `Date` instances returns the day of the week for this date according to local time, where 0 represents Sunday. For the day of the month, see `Date.prototype.getDate()`.

Try it

```
const birthday = new Date("August 19, 1975 23:15:30");
const day1 = birthday.getDay();
// Sunday - Saturday : 0 - 6

console.log(day1);
// Expected output: 2
```

Syntax

```
getDay()
```

Parameters

None.

Return value

An integer, between 0 and 6, representing the day of the week for the given date according to local time: 0 for Sunday, 1 for Monday, 2 for Tuesday, and so on. Returns `NaN` if the date is invalid.

Description

The return value of `getDay()` is zero-based, which is useful for indexing into arrays of days, for example:

```
const valentines = new Date("1995-02-14");
const day = valentines.getDay();
const dayNames = ["Sunday", "Monday", "Tuesday" /* , … */];

console.log(dayNames[day]); // "Monday"
```

However, for the purpose of internationalization, you should prefer using `Intl.DateTimeFormat` with the `options` parameter instead.

```
const options = { weekday: "long" };
console.log(new Intl.DateTimeFormat("en-US", options).format(valentines));
// "Monday"
console.log(new Intl.DateTimeFormat("de-DE", options).format(valentines));
// "Montag"
```

Examples

Using getDay()

The `weekday` variable has value `1`, based on the value of the `Date` object `xmas95`, because December 25, 1995 is a Monday.

```
const xmas95 = new Date("1995-12-25T23:15:30");
const weekday = xmas95.getDay();

console.log(weekday); // 1
```

See also

- `Date.prototype.getUTCDate()`
- `Date.prototype.getUTCDay()`
- `Date.prototype.setDate()`

Date.prototype.getFullYear()

The **`getFullYear()`** method of `Date` instances returns the year for this date according to local time.

Use this method instead of the `getYear()` method.

Try it

```
const moonLanding = new Date("July 20, 69 00:20:18");

console.log(moonLanding.getFullYear());
// Expected output: 1969
```

Syntax

```
getFullYear()
```

Parameters

None.

Return value

An integer representing the year for the given date according to local time. Returns `NaN` if the date is invalid.

Description

Unlike `getYear()`, the value returned by `getFullYear()` is an absolute number. For dates between the years 1000 and 9999, `getFullYear()` returns a four-digit number, for example, 1995. Use this function to make sure a year is compliant with years after 2000.

Examples

Using getFullYear()

The `fullYear` variable has value `1995`, based on the value of the `Date` object `xmas95`.

```
const xmas95 = new Date("1995-12-25T23:15:30");
const fullYear = xmas95.getFullYear();

console.log(fullYear); // 1995
```

See also

- `Date.prototype.getUTCFullYear()`
- `Date.prototype.setFullYear()`
- `Date.prototype.getYear()`

Date.prototype.getHours()

The **`getHours()`** method of `Date` instances returns the hours for this date according to local time.

Try it

```
const birthday = new Date("March 13, 08 04:20");

console.log(birthday.getHours());
// Expected output: 4
```

Syntax

```
getHours()
```

Parameters

None.

Return value

An integer, between 0 and 23, representing the hours for the given date according to local time. Returns `NaN` if the date is invalid.

Examples

Using getHours()

The `hours` variable has value `23`, based on the value of the `Date` object `xmas95`.

```
const xmas95 = new Date("1995-12-25T23:15:30");
const hours = xmas95.getHours();

console.log(hours); // 23
```

See also

- `Date.prototype.getUTCHours()`
- `Date.prototype.setHours()`

Date.prototype.getMilliseconds()

The **`getMilliseconds()`** method of `Date` instances returns the milliseconds for this date according to local time.

Try it

```
const moonLanding = new Date("July 20, 69 00:20:18");
moonLanding.setMilliseconds(123);

console.log(moonLanding.getMilliseconds());
// Expected output: 123
```

Syntax

```
getMilliseconds()
```

Parameters

None.

Return value

An integer, between 0 and 999, representing the milliseconds for the given date according to local time. Returns `NaN` if the date is invalid.

Examples

Using getMilliseconds()

The `milliseconds` variable has value `0`, based on the value of the `Date` object `xmas95`, which doesn't specify the milliseconds component, so it defaults to 0.

```
const xmas95 = new Date("1995-12-25T23:15:30");
const milliseconds = xmas95.getMilliseconds();

console.log(milliseconds); // 0
```

See also

- `Date.prototype.getUTCMilliseconds()`
- `Date.prototype.setMilliseconds()`

Date.prototype.getMinutes()

The **`getMinutes()`** method of `Date` instances returns the minutes for this date according to local time.

Try it

```
const birthday = new Date("March 13, 08 04:20");

console.log(birthday.getMinutes());
// Expected output: 20
```

Syntax

```
getMinutes()
```

Parameters

None.

Return value

An integer, between 0 and 59, representing the minutes for the given date according to local time. Returns `NaN` if the date is invalid.

Examples

Using getMinutes()

The `minutes` variable has value `15`, based on the value of the `Date` object `xmas95`.

```
const xmas95 = new Date("1995-12-25T23:15:30");
const minutes = xmas95.getMinutes();

console.log(minutes); // 15
```

See also

- `Date.prototype.getUTCMinutes()`
- `Date.prototype.setMinutes()`

Date.prototype.getMonth()

The **`getMonth()`** method of `Date` instances returns the month for this date according to local time, as a zero-based value (where zero indicates the first month of the year).

Try it

```
const moonLanding = new Date("July 20, 69 00:20:18");

console.log(moonLanding.getMonth()); // (January gives 0)
// Expected output: 6
```

Syntax

```
getMonth()
```

Parameters

None.

Return value

An integer, between 0 and 11, representing the month for the given date according to local time: 0 for January, 1 for February, and so on. Returns `NaN` if the date is invalid.

Description

The return value of `getMonth()` is zero-based, which is useful for indexing into arrays of months, for example:

```
const valentines = new Date("1995-02-14");
const month = valentines.getMonth();
const monthNames = ["January", "February", "March" /* , … */];

console.log(monthNames[month]); // "February"
```

However, for the purpose of internationalization, you should prefer using `Intl.DateTimeFormat` with the `options` parameter instead.

```
const options = { month: "long" };
console.log(new Intl.DateTimeFormat("en-US", options).format(valentines));
// "February"
console.log(new Intl.DateTimeFormat("de-DE", options).format(valentines));
// "Februar"
```

Examples

Using getMonth()

The `month` variable has value `11`, based on the value of the `Date` object `xmas95`.

```
const xmas95 = new Date("1995-12-25T23:15:30");
const month = xmas95.getMonth();

console.log(month); // 11
```

See also

- `Date.prototype.getUTCMonth()`
- `Date.prototype.setMonth()`

Date.prototype.getSeconds()

The **`getSeconds()`** method of `Date` instances returns the seconds for this date according to local time.

Try it

```
const moonLanding = new Date("July 20, 69 00:20:18");

console.log(moonLanding.getSeconds());
// Expected output: 18
```

Syntax

```
getSeconds()
```

Parameters

None.

Return value

An integer, between 0 and 59, representing the seconds for the given date according to local time. Returns `NaN` if the date is invalid.

Examples

Using getSeconds()

The `seconds` variable has value `30`, based on the value of the `Date` object `xmas95`.

```
const xmas95 = new Date("1995-12-25T23:15:30");
const seconds = xmas95.getSeconds();

console.log(seconds); // 30
```

See also

- `Date.prototype.getUTCSeconds()`
- `Date.prototype.setSeconds()`

Date.prototype.getTime()

The **`getTime()`** method of `Date` instances returns the number of milliseconds for this date since the epoch, which is defined as the midnight at the beginning of January 1, 1970, UTC.

Try it

```
const moonLanding = new Date("July 20, 69 20:17:40 GMT+00:00");

// Milliseconds since Jan 1, 1970, 00:00:00.000 GMT
console.log(moonLanding.getTime());
// Expected output: -14182940000
```

Syntax

```
getTime()
```

Parameters

None.

Return value

A number representing the timestamp, in milliseconds, of this date. Returns `NaN` if the date is invalid.

Description

`Date` objects are fundamentally represented by a timestamp, and this method allows you to retrieve the timestamp. You can use this method to help assign a date and time to another `Date` object. This method is functionally equivalent to the `valueOf()` method.

Examples

Using getTime() for copying dates

Constructing a date object with the identical time value.

```
// Since month is zero based, birthday will be January 10, 1995
const birthday = new Date(1994, 12, 10);
const copy = new Date();
copy.setTime(birthday.getTime());
```

Measuring execution time

Subtracting two subsequent `getTime()` calls on newly generated `Date` objects, give the time span between these two calls. This can be used to calculate the executing time of some operations. See also `Date.now()` to prevent instantiating unnecessary `Date` objects.

```
let end, start;

start = new Date();
for (let i = 0; i < 1000; i++) {
  Math.sqrt(i);
}
end = new Date();

console.log(`Operation took ${end.getTime() - start.getTime()} msec`);
```

> **Note:** In browsers that support the Performance API's high-resolution time feature, `Performance.now()` can provide more reliable and precise measurements of elapsed time than `Date.now()`.

See also

- `Date.prototype.setTime()`
- `Date.prototype.valueOf()`
- `Date.now()`

Date.prototype.getTimezoneOffset()

The **`getTimezoneOffset()`** method of `Date` instances returns the difference, in minutes, between this date as evaluated in the UTC time zone, and the same date as evaluated in the local time zone.

Try it

```
const date1 = new Date("August 19, 1975 23:15:30 GMT+07:00");
const date2 = new Date("August 19, 1975 23:15:30 GMT-02:00");

console.log(date1.getTimezoneOffset());
// Expected output: your local timezone offset in minutes
// (e.g., -120). NOT the timezone offset of the date object.

console.log(date1.getTimezoneOffset() === date2.getTimezoneOffset());
// Expected output: true
```

Syntax

```
getTimezoneOffset()
```

Parameters

None.

Return value

A number representing the difference, in minutes, between the date as evaluated in the UTC time zone and as evaluated in the local time zone. The actual local time algorithm is implementation-defined, and the return value is allowed to be zero in runtimes without appropriate data. Returns `NaN` if the date is invalid.

Description

`date.getTimezoneOffset()` returns the difference, in minutes, between `date` as evaluated in the UTC time zone and as evaluated in the local time zone — that is, the time zone of the host system in which the browser is being used (if the code is run from the Web in a browser), or otherwise the host system of whatever JavaScript runtime (for example, a Node.js environment) the code is executed in.

Negative values and positive values

The number of minutes returned by `getTimezoneOffset()` is positive if the local time zone is behind UTC, and negative if the local time zone is ahead of UTC. For example, for UTC+10, `-600` will be returned.

Current time zone	Return value
UTC-8	480
UTC	0
UTC+3	-180

Varied results in Daylight Saving Time (DST) regions

In a region that annually shifts in and out of Daylight Saving Time (DST), as `date` varies, the number of minutes returned by calling `getTimezoneOffset()` can be non-uniform.

> **Note:** `getTimezoneOffset()`'s behavior will never differ based on the time when the code is run — its behavior is always consistent when running in the same region. Only the value of `date` affects the result.

> **Note:** Many countries have experimented with not changing the time twice a year and this has meant that DST has continued over the winter too. For example in the UK DST lasted from 2:00AM 18 February 1968 to 3:00AM 31 October 1971, so during the winter the clocks were not set back.

In most implementations, the IANA time zone database (tzdata) is used to precisely determine the offset of the local timezone at the moment of the `date`. However, if such information is unavailable, an implementation may return zero.

Examples

Using getTimezoneOffset()

```
// Create a Date instance for the current time
const currentLocalDate = new Date();
// Create a Date instance for 03:24 GMT-0200 on May 1st in 2016
const laborDay2016at0324GMTminus2 = new Date("2016-05-01T03:24:00-02:00");
currentLocalDate.getTimezoneOffset() ===
  laborDay2016at0324GMTminus2.getTimezoneOffset();
// true, always, in any timezone that doesn't annually shift in and out of DST
// false, sometimes, in any timezone that annually shifts in and out of DST
```

getTimezoneOffset() and DST

In regions that use DST, the return value may change based on the time of the year `date` is in. Below is the output in a runtime in New York, where the timezone is UTC-05:00.

```
const nyOffsetSummer = new Date("2022-02-01").getTimezoneOffset(); // 300
const nyOffsetWinter = new Date("2022-08-01").getTimezoneOffset(); // 240
```

getTimezoneOffset() and historical data

Due to historical reasons, the timezone a region is in can be constantly changing, even disregarding DST. For example, below is the output in a runtime in Shanghai, where the timezone is UTC+08:00.

```
const shModernOffset = new Date("2022-01-27").getTimezoneOffset(); // -480
const shHistoricalOffset = new Date("1943-01-27").getTimezoneOffset(); // -540
```

This is because during the Sino-Japanese War when Shanghai was under Japanese control, the timezone was changed to UTC+09:00 to align with Japan's (in effect, it was a "year-round DST"), and this was recorded in the IANA database.

Date.prototype.getUTCDate()

The **`getUTCDate()`** method of `Date` instances returns the day of the month for this date according to universal time.

Try it

```
const date1 = new Date("August 19, 1975 23:15:30 GMT+11:00");
const date2 = new Date("August 19, 1975 23:15:30 GMT-11:00");

console.log(date1.getUTCDate());
// Expected output: 19

console.log(date2.getUTCDate());
// Expected output: 20
```

Syntax

```
getUTCDate()
```

Parameters

None.

Return value

An integer, between 1 and 31, representing day of month for the given date according to universal time. Returns `NaN` if the date is invalid.

Examples

Using getUTCDate()

The following example assigns the day of month of the current date to the variable `dayOfMonth`.

```
const today = new Date();
const dayOfMonth = today.getUTCDate();
```

See also

- `Date.prototype.getUTCDay()`
- `Date.prototype.getDay()`
- `Date.prototype.setUTCDate()`

Date.prototype.getUTCDay()

The **`getUTCDay()`** method of `Date` instances returns the day of the week for this date according to universal time, where 0 represents Sunday.

Try it

```
const date1 = new Date("August 19, 1975 23:15:30 GMT+11:00");
const date2 = new Date("August 19, 1975 23:15:30 GMT-11:00");

// Tuesday
console.log(date1.getUTCDay());
// Expected output: 2

// Wednesday
console.log(date2.getUTCDay());
// Expected output: 3
```

Syntax

```
getUTCDay()
```

Parameters

None.

Return value

An integer corresponding to the day of the week for the given date according to universal time: 0 for Sunday, 1 for Monday, 2 for Tuesday, and so on. Returns `NaN` if the date is invalid.

Examples

Using getUTCDay()

The following example assigns the weekday portion of the current date to the variable `weekday`.

```
const today = new Date();
const weekday = today.getUTCDay();
```

See also

- `Date.prototype.getUTCDate()`
- `Date.prototype.getDay()`
- `Date.prototype.setUTCDate()`

Date.prototype.getUTCFullYear()

The **`getUTCFullYear()`** method of `Date` instances returns the year for this date according to universal time.

Try it

```
const date1 = new Date("December 31, 1975, 23:15:30 GMT+11:00");
const date2 = new Date("December 31, 1975, 23:15:30 GMT-11:00");

console.log(date1.getUTCFullYear());
// Expected output: 1975

console.log(date2.getUTCFullYear());
// Expected output: 1976
```

Syntax

```
getUTCFullYear()
```

Parameters

None.

Return value

An integer representing the year for the given date according to universal time. Returns `NaN` if the date is invalid.

Description

Unlike `getYear()`, the value returned by `getUTCFullYear()` is an absolute number. For dates between the years 1000 and 9999, `getFullYear()` returns a four-digit number, for example, 1995. Use this function to make sure a year is compliant with years after 2000.

Examples

Using getUTCFullYear()

The following example assigns the four-digit value of the current year to the variable `year`.

```
const today = new Date();
const year = today.getUTCFullYear();
```

See also

- `Date.prototype.getFullYear()`
- `Date.prototype.setFullYear()`

Date.prototype.getUTCHours()

The **`getUTCHours()`** method of `Date` instances returns the hours for this date according to universal time.

Try it

```
const date1 = new Date("December 31, 1975, 23:15:30 GMT+11:00");
const date2 = new Date("December 31, 1975, 23:15:30 GMT-11:00");

console.log(date1.getUTCHours());
// Expected output: 12
```

```
console.log(date2.getUTCHours());
// Expected output: 10
```

Syntax

```
getUTCHours()
```

Parameters

None.

Return value

An integer, between 0 and 23, representing the hours for the given date according to universal time. Returns `NaN` if the date is invalid.

Examples

Using getUTCHours()

The following example assigns the hours portion of the current time to the variable `hours`.

```
const today = new Date();
const hours = today.getUTCHours();
```

See also

- `Date.prototype.getHours()`
- `Date.prototype.setUTCHours()`

Date.prototype.getUTCMilliseconds()

The **`getUTCMilliseconds()`** method of `Date` instances returns the milliseconds for this date according to universal time.

Try it

```
const exampleDate = new Date("2018-01-02T03:04:05.678Z"); // 2 January 2018, 03:04:05.678 (UTC)

console.log(exampleDate.getUTCMilliseconds());
// Expected output: 678
```

Syntax

```
getUTCMilliseconds()
```

Parameters

None.

Return value

An integer, between 0 and 999, representing the milliseconds for the given date according to universal time. Returns `NaN` if the date is invalid.

Not to be confused with the timestamp. To get the total milliseconds since the epoch, use the `getTime()` method.

Examples

Using getUTCMilliseconds()

The following example assigns the milliseconds portion of the current time to the variable `milliseconds`.

```
const today = new Date();
const milliseconds = today.getUTCMilliseconds();
```

See also

- `Date.prototype.getMilliseconds()`
- `Date.prototype.setUTCMilliseconds()`

Date.prototype.getUTCMinutes()

The **`getUTCMinutes()`** method of `Date` instances returns the minutes for this date according to universal time.

Try it

```
const date1 = new Date("1 January 2000 03:15:30 GMT+07:00");
const date2 = new Date("1 January 2000 03:15:30 GMT+03:30");

console.log(date1.getUTCMinutes()); // 31 Dec 1999 20:15:30 GMT
// Expected output: 15

console.log(date2.getUTCMinutes()); // 31 Dec 1999 23:45:30 GMT
// Expected output: 45
```

Syntax

```
getUTCMinutes()
```

Parameters

None.

Return value

An integer, between 0 and 59, representing the minutes for the given date according to universal time. Returns `NaN` if the date is invalid.

Examples

Using getUTCMinutes()

The following example assigns the minutes portion of the current time to the variable `minutes`.

```
const today = new Date();
const minutes = today.getUTCMinutes();
```

See also

- `Date.prototype.getMinutes()`
- `Date.prototype.setUTCMinutes()`

Date.prototype.getUTCMonth()

The **`getUTCMonth()`** method of `Date` instances returns the month for this date according to universal time, as a zero-based value (where zero indicates the first month of the year).

Try it

```
const date1 = new Date("December 31, 1975, 23:15:30 GMT+11:00");
const date2 = new Date("December 31, 1975, 23:15:30 GMT-11:00");

// December
console.log(date1.getUTCMonth());
// Expected output: 11

// January
console.log(date2.getUTCMonth());
// Expected output: 0
```

Syntax

```
getUTCMonth()
```

Parameters

None.

Return value

An integer, between 0 and 11, representing the month for the given date according to universal time: 0 for January, 1 for February, and so on. Returns `NaN` if the date is invalid.

Examples

Using getUTCMonth()

The following example assigns the month portion of the current date to the variable `month`.

```
const today = new Date();
const month = today.getUTCMonth();
```

See also

- `Date.prototype.getMonth()`
- `Date.prototype.setUTCMonth()`

Date.prototype.getUTCSeconds()

The **`getUTCSeconds()`** method of `Date` instances returns the seconds in the specified date according to universal time.

Try it

```
const moonLanding = new Date("July 20, 1969, 20:18:04 UTC");

console.log(moonLanding.getUTCSeconds());
// Expected output: 4
```

Syntax

```
getUTCSeconds()
```

Parameters

None.

Return value

An integer, between 0 and 59, representing the seconds for the given date according to universal time. Returns `NaN` if the date is invalid.

Examples

Using getUTCSeconds()

The following example assigns the seconds portion of the current time to the variable `seconds`.

```
const today = new Date();
const seconds = today.getUTCSeconds();
```

See also

- `Date.prototype.getSeconds()`
- `Date.prototype.setUTCSeconds()`

Date.prototype.getYear()

The **`getYear()`** method of `Date` instances returns the year for this date according to local time. Because `getYear()` does not return full years ("year 2000 problem"), it is deprecated and has been replaced by the `getFullYear()` method.

Syntax

```
getYear()
```

Parameters

None.

Return value

An integer representing the year for the given date according to local time, minus 1900. Returns `NaN` if the date is invalid.

- For years greater than or equal to 2000, the value is 100 or greater. For example, if the year is 2026, `getYear()` returns 126.
- For years between and including 1900 and 1999, the value returned by `getYear()` is between 0 and 99. For example, if the year is 1976, `getYear()` returns 76.
- For years less than 1900, the value returned by `getYear()` is less than 0. For example, if the year is 1800, `getYear()` returns -100.

This method essentially returns the value of `getFullYear()` minus 1900. You should use `getFullYear()` instead, so that the year is specified in full.

Examples

Years between 1900 and 1999

The second statement assigns the value 95 to the variable `year`.

```
const xmas = new Date("1995-12-25");
const year = xmas.getYear(); // returns 95
```

Years above 1999

The second statement assigns the value 100 to the variable `year`.

```
const xmas = new Date("2000-12-25");
const year = xmas.getYear(); // returns 100
```

Years below 1900

The second statement assigns the value -100 to the variable `year`.

```
const xmas = new Date("1800-12-25");
const year = xmas.getYear(); // returns -100
```

Setting and getting a year between 1900 and 1999

The third statement assigns the value 95 to the variable `year`, representing the year 1995.

```
const xmas = new Date("2015-12-25");
xmas.setYear(95);
const year = xmas.getYear(); // returns 95
```

Date.now()

The **`Date.now()`** static method returns the number of milliseconds elapsed since the epoch, which is defined as the midnight at the beginning of January 1, 1970, UTC.

Try it

```
// This example takes 2 seconds to run
const start = Date.now();

console.log("starting timer...");
// Expected output: "starting timer..."

setTimeout(() => {
  const ms = Date.now() - start;

  console.log(`seconds elapsed = ${Math.floor(ms / 1000)}`);
  // Expected output: "seconds elapsed = 2"
}, 2000);
```

Syntax

```
Date.now()
```

Parameters

None.

Return value

A number representing the timestamp, in milliseconds, of the current time.

Description

Reduced time precision

To offer protection against timing attacks and fingerprinting, the precision of `Date.now()` may be reduced depending on browser settings.

The timestamp is always an integer number of milliseconds, so its resolution is limited to 1 ms in all contexts. This already satisfies certain basic security and privacy needs.

In Firefox, the `privacy.reduceTimerPrecision` preference is enabled by default. With default settings, the timestamp has 1 ms resolution. If `privacy.resistFingerprinting` is enabled, the rounding interval is 16.667 ms or the interval configured by `privacy.resistFingerprinting.reduceTimerPrecision.microseconds`, whichever is larger. The final output is rounded to an integer.

For example, these are possible values in Firefox:

```
// Reduced time precision (1 ms) with default settings
Date.now();
// Might be:
// 1519211809934
// 1519211810363
// 1519211811671
// …

// Reduced time precision with `privacy.resistFingerprinting` enabled
Date.now();
// Might be:
// 1519129853489
// 1519129853506
// 1519129853522
// …
```

Examples

Measuring time elapsed

You can use `Date.now()` to get the current time in milliseconds, then subtract a previous time to find out how much time elapsed between the two calls.

```
const start = Date.now();
doSomeLongRunningProcess();
console.log(`Time elapsed: ${Date.now() - start} ms`);
```

For more complex scenarios, you may want to use the performance API instead.

- Polyfill of `Date.now` in `core-js`

- `Performance.now()`
- `console.time()`
- `console.timeEnd()`

Date.parse()

The **`Date.parse()`** static method parses a string representation of a date, and returns the date's timestamp.

Try it

```
// Standard date-time string format
const unixTimeZero = Date.parse("1970-01-01T00:00:00Z");
// Non-standard format resembling toUTCString()
const javaScriptRelease = Date.parse("04 Dec 1995 00:12:00 GMT");

console.log(unixTimeZero);
// Expected output: 0

console.log(javaScriptRelease);
// Expected output: 818035920000
```

Syntax

```
Date.parse(dateString)
```

Parameters

`dateString`

A string in the date time string format. See the linked reference for caveats on using different formats.

Return value

A number representing the timestamp of the given date. If `dateString` fails to be parsed as a valid date, `NaN` is returned.

Description

This function is useful for setting date values based on string values, for example in conjunction with the `setTime()` method.

The formats that `parse()` can handle are not explicitly specified, but there are a few invariants:

- The date time string format (produced by `toISOString()`) must be supported.
- If `x` is any Date whose milliseconds amount is zero, then `x.valueOf()` should be equal to any of the following: `Date.parse(x.toString())`, `Date.parse(x.toUTCString())`, `Date.parse(x.toISOString())`. This means the formats produced by `toString()` and `toUTCString()` should be supported too.
- The spec does *not* require support for the format produced by `toLocaleString()`. However, major engines all try to support `toLocaleString("en-US")` format.

Other formats are implementation-defined and may not work across all browsers. A library can help if many different formats are to be accommodated. In fact, the unreliability of `Date.parse()` is one of the motivations for the `Temporal` API to be introduced.

Because `parse()` is a static method of `Date`, you always use it as `Date.parse()`, rather than as a method of a `Date` object you created.

Examples

Using Date.parse()

The following calls all return `1546300800000`. The first will imply UTC time because it's date-only, and the others explicitly specify the UTC timezone.

```
Date.parse("2019-01-01");
Date.parse("2019-01-01T00:00:00.000Z");
Date.parse("2019-01-01T00:00:00.000+00:00");
```

The following call, which does not specify a time zone will be set to 2019-01-01 at 00:00:00 in the local timezone of the system, because it has both date and time.

```
Date.parse("2019-01-01T00:00:00");
```

toString() and toUTCString() formats

Apart from the standard date time string format, the `toString()` and `toUTCString()` formats are supported:

```
// toString() format
Date.parse("Thu Jan 01 1970 00:00:00 GMT-0500 (Eastern Standard Time)");
// 18000000 in all implementations in all timezones

// toUTCString() format
Date.parse("Thu, 01 Jan 1970 00:00:00 GMT");
// 0 in all implementations in all timezones
```

Non-standard date strings

> **Note:** This section contains implementation-specific behavior that may be inconsistent across browsers or different versions of browsers. It is not meant to be a

> comprehensive browser compatibility table and you should always conduct your own tests before using any format in your code.

Implementations usually default to the local time zone when the date string is non-standard. For consistency, we will assume that the runtime uses the UTC timezone, and unless specified otherwise, the output will vary with the device's time zone. Daylight Saving Time (DST), of the local time zone, can also have an effect on this.

Here are some more examples of non-standard date strings. Browsers are very lenient when parsing date strings and may discard any part of a string that they cannot parse. For compatibility reasons, browsers often copy each other's behavior, so these handling patterns tend to propagate cross-browser. As previously stated, the following examples are for illustration only, and are not exhaustive by any means:

Description	Example	Chrome	Firefox	Safari
Single number	`0` (single-digit)	946684800000 (Jan 01 2000); NaN in Firefox ≤122		-62167219200000 (Jan 01 0000)
	`31` (two-digit)	NaN		-61188912000000 (Jan 01 0031)
	`999` (three-/four-digit)	-30641733102000 (Jan 01 0999)		
Date strings that use different separators	`1970-01-01` (standard)	0 in all time zones		
	`1970/01/01`	0		
	`1970,01,01`	0		NaN
	`1970 01 01`	0		NaN

Strings that look like `toString()`	`Thu Jan 01 1970 00:00:00`
	`Thu Jan 01 1970`
	`Jan 01 1970 00:00:00`
	`Jan 01 1970`
		0		

Strings that look like `toUTCString()`	`Thu, 01 Jan 1970 00:00:00`
	`Thu, 01 Jan 1970`
	`01 Jan 1970 00:00:00`
	`01 Jan 1970`
		0		

First date component is 2-digit	`01-02-03` (first segment can be valid month)	1041465600000 (Jan 02 2003)		-62132745600000 (Feb 03 0001) Note: Safari always assumes YY-MM-DD, but MM/DD/YY.
	`27-02-03` (first segment can be valid day but not month)	NaN		-61312291200000 (Feb 03 0027)
	`49-02-03` (first segment cannot be valid day and is <50)	2495923200000 (Feb 03 2049)		-60617980800000 (Feb 03 0049)
	`50-02-03` (first segment cannot be valid day and is ≥50)	-628300800000 (Feb 03 1950)		-60586444800000 (Feb 03 0050)

Out-of-bounds date components	`2014-25-23`
	`Mar 32, 2014`
	`2014/25/23`
		NaN		

	`2014-02-30`	1393718400000 (Mar 02 2014)		NaN
	`02/30/2014`	1393718400000		

Extraneous characters after the month name	`04 Dec 1995`
	`04 Decem 1995`
	`04 December 1995`
		818031600000		

	`04 DecFoo 1995`	818031600000 Only the first three characters are read. Firefox ≤121 reads up to the valid month name, thus returning NaN when it sees "F".		
	`04 De 1995`	NaN		

See also

- `Date.UTC()`

Date.prototype.setDate()

The **`setDate()`** method of `Date` instances changes the day of the month for this date according to local time.

Try it

```
const event = new Date("August 19, 1975 23:15:30");

event.setDate(24);

console.log(event.getDate());
// Expected output: 24

event.setDate(32);
// Only 31 days in August!
```

```
console.log(event.getDate());
// Expected output: 1
```

Syntax

```
setDate(dateValue)
```

Parameters

`dateValue`

An integer representing the day of the month.

Return value

Changes the `Date` object in place, and returns its new timestamp. If `dateValue` is `NaN` (or other values that get coerced to `NaN`, such as `undefined`), the date is set to Invalid Date and `NaN` is returned.

Description

If you specify a number outside the expected range, the date information in the `Date` object is updated accordingly. For example, if the `Date` object holds June 1st, a `dateValue` of 40 changes the date to July 10th, while a `dateValue` of 0 changes the date to the last day of the previous month, May 31st.

Because `setDate()` operates on the local time, crossing a Daylight Saving Time (DST) boundary may result in a different elapsed time than expected. For example, if setting the date crosses a spring-forward transition (losing an hour), the difference in timestamps between the new and old date is one hour less than the nominal day difference multiplied by 24 hours. Conversely, crossing a fall-back transition (gaining an hour) result in an extra hour. If you need to adjust the date by a fixed amount of time, consider using `setUTCDate()` or `setTime()`.

If the new local time falls within an offset transition, the exact time is derived using the same behavior as `Temporal`'s `disambiguation: "compatible"` option. That is, if the local time corresponds to two instants, the earlier one is chosen; if the local time does not exist (there is a gap), we go forward by the gap duration.

Examples

Using setDate()

```
const theBigDay = new Date(1962, 6, 7, 12); // noon of 1962-07-07 (7th of July 1962, month is 0-indexed)
const theBigDay2 = new Date(theBigDay).setDate(24); // 1962-07-24 (24th of July 1962)
const theBigDay3 = new Date(theBigDay).setDate(32); // 1962-08-01 (1st of August 1962)
const theBigDay4 = new Date(theBigDay).setDate(22); // 1962-07-22 (22nd of July 1962)
const theBigDay5 = new Date(theBigDay).setDate(0); // 1962-06-30 (30th of June 1962)
const theBigDay6 = new Date(theBigDay).setDate(98); // 1962-10-06 (6th of October 1962)
const theBigDay7 = new Date(theBigDay).setDate(-50); // 1962-05-11 (11th of May 1962)
```

- `Date.prototype.setUTCDate()`

Date.prototype.setFullYear()

The **`setFullYear()`** method of `Date` instances changes the year, month, and/or day of month for this date according to local time.

Try it

```
const event = new Date("August 19, 1975 23:15:30");

event.setFullYear(1969);

console.log(event.getFullYear());
// Expected output: 1969

event.setFullYear(0);

console.log(event.getFullYear());
// Expected output: 0
```

Syntax

```
setFullYear(yearValue)
setFullYear(yearValue, monthValue)
setFullYear(yearValue, monthValue, dateValue)
```

Parameters

`yearValue`

An integer representing the year. For example, 1995.

`monthValue` Optional

An integer representing the month: 0 for January, 1 for February, and so on.

`dateValue` Optional

An integer between 1 and 31 representing the day of the month. If you specify `dateValue`, you must also specify `monthValue`.

Return value

Changes the `Date` object in place, and returns its new timestamp. If a parameter is `NaN` (or other values that get coerced to `NaN`, such as `undefined`), the date is set to Invalid Date and `NaN` is returned.

Description

If you do not specify the `monthValue` and `dateValue` parameters, the same values as what are returned by `getMonth()` and `getDate()` are used.

If a parameter you specify is outside of the expected range, other parameters and the date information in the `Date` object are updated accordingly. For example, if you specify 15 for `monthValue`, the year is incremented by 1 (`yearValue + 1`), and 3 is used for the month.

Because `setFullYear()` operates on the local time, crossing a Daylight Saving Time (DST) boundary may result in a different elapsed time than expected. For example, if setting the date crosses a spring-forward transition (losing an hour), the difference in timestamps between the new and old date is one hour less than the nominal day difference multiplied by 24 hours. Conversely, crossing a fall-back transition (gaining an hour) result in an extra hour. If you need to adjust the date by a fixed amount of time, consider using `setUTCFullYear()` or `setTime()`.

If the new local time falls within an offset transition, the exact time is derived using the same behavior as `Temporal`'s `disambiguation: "compatible"` option. That is, if the local time corresponds to two instants, the earlier one is chosen; if the local time does not exist (there is a gap), we go forward by the gap duration.

Examples

Using setFullYear()

```
const theBigDay = new Date();
theBigDay.setFullYear(1997);
```

See also

- `Date.prototype.getUTCFullYear()`
- `Date.prototype.setUTCFullYear()`
- `Date.prototype.setYear()`

Date.prototype.setHours()

The **`setHours()`** method of `Date` instances changes the hours, minutes, seconds, and/or milliseconds for this date according to local time.

Try it

```
const event = new Date("August 19, 1975 23:15:30");
event.setHours(20);

console.log(event);
// Expected output: "Tue Aug 19 1975 20:15:30 GMT+0200 (CEST)"
// Note: your timezone may vary

event.setHours(20, 21, 22);

console.log(event);
// Expected output: "Tue Aug 19 1975 20:21:22 GMT+0200 (CEST)"
```

Syntax

```
setHours(hoursValue)
setHours(hoursValue, minutesValue)
setHours(hoursValue, minutesValue, secondsValue)
setHours(hoursValue, minutesValue, secondsValue, msValue)
```

Parameters

`hoursValue`

An integer between 0 and 23 representing the hours.

`minutesValue` Optional

An integer between 0 and 59 representing the minutes.

`secondsValue` Optional

An integer between 0 and 59 representing the seconds. If you specify `secondsValue`, you must also specify `minutesValue`.

`msValue` Optional

An integer between 0 and 999 representing the milliseconds. If you specify `msValue`, you must also specify `minutesValue` and `secondsValue`.

Return value

Changes the `Date` object in place, and returns its new timestamp. If a parameter is `NaN` (or other values that get coerced to `NaN`, such as `undefined`), the date is set to Invalid Date and `NaN` is returned.

Description

If you do not specify the `minutesValue`, `secondsValue`, and `msValue` parameters, the same values as what are returned by `getMinutes()`, `getSeconds()`, and `getMilliseconds()` are used.

If a parameter you specify is outside of the expected range, other parameters and the date information in the `Date` object are updated accordingly. For example, if you specify 100 for `secondsValue`, the minutes are incremented by 1 (`minutesValue + 1`), and 40 is used for seconds.

Because `setHours()` operates on the local time, crossing a Daylight Saving Time (DST) boundary may result in a different elapsed time than expected. For example, if setting the hours crosses a spring-forward transition (losing an hour), the difference in timestamps between the new and old date is one hour less than the nominal hour difference. Conversely, crossing a fall-back transition (gaining an hour) result in an extra hour. If you need to adjust the date by a fixed amount of time, consider using `setUTCHours()` or `setTime()`.

If the new local time falls within an offset transition, the exact time is derived using the same behavior as `Temporal`'s `disambiguation: "compatible"` option. That is, if the local time corresponds to two instants, the earlier one is chosen; if the local time does not exist (there is a gap), we go forward by the gap duration.

Examples

Using setHours()

```
const theBigDay = new Date();
theBigDay.setHours(7);
```

See also

- `Date.prototype.getHours()`
- `Date.prototype.setUTCHours()`

Date.prototype.setMilliseconds()

The **`setMilliseconds()`** method of `Date` instances changes the milliseconds for this date according to local time.

Try it

```
const event = new Date("August 19, 1975 23:15:30");

console.log(event.getMilliseconds());
// Expected output: 0

event.setMilliseconds(456);

console.log(event.getMilliseconds());
// Expected output: 456
```

Syntax

```
setMilliseconds(millisecondsValue)
```

Parameters

`millisecondsValue`

An integer between 0 and 999 representing the milliseconds.

Return value

Changes the `Date` object in place, and returns its new timestamp. If `millisecondsValue` is `NaN` (or other values that get coerced to `NaN`, such as `undefined`), the date is set to Invalid Date and `NaN` is returned.

Description

If you specify a number outside the expected range, the date information in the `Date` object is updated accordingly. For example, if you specify 1005, the number of seconds is incremented by 1, and 5 is used for the milliseconds.

Because `setMilliseconds()` operates on the local time, crossing a Daylight Saving Time (DST) boundary may result in a different elapsed time than expected. For example, if setting the milliseconds crosses a spring-forward transition (losing an hour), the difference in timestamps between the new and old date is one hour less than the nominal time difference. Conversely, crossing a fall-back transition (gaining an hour) result in an extra hour. If you need to adjust the date by a fixed amount of time, consider using `setUTCMilliseconds()` or `setTime()`.

If the new local time falls within an offset transition, the exact time is derived using the same behavior as `Temporal`'s `disambiguation: "compatible"` option. That is, if the local time corresponds to two instants, the earlier one is chosen; if the local time does not exist (there is a gap), we go forward by the gap duration.

Examples

Using setMilliseconds()

```
const theBigDay = new Date();
theBigDay.setMilliseconds(100);
```

See also

- `Date.prototype.getMilliseconds()`
- `Date.prototype.setUTCMilliseconds()`

Date.prototype.setMinutes()

The **`setMinutes()`** method of `Date` instances changes the minutes for this date according to local time.

Try it

```
const event = new Date("August 19, 1975 23:15:30");

event.setMinutes(45);

console.log(event.getMinutes());
// Expected output: 45

console.log(event);
// Expected output: "Tue Aug 19 1975 23:45:30 GMT+0200 (CEST)"
// Note: your timezone may vary
```

Syntax

```
setMinutes(minutesValue)
setMinutes(minutesValue, secondsValue)
setMinutes(minutesValue, secondsValue, msValue)
```

Parameters

`minutesValue`

An integer between 0 and 59 representing the minutes.

`secondsValue` Optional

An integer between 0 and 59 representing the seconds. If you specify `secondsValue`, you must also specify `minutesValue`.

`msValue` Optional

An integer between 0 and 999 representing the milliseconds. If you specify `msValue`, you must also specify `minutesValue` and `secondsValue`.

Return value

Changes the `Date` object in place, and returns its new timestamp. If a parameter is `NaN` (or other values that get coerced to `NaN`, such as `undefined`), the date is set to Invalid Date and `NaN` is returned.

Description

If you do not specify the `secondsValue` and `msValue` parameters, the same values as what are returned by `getSeconds()` and `getMilliseconds()` are used.

If a parameter you specify is outside of the expected range, other parameters and the date information in the `Date` object are updated accordingly. For example, if you specify 100 for `secondsValue`, the minutes is incremented by 1 (`minutesValue + 1`), and 40 is used for seconds.

Because `setMinutes()` operates on the local time, crossing a Daylight Saving Time (DST) boundary may result in a different elapsed time than expected. For example, if setting the minutes crosses a spring-forward transition (losing an hour), the difference in timestamps between the new and old date is one hour less than the nominal time difference. Conversely, crossing a fall-back transition (gaining an hour) result in an extra hour. If you need to adjust the date by a fixed amount of time, consider using `setUTCMinutes()` or `setTime()`.

If the new local time falls within an offset transition, the exact time is derived using the same behavior as `Temporal`'s `disambiguation: "compatible"` option. That is, if the local time corresponds to two instants, the earlier one is chosen; if the local time does not exist (there is a gap), we go forward by the gap duration.

Examples

Using setMinutes()

```
const theBigDay = new Date();
theBigDay.setMinutes(45);
```

See also

- `Date.prototype.getMinutes()`
- `Date.prototype.setUTCMinutes()`

Date.prototype.setMonth()

The **`setMonth()`** method of `Date` instances changes the month and/or day of the month for this date according to local time.

Try it

```
const event = new Date("August 19, 1975 23:15:30");

event.setMonth(3);
```

```
console.log(event.getMonth());
// Expected output: 3

console.log(event);
// Expected output: "Sat Apr 19 1975 23:15:30 GMT+0100 (CET)"
// Note: your timezone may vary
```

Syntax

```
setMonth(monthValue)
setMonth(monthValue, dateValue)
```

Parameters

`monthValue`

An integer representing the month: 0 for January, 1 for February, and so on.

`dateValue` Optional

An integer from 1 to 31 representing the day of the month.

Return value

Changes the `Date` object in place, and returns its new timestamp. If a parameter is `NaN` (or other values that get coerced to `NaN`, such as `undefined`), the date is set to Invalid Date and `NaN` is returned.

Description

If you do not specify the `dateValue` parameter, the same value as what is returned by `getDate()` is used.

If a parameter you specify is outside of the expected range, other parameters and the date information in the `Date` object are updated accordingly. For example, if you specify 15 for `monthValue`, the year is incremented by 1, and 3 is used for month.

The current day of month will have an impact on the behavior of this method. Conceptually it will add the number of days given by the current day of the month to the 1st day of the new month specified as the parameter, to return the new date. For example, if the current value is 31st January 2016, calling setMonth with a value of 1 will return 2nd March 2016. This is because in 2016 February had 29 days.

Because `setMonth()` operates on the local time, crossing a Daylight Saving Time (DST) boundary may result in a different elapsed time than expected. For example, if setting the month crosses a spring-forward transition (losing an hour), the difference in timestamps between the new and old date is one hour less than the nominal day difference multiplied by 24 hours. Conversely, crossing a fall-back transition (gaining an hour) result in an extra hour. If you need to adjust the date by a fixed amount of time, consider using `setUTCMonth()` or `setTime()`.

If the new local time falls within an offset transition, the exact time is derived using the same behavior as `Temporal`'s `disambiguation: "compatible"` option. That is, if the local time corresponds to two instants, the earlier one is chosen; if the local time does not exist (there is a gap), we go forward by the gap duration.

Examples

Using setMonth()

```
const theBigDay = new Date();
theBigDay.setMonth(6);

// Watch out for end of month transitions
const endOfMonth = new Date(2016, 7, 31);
endOfMonth.setMonth(1);
console.log(endOfMonth); // Wed Mar 02 2016 00:00:00
```

See also

- `Date.prototype.getMonth()`
- `Date.prototype.setUTCMonth()`

Date.prototype.setSeconds()

The **`setSeconds()`** method of `Date` instances changes the seconds and/or milliseconds for this date according to local time.

Try it

```
const event = new Date("August 19, 1975 23:15:30");

event.setSeconds(42);

console.log(event.getSeconds());
// Expected output: 42

console.log(event);
// Expected output: "Tue Aug 19 1975 23:15:42 GMT+0100 (CET)"
// Note: your timezone may vary
```

Syntax

```
setSeconds(secondsValue)
setSeconds(secondsValue, msValue)
```

Parameters

`secondsValue`

An integer between 0 and 59 representing the seconds.

`msValue` Optional

An integer between 0 and 999 representing the milliseconds.

Return value

Changes the `Date` object in place, and returns its new timestamp. If a parameter is `NaN` (or other values that get coerced to `NaN`, such as `undefined`), the date is set to Invalid Date and `NaN` is returned.

Description

If you do not specify the `msValue` parameter, the value returned from the `getMilliseconds()` method is used.

If a parameter you specify is outside of the expected range, `setSeconds()` attempts to update the date information in the `Date` object accordingly. For example, if you use 100 for `secondsValue`, the minutes stored in the `Date` object will be incremented by 1, and 40 will be used for seconds.

Because `setSeconds()` operates on the local time, crossing a Daylight Saving Time (DST) boundary may result in a different elapsed time than expected. For example, if setting the seconds crosses a spring-forward transition (losing an hour), the difference in timestamps between the new and old date is one hour less than the nominal time difference. Conversely, crossing a fall-back transition (gaining an hour) result in an extra hour. If you need to adjust the date by a fixed amount of time, consider using `setUTCSeconds()` or `setTime()`.

If the new local time falls within an offset transition, the exact time is derived using the same behavior as `Temporal`'s `disambiguation: "compatible"` option. That is, if the local time corresponds to two instants, the earlier one is chosen; if the local time does not exist (there is a gap), we go forward by the gap duration.

Examples

Using setSeconds()

```
const theBigDay = new Date();
theBigDay.setSeconds(30);
```

See also

- `Date.prototype.getSeconds()`
- `Date.prototype.setUTCSeconds()`

Date.prototype.setTime()

The **`setTime()`** method of `Date` instances changes the timestamp for this date, which is the number of milliseconds since the epoch, defined as the midnight at the beginning of January 1, 1970, UTC.

Try it

```
const launchDate = new Date("July 1, 1999, 12:00:00");
const futureDate = new Date();
futureDate.setTime(launchDate.getTime());

console.log(futureDate);
// Expected output: "Thu Jul 01 1999 12:00:00 GMT+0200 (CEST)"

const fiveMinutesInMs = 5 * 60 * 1000;
futureDate.setTime(futureDate.getTime() + fiveMinutesInMs);

console.log(futureDate);
// Expected output: "Thu Jul 01 1999 12:05:00 GMT+0200 (CEST)"
// Note: your timezone may vary
```

Syntax

```
setTime(timeValue)
```

Parameters

`timeValue`

An integer representing the new timestamp — the number of milliseconds since the midnight at the beginning of January 1, 1970, UTC.

Return value

Changes the `Date` object in place, and returns its new timestamp. If `timeValue` is `NaN` (or other values that get coerced to `NaN`, such as `undefined`), the date is set to Invalid Date and `NaN` is returned.

Examples

Using setTime()

```
const theBigDay = new Date("1999-07-01");
const sameAsBigDay = new Date();
sameAsBigDay.setTime(theBigDay.getTime());
```

See also

- `Date.prototype.getTime()`
- `Date.prototype.setUTCHours()`

Date.prototype.setUTCDate()

The **`setUTCDate()`** method of `Date` instances changes the day of the month for this date according to universal time.

Try it

```
const event = new Date("August 19, 1975 23:15:30 GMT-3:00");

console.log(event.getUTCDate());
// Expected output: 20

event.setUTCDate(19);

console.log(event.getUTCDate());
// Expected output: 19
```

Syntax

```
setUTCDate(dateValue)
```

Parameters

`dateValue`

An integer from 1 to 31 representing the day of the month.

Return value

Changes the `Date` object in place, and returns its new timestamp. If `dateValue` is `NaN` (or other values that get coerced to `NaN`, such as `undefined`), the date is set to Invalid Date and `NaN` is returned.

Description

If the `dateValue` is outside of the range of date values for the month, `setDate()` will update the `Date` object accordingly.

For example, if 0 is provided for `dateValue`, the date will be set to the last day of the previous month. If you use 40 for `dateValue`, and the month stored in the `Date` object is June, the day will be changed to 10 and the month will be incremented to July.

If a negative number is provided for `dateValue`, the date will be set counting backwards from the last day of the previous month. -1 would result in the date being set to 1 day before the last day of the previous month.

Examples

Using setUTCDate()

```
const theBigDay = new Date();
theBigDay.setUTCDate(20);
```

See also

- `Date.prototype.getUTCDate()`
- `Date.prototype.setDate()`

Date.prototype.setUTCFullYear()

The **`setUTCFullYear()`** method of `Date` instances changes the year for this date according to universal time.

Try it

```
const event = new Date("December 31, 1975 23:15:30 GMT-3:00");

console.log(event.getUTCFullYear());
// Expected output: 1976

console.log(event.toUTCString());
// Expected output: "Thu, 01 Jan 1976 02:15:30 GMT"

event.setUTCFullYear(1975);

console.log(event.toUTCString());
// Expected output: "Wed, 01 Jan 1975 02:15:30 GMT"
```

Syntax

```
setUTCFullYear(yearValue)
setUTCFullYear(yearValue, monthValue)
setUTCFullYear(yearValue, monthValue, dateValue)
```

Parameters

`yearValue`

An integer representing the year. For example, 1995.

`monthValue` Optional

An integer representing the month: 0 for January, 1 for February, and so on.

`dateValue` Optional

An integer between 1 and 31 representing the day of the month. If you specify `dateValue`, you must also specify `monthValue`.

Return value

Changes the `Date` object in place, and returns its new timestamp. If a parameter is `NaN` (or other values that get coerced to `NaN`, such as `undefined`), the date is set to Invalid Date and `NaN` is returned.

Description

If you do not specify the `monthValue` and `dateValue` parameters, the values returned from the `getUTCMonth()` and `getUTCDate()` methods are used.

If a parameter you specify is outside of the expected range, `setUTCFullYear()` attempts to update the other parameters and the date information in the `Date` object accordingly. For example, if you specify 15 for `monthValue`, the year is incremented by 1 (`yearValue + 1`), and 3 is used for the month.

Examples

Using setUTCFullYear()

```
const theBigDay = new Date();
theBigDay.setUTCFullYear(1997);
```

See also

- `Date.prototype.getUTCFullYear()`
- `Date.prototype.setFullYear()`

Date.prototype.setUTCHours()

The **`setUTCHours()`** method of `Date` instances changes the hours, minutes, seconds, and/or milliseconds for this date according to universal time.

Try it

```
const event = new Date("August 19, 1975 23:15:30 GMT-3:00");

console.log(event.toUTCString());
// Expected output: "Wed, 20 Aug 1975 02:15:30 GMT"

console.log(event.getUTCHours());
// Expected output: 2

event.setUTCHours(23);

console.log(event.toUTCString());
// Expected output: "Wed, 20 Aug 1975 23:15:30 GMT"
```

Syntax

```
setUTCHours(hoursValue)
setUTCHours(hoursValue, minutesValue)
setUTCHours(hoursValue, minutesValue, secondsValue)
setUTCHours(hoursValue, minutesValue, secondsValue, msValue)
```

Parameters

`hoursValue`

An integer between 0 and 23 representing the hours.

`minutesValue` Optional

An integer between 0 and 59 representing the minutes.

`secondsValue` Optional

An integer between 0 and 59 representing the seconds. If you specify `secondsValue`, you must also specify `minutesValue`.

`msValue` Optional

An integer between 0 and 999 representing the milliseconds. If you specify `msValue`, you must also specify `minutesValue` and `secondsValue`.

Return value

Changes the `Date` object in place, and returns its new timestamp. If a parameter is `NaN` (or other values that get coerced to `NaN`, such as `undefined`), the date is set to Invalid Date and `NaN` is returned.

Description

If you do not specify the `minutesValue`, `secondsValue`, and `msValue` parameters, the values returned from the `getUTCMinutes()`, `getUTCSeconds()`, and `getUTCMilliseconds()` methods are used.

If a parameter you specify is outside of the expected range, `setUTCHours()` attempts to update the date information in the `Date` object accordingly. For example, if you use 100 for `secondsValue`, the minutes will be incremented by 1 (`minutesValue + 1`), and 40 will be used for seconds.

Examples

Using setUTCHours()

```
const theBigDay = new Date();
theBigDay.setUTCHours(8);
```

See also

- `Date.prototype.getUTCHours()`
- `Date.prototype.setHours()`

Date.prototype.setUTCMilliseconds()

The **`setUTCMilliseconds()`** method of `Date` instances changes the milliseconds for this date according to universal time.

Try it

```
const date = new Date("2018-01-24T12:38:29.069Z");

console.log(date.getUTCMilliseconds());
// Expected output: 69

date.setUTCMilliseconds(420);

console.log(date.getUTCMilliseconds());
// Expected output: 420
```

Syntax

```
setUTCMilliseconds(millisecondsValue)
```

Parameters

`millisecondsValue`

An integer between 0 and 999 representing the milliseconds.

Return value

Changes the `Date` object in place, and returns its new timestamp. If `millisecondsValue` is `NaN` (or other values that get coerced to `NaN`, such as `undefined`), the date is set to Invalid Date and `NaN` is returned.

Description

If a parameter you specify is outside of the expected range, `setUTCMilliseconds()` attempts to update the date information in the `Date` object accordingly. For example, if you use 1100 for `millisecondsValue`, the seconds stored in the `Date` object will be incremented by 1, and 100 will be used for milliseconds.

Examples

Using setUTCMilliseconds()

```
const theBigDay = new Date();
theBigDay.setUTCMilliseconds(500);
```

See also

- `Date.prototype.getUTCMilliseconds()`
- `Date.prototype.setMilliseconds()`

Date.prototype.setUTCMinutes()

The **`setUTCMinutes()`** method of `Date` instances changes the minutes for this date according to universal time.

Try it

```
const date = new Date("December 31, 1975, 23:15:30 GMT+11:00");

console.log(date.getUTCMinutes());
// Expected output: 15

date.setUTCMinutes(25);

console.log(date.getUTCMinutes());
// Expected output: 25
```

Syntax

```
setUTCMinutes(minutesValue)
setUTCMinutes(minutesValue, secondsValue)
setUTCMinutes(minutesValue, secondsValue, msValue)
```

Parameters

`minutesValue`

An integer between 0 and 59 representing the minutes.

`secondsValue` Optional

An integer between 0 and 59 representing the seconds. If you specify `secondsValue`, you must also specify `minutesValue`.

`msValue` Optional

An integer between 0 and 999 representing the milliseconds. If you specify `msValue`, you must also specify `minutesValue` and `secondsValue`.

Return value

Changes the `Date` object in place, and returns its new timestamp. If a parameter is `NaN` (or other values that get coerced to `NaN`, such as `undefined`), the date is set to Invalid Date and `NaN` is returned.

Description

If you do not specify the `secondsValue` and `msValue` parameters, the values returned from `getUTCSeconds()` and `getUTCMilliseconds()` methods are used.

If a parameter you specify is outside of the expected range, `setUTCMinutes()` attempts to update the date information in the `Date` object accordingly. For example, if you use 100 for `secondsValue`, the minutes will be incremented by 1 (`minutesValue + 1`), and 40 will be used for seconds.

Examples

Using setUTCMinutes()

```
const theBigDay = new Date();
theBigDay.setUTCMinutes(43);
```

See also

- `Date.prototype.getUTCMinutes()`
- `Date.prototype.setMinutes()`

Date.prototype.setUTCMonth()

The **`setUTCMonth()`** method of `Date` instances changes the month and/or day of the month for this date according to universal time.

Try it

```
const event = new Date("December 31, 1975 23:15:30 GMT-3:00");

console.log(event.toUTCString());
// Expected output: "Thu, 01 Jan 1976 02:15:30 GMT"

console.log(event.getUTCMonth());
// Expected output: 0

event.setUTCMonth(11);

console.log(event.toUTCString());
// Expected output: "Wed, 01 Dec 1976 02:15:30 GMT"
```

Syntax

```
setUTCMonth(monthValue)
setUTCMonth(monthValue, dateValue)
```

Parameters

`monthValue`

An integer representing the month: 0 for January, 1 for February, and so on.

`dateValue` Optional

An integer from 1 to 31 representing the day of the month.

Return value

Changes the `Date` object in place, and returns its new timestamp. If a parameter is `NaN` (or other values that get coerced to `NaN`, such as `undefined`), the date is set to Invalid Date and `NaN` is returned.

Description

If you do not specify the `dateValue` parameter, the value returned from the `getUTCDate()` method is used.

If a parameter you specify is outside of the expected range, `setUTCMonth()` attempts to update the date information in the `Date` object accordingly. For example, if you use 15 for `monthValue`, the year will be incremented by 1, and 3 will be used for month.

Examples

Using setUTCMonth()

```
const theBigDay = new Date();
theBigDay.setUTCMonth(11);
```

See also

- `Date.prototype.getUTCMonth()`
- `Date.prototype.setMonth()`

Date.prototype.setUTCSeconds()

The **`setUTCSeconds()`** method of `Date` instances changes the seconds and/or milliseconds for this date according to universal time.

Try it

```
const date = new Date("December 31, 1975, 23:15:30 GMT+11:00");

console.log(date.getUTCSeconds());
// Expected output: 30

date.setUTCSeconds(39);

console.log(date.getUTCSeconds());
// Expected output: 39
```

Syntax

```
setUTCSeconds(secondsValue)
setUTCSeconds(secondsValue, msValue)
```

Parameters

`secondsValue`

An integer between 0 and 59 representing the seconds.

`msValue` Optional

An integer between 0 and 999 representing the milliseconds.

Return value

Changes the `Date` object in place, and returns its new timestamp. If a parameter is `NaN` (or other values that get coerced to `NaN`, such as `undefined`), the date is set to Invalid Date and `NaN` is returned.

Description

If you do not specify the `msValue` parameter, the value returned from the `getUTCMilliseconds()` method is used.

If a parameter you specify is outside of the expected range, `setUTCSeconds()` attempts to update the date information in the `Date` object accordingly. For example, if you use 100 for `secondsValue`, the minutes stored in the `Date` object will be incremented by 1, and 40 will be used for seconds.

Examples

Using setUTCSeconds()

```
const theBigDay = new Date();
theBigDay.setUTCSeconds(20);
```

See also

- `Date.prototype.getUTCSeconds()`
- `Date.prototype.setSeconds()`

Date.prototype.setYear()

The **`setYear()`** method of `Date` instances sets the year for a specified date according to local time.

However, the way the legacy `setYear()` method sets year values is different from how the preferred `setFullYear()` method sets year values — and in some cases, also different from how `new Date()` and `Date.parse()` set year values. Specifically, given two-digit numbers, such as `22` and `61`:

- `setYear()` interprets any two-digit number as an offset to `1900`; so `date.setYear(22)` results in the year value being set to `1922`, and `date.setYear(61)` results in the year value being set to `1961`. (In contrast, while `new Date(61, 1)` also results in the year value being set to `1961`, `new Date("2/1/22")` results in the year value being set to `2022`; and similarly for `Date.parse()`).
- `setFullYear()` does no special interpretation but instead uses the literal two-digit value as-is to set the year; so `date.setFullYear(61)` results in the year value being set to `0061`, and `date.setFullYear(22)` results in the year value being set to `0022`.

Because of those differences in behavior, you should no longer use the legacy `setYear()` method, but should instead use the preferred `setFullYear()` method.

Syntax

```
setYear(yearValue)
```

Parameters

`yearValue`

An integer.

Return value

Changes the `Date` object in place, and returns its new timestamp. If `yearValue` is `NaN` (or other values that get coerced to `NaN`, such as `undefined`), the date is set to Invalid Date and `NaN` is returned.

Description

If `yearValue` is a number between 0 and 99 (inclusive), then the year for `dateObj` is set to `1900 + yearValue`. Otherwise, the year for `dateObj` is set to `yearValue`.

Examples

Using setYear()

The first two lines set the year to 1996. The third sets the year to 2000.

```
const theBigDay = new Date();

theBigDay.setYear(96);
theBigDay.setYear(1996);
theBigDay.setYear(2000);
```

- `Date.prototype.setUTCFullYear()`

Date.prototype[Symbol.toPrimitive]()

The **`[Symbol.toPrimitive]()`** method of `Date` instances returns a primitive value representing this date. It may either be a string or a number, depending on the hint given.

Try it

```
// Depending on timezone, your results will vary
const date = new Date("20 December 2019 14:48");

console.log(date[Symbol.toPrimitive]("string"));
// Expected output: "Fri Dec 20 2019 14:48:00 GMT+0530 (India Standard Time)"

console.log(date[Symbol.toPrimitive]("number"));
// Expected output: 1576833480000
```

Syntax

```
date[Symbol.toPrimitive](hint)
```

Parameters

`hint`

A string representing the type of the primitive value to return. The following values are valid:

- `"string"` or `"default"`: The method should return a string.

- `"number"`: The method should return a number.

Return value

If `hint` is `"string"` or `"default"`, this method returns a string by coercing the `this` value to a string (first trying `toString()` then trying `valueOf()`).

If `hint` is `"number"`, this method returns a number by coercing the `this` value to a number (first trying `valueOf()` then trying `toString()`).

Exceptions

`TypeError`

Thrown if the `hint` argument is not one of the three valid values.

Description

The `[Symbol.toPrimitive]()` method is part of the type coercion protocol. JavaScript always calls the `[Symbol.toPrimitive]()` method in priority to convert an object to a primitive value. You rarely need to invoke the `[Symbol.toPrimitive]()` method yourself; JavaScript automatically invokes it when encountering an object where a primitive value is expected.

The `[Symbol.toPrimitive]()` method of the `Date` object returns a primitive value by either invoking `this.valueOf()` and returning a number, or invoking `this.toString()` and returning a string. It exists to override the default primitive coercion process to return a string instead of a number, because primitive coercion, by default, calls `valueOf()` before `toString()`. With the custom `[Symbol.toPrimitive]()`, `new Date(0) + 1` returns `"Thu Jan 01 1970 00:00:00 GMT+0000 (Coordinated Universal Time)1"` (a string) instead of `1` (a number).

Examples

Using [Symbol.toPrimitive]()

```
const d = new Date(0); // 1970-01-01T00:00:00.000Z

d[Symbol.toPrimitive]("string"); // "Thu Jan 01 1970 00:00:00 GMT+0000 (Coordinated Universal Time)"
d[Symbol.toPrimitive]("number"); // 0
d[Symbol.toPrimitive]("default"); // "Thu Jan 01 1970 00:00:00 GMT+0000 (Coordinated Universal Time)"
```

See also

- `Symbol.toPrimitive`

Date.prototype.toDateString()

The **`toDateString()`** method of `Date` instances returns a string representing the date portion of this date interpreted in the local timezone.

Try it

```
const event = new Date(1993, 6, 28, 14, 39, 7);

console.log(event.toString());
// Expected output: "Wed Jul 28 1993 14:39:07 GMT+0200 (CEST)"
// Note: your timezone may vary

console.log(event.toDateString());
// Expected output: "Wed Jul 28 1993"
```

Syntax

```
toDateString()
```

Parameters

None.

Return value

A string representing the date portion of the given date (see description for the format). Returns `"Invalid Date"` if the date is invalid.

Description

`Date` instances refer to a specific point in time. `toDateString()` interprets the date in the local timezone and formats the *date* part in English. It always uses the following format, separated by spaces:

1. First three letters of the week day name
2. First three letters of the month name
3. Two-digit day of the month, padded on the left a zero if necessary
4. Four-digit year (at least), padded on the left with zeros if necessary. May have a negative sign

For example: "Thu Jan 01 1970".

- If you only want to get the *time* part, use `toTimeString()`.
- If you want to get both the date and time, use `toString()`.
- If you want to make the date interpreted as UTC instead of local timezone, use `toUTCString()`.
- If you want to format the date in a more user-friendly format (e.g., localization), use `toLocaleDateString()`.

Examples

Using toDateString()

```
const d = new Date(0);

console.log(d.toString()); // "Thu Jan 01 1970 00:00:00 GMT+0000 (Coordinated Universal Time)"
console.log(d.toDateString()); // "Thu Jan 01 1970"
```

See also

- `Date.prototype.toLocaleDateString()`
- `Date.prototype.toTimeString()`
- `Date.prototype.toString()`

Date.prototype.toISOString()

The **`toISOString()`** method of `Date` instances returns a string representing this date in the date time string format, a *simplified* format based on ISO 8601, which is always 24 or 27 characters long (`YYYY-MM-DDTHH:mm:ss.sssZ` or `±YYYYYY-MM-DDTHH:mm:ss.sssZ`, respectively). The timezone is always UTC, as denoted by the suffix `Z`.

Try it

```
const event = new Date("05 October 2011 14:48 UTC");
console.log(event.toString());
// Expected output: "Wed Oct 05 2011 16:48:00 GMT+0200 (CEST)"
// Note: your timezone may vary

console.log(event.toISOString());
// Expected output: "2011-10-05T14:48:00.000Z"
```

Syntax

```
toISOString()
```

Parameters

None.

Return value

A string representing the given date in the date time string format according to universal time. It's the same format as the one required to be recognized by `Date.parse()`.

Exceptions

`RangeError`

Thrown if the date is invalid or if it corresponds to a year that cannot be represented in the date string format.

Examples

Using toISOString()

```
const d = new Date(0);

console.log(d.toISOString()); // "1970-01-01T00:00:00.000Z"
```

See also

- `Date.prototype.toLocaleDateString()`
- `Date.prototype.toString()`
- `Date.prototype.toUTCString()`

Date.prototype.toJSON()

The **`toJSON()`** method of `Date` instances returns a string representing this date in the same ISO format as `toISOString()`.

Try it

```
const event = new Date("August 19, 1975 23:15:30 UTC");

const jsonDate = event.toJSON();

console.log(jsonDate);
// Expected output: "1975-08-19T23:15:30.000Z"

console.log(new Date(jsonDate).toUTCString());
// Expected output: "Tue, 19 Aug 1975 23:15:30 GMT"
```

Syntax

```
toJSON()
```

Parameters

None.

Return value

A string representing the given date in the date time string format according to universal time, or `null` when the date is invalid. For valid dates, the return value is the same as that of `toISOString()`.

Description

The `toJSON()` method is automatically called by `JSON.stringify()` when a `Date` object is stringified. This method is generally intended to, by default, usefully serialize `Date` objects during JSON serialization, which can then be deserialized using the `Date()` constructor within the reviver of `JSON.parse()`.

The method first attempts to convert its `this` value to a primitive by calling its `[Symbol.toPrimitive]()` (with `"number"` as hint), `valueOf()`, and `toString()` methods, in that order. If the result is a non-finite number, `null` is returned. (This generally corresponds to an invalid date, whose `valueOf()` returns `NaN`.) Otherwise, if the converted primitive is not a number or is a finite number, the return value of `this.toISOString()` is returned.

Note that the method does not check whether the `this` value is a valid `Date` object. However, calling `Date.prototype.toJSON()` on non-`Date` objects fails unless the object's number primitive representation is `NaN`, or the object also has a `toISOString()` method.

Examples

Using toJSON()

```
const jsonDate = new Date(0).toJSON(); // '1970-01-01T00:00:00.000Z'
const backToDate = new Date(jsonDate);

console.log(jsonDate); // 1970-01-01T00:00:00.000Z
```

Serialization round-tripping

When parsing JSON containing date strings, you can use the `Date()` constructor to revive them into the original date objects.

```
const fileData = {
  author: "Maria",
  title: "Date.prototype.toJSON()",
  createdAt: new Date(2019, 3, 15),
  updatedAt: new Date(2020, 6, 26),
};
const response = JSON.stringify(fileData);

// Imagine transmission through network

const data = JSON.parse(response, (key, value) => {
  if (key === "createdAt" || key === "updatedAt") {
    return new Date(value);
  }
  return value;
});

console.log(data);
```

> **Note:** The reviver of `JSON.parse()` must be specific to the payload shape you expect, because the serialization is *irreversible*: it's not possible to distinguish between a string that represents a Date and a normal string.

Date.prototype.toLocaleDateString()

The **`toLocaleDateString()`** method of `Date` instances returns a string with a language-sensitive representation of the date portion of this date in the local timezone. In implementations with `Intl.DateTimeFormat` API support, this method delegates to `Intl.DateTimeFormat`.

Every time `toLocaleDateString` is called, it has to perform a search in a big database of localization strings, which is potentially inefficient. When the method is called many times with the same arguments, it is better to create an `Intl.DateTimeFormat` object and use its `format()` method, because a `DateTimeFormat` object remembers the arguments passed to it and may decide to cache a slice of the database, so future `format` calls can search for localization strings within a more constrained context.

Try it

```
const event = new Date(Date.UTC(2012, 11, 20, 3, 0, 0));
const options = {
  weekday: "long",
  year: "numeric",
  month: "long",
  day: "numeric",
};
```

```
console.log(event.toLocaleDateString("de-DE", options));
// Expected output (varies according to local timezone): Donnerstag, 20. Dezember 2012

console.log(event.toLocaleDateString("ar-EG", options));
// Expected output (varies according to local timezone): الخميس، ٢٠ ديسمبر، ٢٠١٢

console.log(event.toLocaleDateString(undefined, options));
// Expected output (varies according to local timezone and default locale): Thursday, December 20, 2012
```

Syntax

```
toLocaleDateString()
toLocaleDateString(locales)
toLocaleDateString(locales, options)
```

Parameters

The `locales` and `options` parameters customize the behavior of the function and let applications specify the language whose formatting conventions should be used.

In implementations that support the `Intl.DateTimeFormat` API, these parameters correspond exactly to the `Intl.DateTimeFormat()` constructor's parameters. Implementations without `Intl.DateTimeFormat` support are asked to ignore both parameters, making the locale used and the form of the string returned entirely implementation-dependent.

`locales` Optional

> A string with a BCP 47 language tag, or an array of such strings. Corresponds to the `locales` parameter of the `Intl.DateTimeFormat()` constructor.
>
> In implementations without `Intl.DateTimeFormat` support, this parameter is ignored and the host's locale is usually used.

`options` Optional

> An object adjusting the output format. Corresponds to the `options` parameter of the `Intl.DateTimeFormat()` constructor. The `timeStyle` option must be undefined, or a `TypeError` would be thrown. If `weekday`, `year`, `month`, and `day` are all undefined, then `year`, `month`, and `day` will be set to `"numeric"`.
>
> In implementations without `Intl.DateTimeFormat` support, this parameter is ignored.

See the `Intl.DateTimeFormat()` constructor for details on these parameters and how to use them.

Return value

A string representing the date portion of the given date according to language-specific conventions.

In implementations with `Intl.DateTimeFormat`, this is equivalent to `new Intl.DateTimeFormat(locales, options).format(date)`, where `options` has been normalized as described above.

> **Note:** Most of the time, the formatting returned by `toLocaleDateString()` is consistent. However, the output may vary between implementations, even within the same locale — output variations are by design and allowed by the specification. It may also not be what you expect. For example, the string may use non-breaking spaces or be surrounded by bidirectional control characters. You should not compare the results of `toLocaleDateString()` to hardcoded constants.

Examples

Using toLocaleDateString()

Basic use of this method without specifying a `locale` returns a formatted string in the default locale and with default options.

```
const date = new Date(Date.UTC(2012, 11, 12, 3, 0, 0));

// toLocaleDateString() without arguments depends on the implementation,
// the default locale, and the default time zone
console.log(date.toLocaleDateString());
// "12/11/2012" if run in en-US locale with time zone America/Los_Angeles
```

Checking for support for locales and options parameters

The `locales` and `options` parameters may not be supported in all implementations, because support for the internationalization API is optional, and some systems may not have the necessary data. For implementations without internationalization support, `toLocaleDateString()` always uses the system's locale, which may not be what you want. Because any implementation that supports the `locales` and `options` parameters must support the `Intl` API, you can check the existence of the latter for support:

```
function toLocaleDateStringSupportsLocales() {
  return (
    typeof Intl === "object" &&
    !!Intl &&
    typeof Intl.DateTimeFormat === "function"
  );
}
```

Using locales

This example shows some of the variations in localized date formats. In order to get the format of the language used in the user interface of your application, make sure to specify that language (and possibly some fallback languages) using the `locales` argument:

```
const date = new Date(Date.UTC(2012, 11, 20, 3, 0, 0));

// formats below assume the local time zone of the locale;
// America/Los_Angeles for the US

// US English uses month-day-year order
console.log(date.toLocaleDateString("en-US"));
// "12/20/2012"

// British English uses day-month-year order
console.log(date.toLocaleDateString("en-GB"));
// "20/12/2012"

// Korean uses year-month-day order
console.log(date.toLocaleDateString("ko-KR"));
// "2012. 12. 20."

// Event for Persian, It's hard to manually convert date to Solar Hijri
console.log(date.toLocaleDateString("fa-IR"));
// "۱۳۹۱/۹/۳۰"

// Arabic in most Arabic speaking countries uses real Arabic digits
console.log(date.toLocaleDateString("ar-EG"));
// "٢٠١٢/١٢/٢٠"

// for Japanese, applications may want to use the Japanese calendar,
// where 2012 was the year 24 of the Heisei era
console.log(date.toLocaleDateString("ja-JP-u-ca-japanese"));
// "24/12/20"

// when requesting a language that may not be supported, such as
// Balinese, include a fallback language, in this case Indonesian
console.log(date.toLocaleDateString(["ban", "id"]));
// "20/12/2012"
```

Using options

The results provided by `toLocaleDateString()` can be customized using the `options` parameter:

```
const date = new Date(Date.UTC(2012, 11, 20, 3, 0, 0));

// Request a weekday along with a long date
const options = {
  weekday: "long",
  year: "numeric",
  month: "long",
  day: "numeric",
};
console.log(date.toLocaleDateString("de-DE", options));
// "Donnerstag, 20. Dezember 2012"

// An application may want to use UTC and make that visible
options.timeZone = "UTC";
options.timeZoneName = "short";
console.log(date.toLocaleDateString("en-US", options));
// "Thursday, December 20, 2012, UTC"
```

- `Date.prototype.toLocaleTimeString()`
- `Date.prototype.toString()`

Date.prototype.toLocaleString()

The **`toLocaleString()`** method of `Date` instances returns a string with a language-sensitive representation of this date in the local timezone. In implementations with `Intl.DateTimeFormat` API support, this method delegates to `Intl.DateTimeFormat`.

Every time `toLocaleString` is called, it has to perform a search in a big database of localization strings, which is potentially inefficient. When the method is called many times with the same arguments, it is better to create an `Intl.DateTimeFormat` object and use its `format()` method, because a `DateTimeFormat` object remembers the arguments passed to it and may decide to cache a slice of the database, so future `format` calls can search for localization strings within a more constrained context.

Try it

```
const event = new Date(Date.UTC(2012, 11, 20, 3, 0, 0));

// British English uses day-month-year order and 24-hour time without AM/PM
console.log(event.toLocaleString("en-GB", { timeZone: "UTC" }));
// Expected output: "20/12/2012, 03:00:00"

// Korean uses year-month-day order and 12-hour time with AM/PM
```

```
console.log(event.toLocaleString("ko-KR", { timeZone: "UTC" }));
// Expected output: "2012. 12. 20. 오전 3:00:00"
```

Syntax

```
toLocaleString()
toLocaleString(locales)
toLocaleString(locales, options)
```

Parameters

The `locales` and `options` parameters customize the behavior of the function and let applications specify the language whose formatting conventions should be used.

In implementations that support the `Intl.DateTimeFormat` API, these parameters correspond exactly to the `Intl.DateTimeFormat()` constructor's parameters. Implementations without `Intl.DateTimeFormat` support are asked to ignore both parameters, making the locale used and the form of the string returned entirely implementation-dependent.

`locales` Optional

> A string with a BCP 47 language tag, or an array of such strings. Corresponds to the `locales` parameter of the `Intl.DateTimeFormat()` constructor.
>
> In implementations without `Intl.DateTimeFormat` support, this parameter is ignored and the host's locale is usually used.

`options` Optional

> An object adjusting the output format. Corresponds to the `options` parameter of the `Intl.DateTimeFormat()` constructor. If `weekday`, `year`, `month`, `day`, `dayPeriod`, `hour`, `minute`, `second`, and `fractionalSecondDigits` are all undefined, then `year`, `month`, `day`, `hour`, `minute`, `second` will be set to `"numeric"`.
>
> In implementations without `Intl.DateTimeFormat` support, this parameter is ignored.

See the `Intl.DateTimeFormat()` constructor for details on these parameters and how to use them.

Return value

A string representing the given date according to language-specific conventions.

In implementations with `Intl.DateTimeFormat`, this is equivalent to `new Intl.DateTimeFormat(locales, options).format(date)`.

> **Note:** Most of the time, the formatting returned by `toLocaleString()` is consistent. However, the output may vary between implementations, even within the same locale — output variations are by design and allowed by the specification. It may also not be what you expect. For example, the string may use non-breaking spaces or be surrounded by bidirectional control characters. You should not compare the results of `toLocaleString()` to hardcoded constants.

Examples

Using toLocaleString()

Basic use of this method – without specifying `locale` or `options` – depends on the implementation and returns a string formatted based on the default locale and time zone, and with default options.

```
const date = new Date(Date.UTC(2012, 11, 12, 3, 0, 0));

console.log(date.toLocaleString());
// "12/11/2012, 7:00:00 PM" if run in en-US locale with time zone America/Los_Angeles
```

Checking for support for locales and options parameters

The `locales` and `options` parameters may not be supported in all implementations, because support for the internationalization API is optional, and some systems may not have the necessary data. For implementations without internationalization support, `toLocaleString()` always uses the system's locale, which may not be what you want. Because any implementation that supports the `locales` and `options` parameters must support the `Intl` API, you can check the existence of the latter for support:

```
function toLocaleStringSupportsLocales() {
  return (
    typeof Intl === "object" &&
    !!Intl &&
    typeof Intl.DateTimeFormat === "function"
  );
}
```

Using locales

This example shows some of the variations in localized date and time formats. In order to get the format of the language used in the user interface of your application, make sure to specify that language (and possibly some fallback languages) using the `locales` argument:

```
const date = new Date(Date.UTC(2012, 1, 2, 3, 0, 0));

// Formats below assume the local time zone of the locale;
// America/Los_Angeles for the US

// US English uses month-day-year order and 12-hour time with AM/PM
console.log(date.toLocaleString("en-US"));
```

```
// "2/1/2012, 7:00:00 PM" (UTC-8 is the previous day)

// British English uses day-month-year order and 24-hour time without AM/PM
console.log(date.toLocaleString("en-GB"));
// "02/02/2012, 03:00:00" (UTC+0 or UTC+1 depending on time of the year)

// Korean uses year-month-day order and 12-hour time with AM/PM
console.log(date.toLocaleString("ko-KR"));
// "2012. 2. 2. 오후 12:00:00"

// Arabic in most Arabic-speaking countries uses Eastern Arabic numerals
console.log(date.toLocaleString("ar-EG"));
// "٢/٢/٢٠١٢ ٥:٠٠:٠٠ ص"

// For Japanese, applications may want to use the Japanese calendar,
// where 2012 was the year 24 of the Heisei era
console.log(date.toLocaleString("ja-JP-u-ca-japanese"));
// "H24/2/2 12:00:00"

// When requesting a language that may not be supported, such as
// Balinese, include a fallback language (in this case, Indonesian)
console.log(date.toLocaleString(["ban", "id"]));
// "2/2/2012 11.00.00"
```

Using options

The results provided by `toLocaleString()` can be customized using the `options` parameter:

```
const date = new Date(Date.UTC(2012, 11, 20, 3, 0, 0));

// Request a weekday along with a long date
const options = {
  weekday: "long",
  year: "numeric",
  month: "long",
  day: "numeric",
};
console.log(date.toLocaleString("de-DE", options));
// Example output: "Donnerstag, 20. Dezember 2012"
// The exact date may shift depending on your local time zone.

// An application may want to use UTC and make that visible
options.timeZone = "UTC";
options.timeZoneName = "short";
console.log(date.toLocaleString("en-US", options));
// Example output: "Thursday, December 20, 2012 at UTC"

// Sometimes even the US needs 24-hour time
console.log(date.toLocaleString("en-US", { hour12: false }));
// Example output: "12/19/2012, 19:00:00"
// The exact date and time may shift depending on your local time zone.
```

Date.prototype.toLocaleTimeString()

The **`toLocaleTimeString()`** method of `Date` instances returns a string with a language-sensitive representation of the time portion of this date in the local timezone. In implementations with `Intl.DateTimeFormat` API support, this method delegates to `Intl.DateTimeFormat`.

Every time `toLocaleTimeString` is called, it has to perform a search in a big database of localization strings, which is potentially inefficient. When the method is called many times with the same arguments, it is better to create an `Intl.DateTimeFormat` object and use its `format()` method, because a `DateTimeFormat` object remembers the arguments passed to it and may decide to cache a slice of the database, so future `format` calls can search for localization strings within a more constrained context.

Try it

```
// Depending on timezone, your results will vary
const event = new Date("August 19, 1975 23:15:30 GMT+00:00");

console.log(event.toLocaleTimeString("en-US"));
// Expected output: "1:15:30 AM"

console.log(event.toLocaleTimeString("it-IT"));
// Expected output: "01:15:30"

console.log(event.toLocaleTimeString("ar-EG"));
// Expected output: "١:١٥:٣٠ ص"
```

Syntax

```
toLocaleTimeString()
toLocaleTimeString(locales)
toLocaleTimeString(locales, options)
```

Parameters

The `locales` and `options` parameters customize the behavior of the function and let applications specify the language whose formatting conventions should be used.

In implementations that support the `Intl.DateTimeFormat` API, these parameters correspond exactly to the `Intl.DateTimeFormat()` constructor's parameters. Implementations without `Intl.DateTimeFormat` support are asked to ignore both parameters, making the locale used and the form of the string returned entirely implementation-dependent.

`locales` Optional

> A string with a BCP 47 language tag, or an array of such strings. Corresponds to the `locales` parameter of the `Intl.DateTimeFormat()` constructor.
>
> In implementations without `Intl.DateTimeFormat` support, this parameter is ignored and the host's locale is usually used.

`options` Optional

> An object adjusting the output format. Corresponds to the `options` parameter of the `Intl.DateTimeFormat()` constructor. If `dayPeriod`, `hour`, `minute`, `second`, and `fractionalSecondDigits` are all undefined, then `hour`, `minute`, `second` will be set to `"numeric"`.
>
> In implementations without `Intl.DateTimeFormat` support, this parameter is ignored.

See the `Intl.DateTimeFormat()` constructor for details on these parameters and how to use them.

Return value

A string representing the time portion of the given date according to language-specific conventions.

In implementations with `Intl.DateTimeFormat`, this is equivalent to `new Intl.DateTimeFormat(locales, options).format(date)`, where `options` has been normalized as described above.

> **Note:** Most of the time, the formatting returned by `toLocaleTimeString()` is consistent. However, the output may vary between implementations, even within the same locale — output variations are by design and allowed by the specification. It may also not be what you expect. For example, the string may use non-breaking spaces or be surrounded by bidirectional control characters. You should not compare the results of `toLocaleTimeString()` to hardcoded constants.

Examples

Using toLocaleTimeString()

Basic use of this method without specifying a `locale` returns a formatted string in the default locale and with default options.

```
const date = new Date(Date.UTC(2012, 11, 12, 3, 0, 0));

// toLocaleTimeString() without arguments depends on the implementation,
// the default locale, and the default time zone
console.log(date.toLocaleTimeString());
// "7:00:00 PM" if run in en-US locale with time zone America/Los_Angeles
```

Checking for support for locales and options parameters

The `locales` and `options` parameters may not be supported in all implementations, because support for the internationalization API is optional, and some systems may not have the necessary data. For implementations without internationalization support, `toLocaleTimeString()` always uses the system's locale, which may not be what you want. Because any implementation that supports the `locales` and `options` parameters must support the `Intl` API, you can check the existence of the latter for support:

```
function toLocaleTimeStringSupportsLocales() {
  return (
    typeof Intl === "object" &&
    !!Intl &&
    typeof Intl.DateTimeFormat === "function"
  );
}
```

Using locales

This example shows some of the variations in localized time formats. In order to get the format of the language used in the user interface of your application, make sure to specify that language (and possibly some fallback languages) using the `locales` argument:

```
const date = new Date(Date.UTC(2012, 11, 20, 3, 0, 0));

// formats below assume the local time zone of the locale;
// America/Los_Angeles for the US

// US English uses 12-hour time with AM/PM
console.log(date.toLocaleTimeString("en-US"));
// "7:00:00 PM"
```

```
// British English uses 24-hour time without AM/PM
console.log(date.toLocaleTimeString("en-GB"));
// "03:00:00"

// Korean uses 12-hour time with AM/PM
console.log(date.toLocaleTimeString("ko-KR"));
// "오후 12:00:00"

// Arabic in most Arabic speaking countries uses real Arabic digits
console.log(date.toLocaleTimeString("ar-EG"));
// "٩ ٧:٠٠:٠٠"

// when requesting a language that may not be supported, such as
// Balinese, include a fallback language, in this case Indonesian
console.log(date.toLocaleTimeString(["ban", "id"]));
// "11.00.00"
```

Using options

The results provided by `toLocaleTimeString()` can be customized using the `options` parameter:

```
const date = new Date(Date.UTC(2012, 11, 20, 3, 0, 0));

// An application may want to use UTC and make that visible
const options = { timeZone: "UTC", timeZoneName: "short" };
console.log(date.toLocaleTimeString("en-US", options));
// "3:00:00 AM GMT"

// Sometimes even the US needs 24-hour time
console.log(date.toLocaleTimeString("en-US", { hour12: false }));
// "19:00:00"

// Show only hours and minutes, use options with the default locale - use an empty array
console.log(
  date.toLocaleTimeString([], { hour: "2-digit", minute: "2-digit" }),
);
// "20:01"
```

- `Date.prototype.toString()`

Date.prototype.toString()

The **`toString()`** method of `Date` instances returns a string representing this date interpreted in the local timezone.

Try it

```
const event = new Date("August 19, 1975 23:15:30");

console.log(event.toString());
// Expected output: "Tue Aug 19 1975 23:15:30 GMT+0200 (CEST)"
// Note: your timezone may vary
```

Syntax

```
toString()
```

Parameters

None.

Return value

A string representing the given date (see description for the format). Returns `"Invalid Date"` if the date is invalid.

Description

The `toString()` method is part of the type coercion protocol. Because `Date` has a `[Symbol.toPrimitive]()` method, that method always takes priority over `toString()` when a `Date` object is implicitly coerced to a string. However, `Date.prototype[Symbol.toPrimitive]()` still calls `this.toString()` internally.

The `Date` object overrides the `toString()` method of `Object`. `Date.prototype.toString()` returns a string representation of the Date as interpreted in the local timezone, containing both the date and the time — it joins the string representation specified in `toDateString()` and `toTimeString()` together, adding a space in between. For example: "Thu Jan 01 1970 00:00:00 GMT+0000 (Coordinated Universal Time)".

`Date.prototype.toString()` must be called on `Date` instances. If the `this` value does not inherit from `Date.prototype`, a `TypeError` is thrown.

- If you only want to get the *date* part, use `toDateString()`.
- If you only want to get the *time* part, use `toTimeString()`.

- If you want to make the date interpreted as UTC instead of local timezone, use `toUTCString()`.
- If you want to format the date in a more user-friendly format (e.g., localization), use `toLocaleString()`.

Examples

Using toString()

```
const d = new Date(0);
console.log(d.toString()); // "Thu Jan 01 1970 00:00:00 GMT+0000 (Coordinated Universal Time)"
```

See also

Date.prototype.toTemporalInstant()

The **`toTemporalInstant()`** method of `Date` instances returns a new `Temporal.Instant` object with the same `epochMilliseconds` value as this date's timestamp.

Use this method to convert legacy `Date` values to the `Temporal` API, then further convert it to other `Temporal` classes as necessary.

Syntax

```
toTemporalInstant()
```

Parameters

None.

Return value

A new `Temporal.Instant` object with the same `epochMilliseconds` value as this date's timestamp. Its microsecond and nanosecond components are always `0`.

Exceptions

`RangeError`

Thrown if the date is invalid (it has a timestamp of `NaN`).

Examples

Using toTemporalInstant()

```
const legacyDate = new Date("2021-07-01T12:34:56.789Z");
const instant = legacyDate.toTemporalInstant();

// Further convert it to other objects
const zdt = instant.toZonedDateTimeISO("UTC");
const date = zdt.toPlainDate();
console.log(date.toString()); // 2021-07-01
```

See also

- `Temporal.Instant`
- `Temporal.ZonedDateTime`
- `Temporal.Instant.fromEpochMilliseconds()`

Date.prototype.toTimeString()

The **`toTimeString()`** method of `Date` instances returns a string representing the time portion of this date interpreted in the local timezone.

Try it

```
const event = new Date("August 19, 1975 23:15:30");

console.log(event.toTimeString());
// Expected output: "23:15:30 GMT+0200 (CEST)"
// Note: your timezone may vary
```

Syntax

```
toTimeString()
```

Parameters

None.

Return value

A string representing the time portion of the given date (see description for the format). Returns `"Invalid Date"` if the date is invalid.

Description

`Date` instances refer to a specific point in time. `toTimeString()` interprets the date in the local timezone and formats the *time* part in English. It always uses the format of `HH:mm:ss GMT±xxxx (TZ)`, where:

Format String	Description
`HH`	Hour, as two digits with leading zero if required
`mm`	Minute, as two digits with leading zero if required
`ss`	Seconds, as two digits with leading zero if required
`±xxxx`	The local timezone's offset — two digits for hours and two digits for minutes (e.g., `-0500`, `+0800`)
`TZ`	The timezone's name (e.g., `PDT`, `PST`)

For example: "04:42:04 GMT+0000 (Coordinated Universal Time)".

- If you only want to get the *date* part, use `toDateString()`.
- If you want to get both the date and time, use `toString()`.
- If you want to make the date interpreted as UTC instead of local timezone, use `toUTCString()`.
- If you want to format the date in a more user-friendly format (e.g., localization), use `toLocaleTimeString()`.

Examples

Using toTimeString()

```
const d = new Date(0);

console.log(d.toString()); // "Thu Jan 01 1970 00:00:00 GMT+0000 (Coordinated Universal Time)"
console.log(d.toTimeString()); // "00:00:00 GMT+0000 (Coordinated Universal Time)"
```

See also

- `Date.prototype.toLocaleTimeString()`
- `Date.prototype.toDateString()`
- `Date.prototype.toString()`

Date.prototype.toUTCString()

The **`toUTCString()`** method of `Date` instances returns a string representing this date in the RFC 7231 format, with negative years allowed. The timezone is always UTC. `toGMTString()` is an alias of this method.

Try it

```
const event = new Date("14 Jun 2017 00:00:00 PDT");

console.log(event.toUTCString());
// Expected output: "Wed, 14 Jun 2017 07:00:00 GMT"
```

Syntax

```
toUTCString()
```

Parameters

None.

Return value

A string representing the given date using the UTC time zone (see description for the format). Returns `"Invalid Date"` if the date is invalid.

Description

The value returned by `toUTCString()` is a string in the form `Www, dd Mmm yyyy HH:mm:ss GMT`, where:

Format String	Description
`Www`	Day of week, as three letters (e.g., `Sun`, `Mon`)
`dd`	Day of month, as two digits with leading zero if required
`Mmm`	Month, as three letters (e.g., `Jan`, `Feb`)
`yyyy`	Year, as four or more digits with leading zeroes if required
`HH`	Hour, as two digits with leading zero if required
`mm`	Minute, as two digits with leading zero if required
`ss`	Seconds, as two digits with leading zero if required

Aliasing

JavaScript's `Date` API was inspired by Java's `java.util.Date` library (while the latter had become de facto legacy since Java 1.1 in 1997). In particular, the Java `Date` class had a method called `toGMTString` — which was poorly named, because the Greenwich Mean Time is not equivalent to the Coordinated Universal Time, while JavaScript

dates always operate by UTC time. For web compatibility reasons, `toGMTString` remains as an alias to `toUTCString`, and they refer to the exact same function object. This means:

```
Date.prototype.toGMTString.name === "toUTCString";
```

Examples

Using toUTCString()

```
const d = new Date(0);
console.log(d.toUTCString()); // 'Thu, 01 Jan 1970 00:00:00 GMT'
```

See also

- `Date.prototype.toLocaleString()`
- `Date.prototype.toString()`
- `Date.prototype.toISOString()`

Date.UTC()

The **`Date.UTC()`** static method accepts parameters representing the date and time components similar to the `Date` constructor, but treats them as UTC. It returns the number of milliseconds since January 1, 1970, 00:00:00 UTC.

Try it

```
const utcDate1 = new Date(Date.UTC(96, 1, 2, 3, 4, 5));
const utcDate2 = new Date(Date.UTC(0, 0, 0, 0, 0, 0));

console.log(utcDate1.toUTCString());
// Expected output: "Fri, 02 Feb 1996 03:04:05 GMT"

console.log(utcDate2.toUTCString());
// Expected output: "Sun, 31 Dec 1899 00:00:00 GMT"
```

Syntax

```
Date.UTC(year)
Date.UTC(year, monthIndex)
Date.UTC(year, monthIndex, day)
Date.UTC(year, monthIndex, day, hours)
Date.UTC(year, monthIndex, day, hours, minutes)
Date.UTC(year, monthIndex, day, hours, minutes, seconds)
Date.UTC(year, monthIndex, day, hours, minutes, seconds, milliseconds)
```

Parameters

`year`

Integer value representing the year. Values from `0` to `99` map to the years `1900` to `1999`. All other values are the actual year. See the example.

`monthIndex` Optional

Integer value representing the month, beginning with `0` for January to `11` for December. Defaults to `0`.

`day` Optional

Integer value representing the day of the month. Defaults to `1`.

`hours` Optional

Integer value between `0` and `23` representing the hour of the day. Defaults to `0`.

`minutes` Optional

Integer value representing the minute segment of a time. Defaults to `0`.

`seconds` Optional

Integer value representing the second segment of a time. Defaults to `0`.

`milliseconds` Optional

Integer value representing the millisecond segment of a time. Defaults to `0`.

Return value

A number representing the timestamp of the given date. Returns `NaN` if the date is invalid.

Description

Years between `0` and `99` are converted to a year in the 20th century `(1900 + year)`. For example, `95` is converted to the year `1995`.

The `UTC()` method differs from the `Date()` constructor in three ways:

1. `Date.UTC()` uses universal time instead of the local time.
2. `Date.UTC()` returns a time value as a number instead of creating a `Date` object.
3. When passed a single number, `Date.UTC()` interprets it as a year instead of a timestamp.

If a parameter is outside of the expected range, the `UTC()` method updates the other parameters to accommodate the value. For example, if `15` is used for `monthIndex`, the year will be incremented by 1 (`year + 1`) and `3` will be used for the month.

Because `UTC()` is a static method of `Date`, you always use it as `Date.UTC()`, rather than as a method of a `Date` object you created.

Examples

Using Date.UTC()

The following statement creates a `Date` object with the arguments treated as UTC instead of local:

```
const utcDate = new Date(Date.UTC(2018, 11, 1, 0, 0, 0));
```

Behavior of Date.UTC() with one argument

`Date.UTC()` when passed one argument used to have inconsistent behavior, because implementations only kept the behavior consistent with the `Date()` constructor, which does not interpret a single argument as the year number. Implementations are now required to treat omitted `monthIndex` as `0`, instead of coercing it to `NaN`.

```
Date.UTC(2017); // 1483228800000
```

See also

- `Date.parse()`
- `Date`

Date.prototype.valueOf()

The **`valueOf()`** method of `Date` instances returns the number of milliseconds for this date since the epoch, which is defined as the midnight at the beginning of January 1, 1970, UTC.

Try it

```
const date1 = new Date(Date.UTC(96, 1, 2, 3, 4, 5));

console.log(date1.valueOf());
// Expected output: 823230245000

const date2 = new Date("02 Feb 1996 03:04:05 GMT");

console.log(date2.valueOf());
// Expected output: 823230245000
```

Syntax

```
valueOf()
```

Parameters

None.

Return value

A number representing the timestamp, in milliseconds, of this date. Returns `NaN` if the date is invalid.

Description

The `valueOf()` method is part of the type coercion protocol. Because `Date` has a `[Symbol.toPrimitive]()` method, that method always takes priority over `valueOf()` when a `Date` object is implicitly coerced to a number. However, `Date.prototype[Symbol.toPrimitive]()` still calls `this.valueOf()` internally.

The `Date` object overrides the `valueOf()` method of `Object`. `Date.prototype.valueOf()` returns the timestamp of the date, which is functionally equivalent to the `Date.prototype.getTime()` method.

Examples

Using valueOf()

```
const d = new Date(0); // 1970-01-01T00:00:00.000Z
console.log(d.valueOf()); // 0
```

See also

- `Object.prototype.valueOf()`
- `Date.prototype.getTime()`

decodeURI()

The **`decodeURI()`** function decodes a Uniform Resource Identifier (URI) previously created by `encodeURI()` or a similar routine.

Try it

```
const uri = "https://mozilla.org/?x=шеллы";
const encoded = encodeURI(uri);
console.log(encoded);
// Expected output: "https://mozilla.org/?x=%D1%88%D0%B5%D0%BB%D0%BB%D1%8B"

try {
  console.log(decodeURI(encoded));
  // Expected output: "https://mozilla.org/?x=шеллы"
} catch (e) {
  // Catches a malformed URI
  console.error(e);
}
```

Syntax

```
decodeURI(encodedURI)
```

Parameters

`encodedURI`

A complete, encoded Uniform Resource Identifier.

Return value

A new string representing the unencoded version of the given encoded Uniform Resource Identifier (URI).

Exceptions

`URIError`

Thrown if `encodedURI` contains a `%` not followed by two hexadecimal digits, or if the escape sequence does not encode a valid UTF-8 character.

Description

`decodeURI()` is a function property of the global object.

The `decodeURI()` function decodes the URI by treating each escape sequence in the form `%XX` as one UTF-8 code unit (one byte). In UTF-8, the number of leading 1 bits in the first byte, which may be 0 (for 1-byte ASCII characters), 2, 3, or 4, indicates the number of bytes in the character. So by reading the first escape sequence, `decodeURI()` can determine how many more escape sequences to consume. If `decodeURI()` fails to find the expected number of sequences, or if the escape sequences don't encode a valid UTF-8 character, a `URIError` is thrown.

`decodeURI()` decodes all escape sequences, but if the escape sequence encodes one of the following characters, the escape sequence is preserved in the output string (because they are part of the URI syntax):

```
; / ? : @ & = + $ , #
```

Examples

Decoding a Cyrillic URL

```
decodeURI(
  "https://developer.mozilla.org/ru/docs/JavaScript_%D1%88%D0%B5%D0%BB%D0%BB%D1%8B",
);
// "https://developer.mozilla.org/ru/docs/JavaScript_шеллы"
```

decodeURI() vs. decodeURIComponent()

`decodeURI()` assumes the input is a full URI, so it does not decode characters that are part of the URI syntax.

```
decodeURI(
  "https://developer.mozilla.org/docs/JavaScript%3A%20a_scripting_language",
);
// "https://developer.mozilla.org/docs/JavaScript%3A a_scripting_language"

decodeURIComponent(
  "https://developer.mozilla.org/docs/JavaScript%3A%20a_scripting_language",
);
// "https://developer.mozilla.org/docs/JavaScript: a_scripting_language"
```

Catching errors

```
try {
  const a = decodeURI("%E0%A4%A");
} catch (e) {
  console.error(e);
}

// URIError: malformed URI sequence
```

See also

- `decodeURIComponent()`
- `encodeURI()`
- `encodeURIComponent()`

decodeURIComponent()

The **`decodeURIComponent()`** function decodes a Uniform Resource Identifier (URI) component previously created by `encodeURIComponent()` or by a similar routine.

Try it

```
function containsEncodedComponents(x) {
  // ie ?,=,&,/ etc
  return decodeURI(x) !== decodeURIComponent(x);
}

console.log(containsEncodedComponents("%3Fx%3Dtest")); // ?x=test
// Expected output: true

console.log(containsEncodedComponents("%D1%88%D0%B5%D0%BB%D0%BB%D1%8B")); // шеллы
// Expected output: false
```

Syntax

```
decodeURIComponent(encodedURI)
```

Parameters

`encodedURI`

An encoded component of a Uniform Resource Identifier.

Return value

A new string representing the decoded version of the given encoded Uniform Resource Identifier (URI) component.

Exceptions

`URIError`

Thrown if `encodedURI` contains a `%` not followed by two hexadecimal digits, or if the escape sequence does not encode a valid UTF-8 character.

Description

`decodeURIComponent()` is a function property of the global object.

`decodeURIComponent()` uses the same decoding algorithm as described in `decodeURI()`. It decodes *all* escape sequences, including those that are not created by `encodeURIComponent`, like `-.!~*'()`.

Examples

Decoding a Cyrillic URL component

```
decodeURIComponent("JavaScript_%D1%88%D0%B5%D0%BB%D0%BB%D1%8B");
// "JavaScript_шеллы"
```

Catching errors

```
try {
  const a = decodeURIComponent("%E0%A4%A");
} catch (e) {
  console.error(e);
}

// URIError: malformed URI sequence
```

Decoding query parameters from a URL

`decodeURIComponent()` cannot be used directly to parse query parameters from a URL. It needs a bit of preparation.

```
function decodeQueryParam(p) {
  return decodeURIComponent(p.replace(/\+/g, " "));
}

decodeQueryParam("search+query%20%28correct%29");
// 'search query (correct)'
```

See also

- `decodeURI`
- `encodeURI`

- `encodeURIComponent`

DisposableStack

The **`DisposableStack`** object represents a stack of disposers to run when the stack itself is disposed. Disposer functions are executed in reverse order of registration, with strong error handling guarantees. Calling its `move()` method will transfer responsibility for calling the current registered disposers to a new `DisposableStack` and prevent registering any additional disposers.

Description

A `DisposableStack` is not exactly a "stack" in terms of its interface. It has several methods for pushing disposers to it, but it has no way to pop one disposer off. Rather, *all* disposers are popped and executed one-by-one when the stack is disposed.

You register disposable resources to the `DisposableStack` using its `use()`, `adopt()`, or `defer()` methods.

```
using disposer = new DisposableStack();
const reader = disposer.use(stream.getReader());
```

Then, when the `disposer` goes out of scope, all resources registered to it are disposed in reverse order of registration, unless they have been moved out with `move()`.

It is good practice to *not* extract the resource acquisition expression to a separate statement, no matter how long the expression is. You should always wrap the `use()` or `adopt()` call around the resource acquisition expression to ensure that the resource is registered to the stack immediately.

```
using disposer = new DisposableStack();
const reader = stream.getReader();
disposer.use(reader);
```

Functionally, these two code snippets are equivalent. However, the first one is less error-prone because the resource is declared and registered in a single line. If someone puts more code between the second and third lines of the second snippet, an error could occur, causing the resource to leak.

Constructor

`DisposableStack()`

Creates a new `DisposableStack` object.

Instance properties

These properties are defined on `DisposableStack.prototype` and shared by all `DisposableStack` instances.

`DisposableStack.prototype.constructor`

The constructor function that created the instance object. For `DisposableStack` instances, the initial value is the `DisposableStack` constructor.

`DisposableStack.prototype.disposed`

Read-only. Returns `true` if the `DisposableStack` has been disposed, or `false` if not.

`DisposableStack.prototype[Symbol.toStringTag]`

The initial value of the `[Symbol.toStringTag]` property is the string `"DisposableStack"`. This property is used in `Object.prototype.toString()`.

Instance methods

`DisposableStack.prototype.adopt()`

Registers a value that doesn't implement the disposable protocol to the stack by providing a custom disposer function.

`DisposableStack.prototype.defer()`

Takes a callback function to be called when the stack is disposed.

`DisposableStack.prototype.dispose()`

Disposes this stack by calling all disposers registered to it in reverse order of registration.

`DisposableStack.prototype.move()`

Creates a new `DisposableStack` instance that contains the same disposers as this stack, and then marks this stack as disposed, without calling any disposers.

`DisposableStack.prototype.use()`

Registers a value that implements the disposable protocol to the stack.

`DisposableStack.prototype[Symbol.dispose]`

An alias for the `dispose()` method.

See also

- Polyfill of `DisposableStack` in `core-js`
- JavaScript resource management
- `Symbol.dispose`
- `using`

- `AsyncDisposableStack`

DisposableStack.prototype.adopt()

The **`adopt()`** method of `DisposableStack` instances registers a value that doesn't implement the disposable protocol to the stack by providing a custom disposer function.

Syntax

```
adopt(value, onDispose)
```

Parameters

`value`

Any value to be registered to the stack.

`onDispose`

A function that will be called when the stack is disposed. The function receives `value` as its only argument.

Return value

The same `value` that was passed in.

Exceptions

`TypeError`

Thrown if `onDispose` is not a function.

`ReferenceError`

Thrown if the stack is already disposed.

Description

The primary purpose of `adopt()` is to register a value that doesn't implement the disposable protocol to the stack. If the value is already disposable, you can use `use()` instead, which automatically uses the value's `[Symbol.dispose]()` method as the disposer.

`adopt(value, onDispose)` is almost the same as `defer(() => onDispose(value))`, but it allows you to declare the resource and register it on the same line. This way, there's minimal chance of an error happening between the resource creation and registration, which will cause the resource to leak.

```
using disposer = new DisposableStack();
const reader = disposer.adopt(stream.getReader(), (reader) =>
  reader.releaseLock(),
);
```

```
using disposer = new DisposableStack();
const reader = stream.getReader();
// If someone adds code in between these lines and an error occurs,
// the stream will be locked forever.
disposer.defer(() => reader.close());
```

In the same spirit of "make your resource registered as soon as it's declared", you should always wrap your resource acquisition expression in `adopt()`, instead of extracting it to a separate statement.

```
using disposer = new DisposableStack();
const reader = stream.getReader();
disposer.adopt(reader, (reader) => reader.close());
```

Examples

Using adopt()

This code consumes a `ReadableStream` via a `ReadableStreamDefaultReader`. The reader does not implement the disposable protocol, so we use `adopt()` to register it to the stack.

```
{
  using disposer = new DisposableStack();
  const reader = disposer.adopt(stream.getReader(), (reader) =>
    reader.releaseLock(),
  );
  const { value, done } = reader.read();
  if (!done) {
    // Process the value
  }
  // The reader.releaseLock() method is called here before exiting
}
```

See also

- JavaScript resource management
- `DisposableStack`
- `DisposableStack.prototype.defer()`
- `DisposableStack.prototype.use()`

DisposableStack.prototype.defer()

The **`defer()`** method of `DisposableStack` instances takes a callback function to be called when the stack is disposed.

Syntax

```
defer(onDispose)
```

Parameters

`onDispose`

A function that will be called when the stack is disposed. The function receives no arguments.

Return value

None (`undefined`).

Exceptions

`TypeError`

Thrown if `onDispose` is not a function.

`ReferenceError`

Thrown if the stack is already disposed.

Description

The primary purpose of `defer()` is to register a cleanup callback that's not specific to the disposal of a particular resource. If the callback is specific to a resource, you should use `use()` or `adopt()` instead. You can also use `defer` when the resource is not claimed within your code:

```
function consumeReader(reader) {
  using disposer = new DisposableStack();
  disposer.defer(() => reader.releaseLock());
  // Do something with reader
}
```

Examples

Using defer()

This function sets a simple lock to prevent multiple async operations from running at the same time. The lock is released when the function completes.

```
let isLocked = false;

async function requestWithLock(url, options) {
  if (isLocked) {
    return undefined;
  }
  using disposer = new DisposableStack();
  isLocked = true;
  disposer.defer(() => (isLocked = false));
  const data = await fetch(url, options).then((res) => res.json());
  return data;
}
```

See also

- `DisposableStack`
- `DisposableStack.prototype.adopt()`
- `DisposableStack.prototype.use()`

DisposableStack() constructor

The **`DisposableStack()`** constructor creates `DisposableStack` objects.

Syntax

```
new DisposableStack()
```

> **Note:** `DisposableStack()` can only be constructed with `new`. Attempting to call it without `new` throws a `TypeError`.

Parameters

None.

Return value

A new `DisposableStack` object.

Examples

Creating a DisposableStack

```
const disposer = new DisposableStack();
disposer.defer(() => console.log("Disposed!"));
disposer.dispose();
// Logs: Disposed!
```

See also

- JavaScript resource management

DisposableStack.prototype.dispose()

The **`dispose()`** method of `DisposableStack` instances disposes this stack by calling all disposers registered to it in reverse order of registration. If the stack is already disposed, this method does nothing.

It performs the same action as `using disposer = new DisposableStack()` at scope exit. It can be used if you need to clean up at a point other than scope exit.

Syntax

```
dispose()
```

Parameters

None.

Return value

None (`undefined`).

Exceptions

`SuppressedError`

> Thrown if multiple disposers in the stack threw an error. If only one error is thrown, it is rethrown as-is. Otherwise, for each additional error, a new `SuppressedError` is created, with the original error as the `suppressed` property, and the new error as the `error` property.

Examples

Disposing a stack

Here we push three disposers to the stack, using the `use()`, `adopt()`, and `defer()` methods. When `dispose()` is called, the disposers are called in reverse order of registration.

Note that usually you don't need to call `dispose()` manually. Declare the stack with `using`, and its `[Symbol.dispose]()` method will be automatically called when the stack goes out of scope.

```
class Resource {
  dispose() {
    console.log("Resource disposed");
  }
  [Symbol.dispose]() {
    console.log("Resource disposed via Symbol.dispose");
  }
}

{
  const disposer = new DisposableStack();
  const resource = disposer.use(new Resource());
  const resource2 = disposer.adopt(new Resource(), (resource) =>
    resource.dispose(),
  );
  disposer.defer(() => console.log("Deferred disposer"));
  disposer.dispose();
  // Logs in order:
  // Deferred disposer
  // Resource disposed
  // Resource disposed via Symbol.dispose
}
```

- `DisposableStack.prototype.defer()`
- `DisposableStack.prototype.use()`
- `DisposableStack.prototype[Symbol.dispose]()`

DisposableStack.prototype.disposed

The **`disposed`** accessor property of `DisposableStack` instances returns a boolean indicating whether or not this `DisposableStack` has been disposed or moved by doing any of the following:

- Calling its `dispose()` method
- Calling its `move()` method
- Declaring it with `using` and letting the variable go out of scope, which automatically calls the `[Symbol.dispose]()` method.

Examples

Checking if a stack is disposed

```
const disposer = new DisposableStack();
console.log(disposer.disposed); // false
disposer.dispose();
console.log(disposer.disposed); // true
```

See also

- JavaScript resource management

DisposableStack.prototype.move()

The **`move()`** method of `DisposableStack` instances creates a new `DisposableStack` instance that contains the same disposers as this stack, and then marks this stack as disposed, without calling any disposers.

Syntax

```
move()
```

Parameters

None.

Return value

A new `DisposableStack` instance.

Exceptions

`ReferenceError`

Thrown if the stack is already disposed.

Description

The primary purpose of `move()` is to enable transferring responsibility for disposal out of the current scope. For example, your function can claim ownership of some resources and dispose them if an error occurs; if everything completes successfully, then you return these resources and transfer ownership to the caller.

When using `move()` to transfer ownership, calling `move()` should be the very last step in your control flow, because there will be no owner in between your code dropping ownership via `move()` and the caller picking up ownership from the return value.

```
let resource1;

function init() {
  using disposer = new DisposableStack();
  resource1 = disposer.use(getResource1());
  // ...
  // Drop ownership immediately before returning
  return disposer.move();
}

// Pick up ownership immediately after returning
using disposer = init();
```

```
let resource1;

function init() {
  using disposer = new DisposableStack();
  resource1 = disposer.use(getResource1());
  // ...
  const newDisposer = disposer.move();
  // If someone adds code in between these lines and an error occurs,
  // there would be no owner to free resource1
  return newDisposer;
}

using disposer = init();
```

Also be cautious with the following pattern, although using the "good" pattern may be very awkward in many cases:

```
function init() {
  using disposer = new DisposableStack();
  const resource1 = disposer.use(getResource1());
  // ...
  return { disposer: disposer.move(), resource1 };
}

const { resource1, ...rest } = init();
// If someone adds code in between these lines and an error occurs,
// there would be no owner to free resource1
using disposer = rest.disposer;
```

`move()` can also be used for conditional disposal in cases where you may sometimes not want to dispose the resources at all. For example:

```
using disposer = new DisposableStack();
const server = disposer.use(makeServer());
await server.init();
if (server.ready) {
  // Successfully initialized server; it now should live through the rest
  // of the program. Drop its disposer and don't pick it up. It will no
  // longer be disposed at all.
  disposer.move();
}
// If we reach the end of the scope without running disposer.move(),
// then server isn't ready for any reason, and we dispose its resources
// by disposing the disposer.
```

Examples

Claiming ownership of a stack

```
function consumeStack(stack) {
  using newStack = stack.move(); // newStack now owns the disposers
  console.log(stack.disposed); // true
  console.log(newStack.disposed); // false
  // newStack is disposed here immediately before the function exits
}

const stack = new DisposableStack();
console.log(stack.disposed); // false
consumeStack(stack);
console.log(stack.disposed); // true
```

Allowing resources to be disposed within two code paths

The major use case of `move()` is when you have one or more resources which could either be disposed right here or could be persisted for later use. In this case, you can put the resources in a `DisposableStack` and then call `move()` when you need to persist the resources for later usage.

```
class PluginHost {
  #disposed = false;
  #disposables;
  #channel;
  #socket;

  constructor() {
    // Create a DisposableStack that is disposed when the constructor exits.
    // If construction succeeds, we move everything out of `disposer` and into
    // `#disposables` to be disposed later.
    using disposer = new DisposableStack();

    // Create an IPC adapter around process.send/process.on("message").
    // When disposed, it unsubscribes from process.on("message").
    this.#channel = disposer.use(new NodeProcessIpcChannelAdapter(process));

    // Create a pseudo-websocket that sends and receives messages over
    // a NodeJS IPC channel.
    this.#socket = disposer.use(new NodePluginHostIpcSocket(this.#channel));

    // If we made it here, then there were no errors during construction and
    // we can safely move the disposables out of `disposer` and into `#disposables`.
    this.#disposables = disposer.move();

    // If construction failed, then `disposer` would be disposed before reaching
    // the line above. Event handlers would be removed, allowing `#channel` and
    // `#socket` to be GC'd.
  }

  [Symbol.dispose]() {
    if (this.#disposed) {
      return;
    }
    this.#disposed = true;
```

```
    // Put `this.#disposables` into a `using` variable, so it is automatically
    // disposed when the function exits.
    using disposables = this.#disposables;

    // NOTE: we can free `#socket` and `#channel` here since they will be
    // disposed by the call to `disposables[Symbol.dispose]()`, below.
    // This isn't strictly a requirement for every disposable, but is
    // good housekeeping since these objects will no longer be useable.
    this.#socket = undefined;
    this.#channel = undefined;
    this.#disposables = undefined;
  }
}
```

- `DisposableStack`
- `DisposableStack.prototype.dispose()`

DisposableStack.prototype[Symbol.dispose]()

The **`[Symbol.dispose]()`** method of `DisposableStack` instances implements the *disposable protocol* and allows it to be disposed when used with `using` or `await using`. It is an alias for the `dispose()` method.

Syntax

```
disposableStack[Symbol.dispose]()
```

Parameters

None.

Return value

None (`undefined`).

Examples

Declaring a stack with <code>using</code>

The `Symbol.dispose` method is intended to be automatically called in a `using` declaration.

```
{
  using disposer = new DisposableStack();
  const resource = disposer.use(new Resource());
  resource.doSomething();
  // stack is disposed here immediately before the function exits
  // which causes the resource to be disposed
}
```

See also

- JavaScript resource management
- `DisposableStack`
- `DisposableStack.prototype.dispose()`

DisposableStack.prototype.use()

The **`use()`** method of `DisposableStack` instances registers a value that implements the disposable protocol to the stack.

Syntax

```
use(value)
```

Parameters

`value`

The value to register to the stack. Must either contain a `[Symbol.dispose]()` method, or be `null` or `undefined`.

Return value

The same `value` that was passed in.

Exceptions

`TypeError`

Thrown if `value` is not `null` or `undefined`, and does not contain a `[Symbol.dispose]()` method.

`ReferenceError`

Thrown if the stack is already disposed.

Description

The primary purpose of `use()` is to register a value that implements the disposable protocol to the stack, as the equivalent of the `using` declaration. If the value does not implement the disposable protocol (it doesn't have the `[Symbol.dispose]()` method), use `adopt()` instead, passing a callback that calls the resource's cleanup method.

You should make your resource registered as soon as it's declared. This means you should always wrap your resource acquisition expression in `use()`, instead of extracting it to a separate statement.

```
using disposer = new DisposableStack();
const reader = stream.getReader();
disposer.use(reader);
```

Examples

Using use()

This code consumes a `ReadableStream` via a `ReadableStreamDefaultReader`. The reader is automatically closed when the function completes, assuming it implements a `[Symbol.dispose]()` method that synchronously releases the lock on the stream.

```
{
  using disposer = new DisposableStack();
  const reader = disposer.use(stream.getReader());
  const { value, done } = reader.read();
  if (!done) {
    // Process the value
  }
  // The reader.releaseLock() method is called here before exiting
}
```

encodeURI()

The **`encodeURI()`** function encodes a URI by replacing each instance of certain characters by one, two, three, or four escape sequences representing the UTF-8 encoding of the character (will only be four escape sequences for characters composed of two surrogate characters). Compared to `encodeURIComponent()`, this function encodes fewer characters, preserving those that are part of the URI syntax.

Try it

```
const uri = "https://mozilla.org/?x=шеллы";
const encoded = encodeURI(uri);
console.log(encoded);
// Expected output: "https://mozilla.org/?x=%D1%88%D0%B5%D0%BB%D0%BB%D1%8B"

try {
  console.log(decodeURI(encoded));
  // Expected output: "https://mozilla.org/?x=шеллы"
} catch (e) {
  // Catches a malformed URI
  console.error(e);
}
```

Syntax

```
encodeURI(uri)
```

Parameters

`uri`

A string to be encoded as a URI.

Return value

A new string representing the provided string encoded as a URI.

Exceptions

`URIError`

Thrown if `uri` contains a lone surrogate.

Description

`encodeURI()` is a function property of the global object.

The `encodeURI()` function escapes characters by UTF-8 code units, with each octet encoded in the format `%xx`, left-padded with 0 if necessary. Because lone surrogates in UTF-16 do not encode any valid Unicode character, they cause `encodeURI()` to throw a `URIError`.

`encodeURI()` escapes all characters **except**:

```
A–Z a–z 0–9 - _ . ! ~ * ' ( )

; / ? : @ & = + $ , #
```

The characters on the second line are characters that may be part of the URI syntax, and are only escaped by `encodeURIComponent()`. Both `encodeURI()` and `encodeURIComponent()` do not encode the characters `-.!~*'()`, known as "unreserved marks", which do not have a reserved purpose but are allowed in a URI "as is". (See RFC2396)

The `encodeURI()` function does not encode characters that have special meaning (reserved characters) for a URI. The following example shows all the parts that a URI can possibly contain. Note how certain characters are used to signify special meaning:

```
http://username:password@www.example.com:80/path/to/file.php?foo=316&bar=this+has+spaces#anchor
```

`encodeURI`, as the name implies, is used to encode a URL as a whole, assuming it is already well-formed. If you want to dynamically assemble string values into a URL, you probably want to use `encodeURIComponent()` on each dynamic segment instead, to avoid URL syntax characters in unwanted places.

```
const name = "Ben & Jerry's";

// This is bad:
const badLink = encodeURI(`https://example.com/?choice=${name}`); // "https://example.com/?choice=Ben%20&%20Jerry's"
console.log([...new URL(badLink).searchParams]); // [['choice', 'Ben '], [" Jerry's", '']]

// Instead:
const goodLink = `https://example.com/?choice=${encodeURIComponent(name)}`;
// "https://example.com/?choice=Ben%20%26%20Jerry's"
console.log([...new URL(goodLink).searchParams]); // [['choice', "Ben & Jerry's"]]
```

Examples

encodeURI() vs. encodeURIComponent()

`encodeURI()` differs from `encodeURIComponent()` as follows:

```
const set1 = ";/?:@&=+$,#"; // Reserved Characters
const set2 = "-.!~*'()"; // Unreserved Marks
const set3 = "ABC abc 123"; // Alphanumeric Characters + Space

console.log(encodeURI(set1)); // ;/?:@&=+$,#
console.log(encodeURI(set2)); // -.!~*'()
console.log(encodeURI(set3)); // ABC%20abc%20123 (the space gets encoded as %20)

console.log(encodeURIComponent(set1)); // %3B%2C%2F%3F%3A%40%26%3D%2B%24%23
console.log(encodeURIComponent(set2)); // -.!~*'()
console.log(encodeURIComponent(set3)); // ABC%20abc%20123 (the space gets encoded as %20)
```

Encoding a lone surrogate throws

A `URIError` will be thrown if one attempts to encode a surrogate which is not part of a high-low pair. For example:

```
// High-low pair OK
encodeURI("\uD800\uDFFF"); // "%F0%90%8F%BF"

// Lone high-surrogate code unit throws "URIError: malformed URI sequence"
encodeURI("\uD800");

// Lone low-surrogate code unit throws "URIError: malformed URI sequence"
encodeURI("\uDFFF");
```

You can use `String.prototype.toWellFormed()`, which replaces lone surrogates with the Unicode replacement character (U+FFFD), to avoid this error. You can also use `String.prototype.isWellFormed()` to check if a string contains lone surrogates before passing it to `encodeURI()`.

Encoding for RFC3986

The more recent RFC3986 makes square brackets reserved (for IPv6) and thus not encoded when forming something which could be part of a URL (such as a host). It also reserves !, ', (,), and *, even though these characters have no formalized URI delimiting uses. The following function encodes a string for RFC3986-compliant URL format.

```
function encodeRFC3986URI(str) {
  return encodeURI(str)
    .replace(/%5B/g, "[")
    .replace(/%5D/g, "]")
    .replace(
      /[!'()*]/g,
      (c) => `%${c.charCodeAt(0).toString(16).toUpperCase()}`,
```

```
    );
}
```

See also

- `decodeURI()`
- `encodeURIComponent()`
- `decodeURIComponent()`

encodeURIComponent()

The **`encodeURIComponent()`** function encodes a URI by replacing each instance of certain characters by one, two, three, or four escape sequences representing the UTF-8 encoding of the character (will only be four escape sequences for characters composed of two surrogate characters). Compared to `encodeURI()`, this function encodes more characters, including those that are part of the URI syntax.

Try it

```
// Encodes characters such as ?,=,/,&,:
console.log(`?x=${encodeURIComponent("test?")}`);
// Expected output: "?x=test%3F"

console.log(`?x=${encodeURIComponent("шеллы")}`);
// Expected output: "?x=%D1%88%D0%B5%D0%BB%D0%BB%D1%8B"
```

Syntax

```
encodeURIComponent(uriComponent)
```

Parameters

`uriComponent`

A string to be encoded as a URI component (a path, query string, fragment, etc.). Other values are converted to strings.

Return value

A new string representing the provided `uriComponent` encoded as a URI component.

Exceptions

`URIError`

Thrown if `uriComponent` contains a lone surrogate.

Description

`encodeURIComponent()` is a function property of the global object.

`encodeURIComponent()` uses the same encoding algorithm as described in `encodeURI()`. It escapes all characters **except**:

```
A–Z a–z 0–9 - _ . ! ~ * ' ( )
```

Compared to `encodeURI()`, `encodeURIComponent()` escapes a larger set of characters. Use `encodeURIComponent()` on user-entered fields from forms sent to the server — this will encode `&` symbols that may inadvertently be generated during data entry for character references or other characters that require encoding/decoding. For example, if a user writes `Jack & Jill`, without `encodeURIComponent()`, the ampersand could be interpreted on the server as the start of a new field and jeopardize the integrity of the data.

For `application/x-www-form-urlencoded`, spaces are to be replaced by `+`, so one may wish to follow an `encodeURIComponent()` replacement with an additional replacement of `%20` with `+`.

Examples

Encoding for Content-Disposition and Link headers

The following example provides the special encoding required within UTF-8 `Content-Disposition` and `Link` server response header parameters (e.g., UTF-8 filenames):

```
const fileName = "my file(2).txt";
const header = `Content-Disposition: attachment; filename*=UTF-8''${encodeRFC5987ValueChars(
  fileName,
)}`;

console.log(header);
// "Content-Disposition: attachment; filename*=UTF-8''my%20file%282%29.txt"

function encodeRFC5987ValueChars(str) {
  return (
    encodeURIComponent(str)
      // The following creates the sequences %27 %28 %29 %2A (Note that
      // the valid encoding of "*" is %2A, which necessitates calling
      // toUpperCase() to properly encode). Although RFC3986 reserves "!",
      // RFC5987 does not, so we do not need to escape it.
      .replace(
```

```
        /['()*]/g,
        (c) => `%${c.charCodeAt(0).toString(16).toUpperCase()}`,
      )
      // The following are not required for percent-encoding per RFC5987,
      // so we can allow for a little better readability over the wire: |`^
      .replace(/%(7C|60|5E)/g, (str, hex) =>
        String.fromCharCode(parseInt(hex, 16)),
      )
  );
}
```

Encoding for RFC3986

The more recent RFC3986 reserves `!`, `'`, `(`, `)`, and `*`, even though these characters have no formalized URI delimiting uses. The following function encodes a string for RFC3986-compliant URL component format. It also encodes `[` and `]`, which are part of the IPv6 URI syntax. An RFC3986-compliant `encodeURI` implementation should not escape them, which is demonstrated in the `encodeURI()` example.

```
function encodeRFC3986URIComponent(str) {
  return encodeURIComponent(str).replace(
    /[!'()*]/g,
    (c) => `%${c.charCodeAt(0).toString(16).toUpperCase()}`,
  );
}
```

Encoding a lone surrogate throws

A `URIError` will be thrown if one attempts to encode a surrogate which is not part of a high-low pair. For example:

```
// High-low pair OK
encodeURIComponent("\uD800\uDFFF"); // "%F0%90%8F%BF"

// Lone high-surrogate code unit throws "URIError: malformed URI sequence"
encodeURIComponent("\uD800");

// Lone high-surrogate code unit throws "URIError: malformed URI sequence"
encodeURIComponent("\uDFFF");
```

You can use `String.prototype.toWellFormed()`, which replaces lone surrogates with the Unicode replacement character (U+FFFD), to avoid this error. You can also use `String.prototype.isWellFormed()` to check if a string contains lone surrogates before passing it to `encodeURIComponent()`.

- `encodeURI()`
- `decodeURIComponent()`

Error

`Error` objects are thrown when runtime errors occur. The `Error` object can also be used as a base object for user-defined exceptions. See below for standard built-in error types.

Description

Runtime errors result in new `Error` objects being created and thrown.

`Error` is a serializable object, so it can be cloned with `structuredClone()` or copied between Workers using `postMessage()`.

Error types

Besides the generic `Error` constructor, there are other core error constructors in JavaScript. For client-side exceptions, see Exception handling statements.

`EvalError`

: Creates an instance representing an error that occurs regarding the global function `eval()`.

`RangeError`

: Creates an instance representing an error that occurs when a numeric variable or parameter is outside its valid range.

`ReferenceError`

: Creates an instance representing an error that occurs when de-referencing an invalid reference.

`SyntaxError`

: Creates an instance representing a syntax error.

`TypeError`

: Creates an instance representing an error that occurs when a variable or parameter is not of a valid type.

`URIError`

: Creates an instance representing an error that occurs when `encodeURI()` or `decodeURI()` are passed invalid parameters.

`AggregateError`

Creates an instance representing several errors wrapped in a single error when multiple errors need to be reported by an operation, for example by `Promise.any()`.

`InternalError`

Creates an instance representing an error that occurs when an internal error in the JavaScript engine is thrown. E.g. "too much recursion".

Constructor

`Error()`

Creates a new `Error` object.

Static properties

`Error.stackTraceLimit`

A non-standard numerical property that limits how many stack frames to include in an error stack trace.

Static methods

`Error.captureStackTrace()`

A non-standard function that creates the `stack` property on the provided object.

`Error.isError()`

Returns `true` if the argument is an error, or `false` otherwise.

`Error.prepareStackTrace()` Optional

A non-standard function that, if provided by user code, is called by the JavaScript engine for thrown exceptions, allowing the user to provide custom formatting for stack traces. See the V8 Stack Trace API docs.

Instance properties

These properties are defined on `Error.prototype` and shared by all `Error` instances.

`Error.prototype.constructor`

The constructor function that created the instance object. For `Error` instances, the initial value is the `Error` constructor.

`Error.prototype.name`

Represents the name for the type of error. For `Error.prototype.name`, the initial value is `"Error"`. Subclasses like `TypeError` and `SyntaxError` provide their own `name` properties.

`Error.prototype.stack`

A non-standard property for a stack trace.

These properties are own properties of each `Error` instance.

`cause`

Error cause indicating the reason why the current error is thrown — usually another caught error. For user-created `Error` objects, this is the value provided as the `cause` property of the constructor's second argument.

`columnNumber`

A non-standard Mozilla property for the column number in the line that raised this error.

`fileName`

A non-standard Mozilla property for the path to the file that raised this error.

`lineNumber`

A non-standard Mozilla property for the line number in the file that raised this error.

`message`

Error message. For user-created `Error` objects, this is the string provided as the constructor's first argument.

Instance methods

`Error.prototype.toString()`

Returns a string representing the specified object. Overrides the `Object.prototype.toString()` method.

Examples

Throwing a generic error

Usually you create an `Error` object with the intention of raising it using the `throw` keyword. You can handle the error using the `try...catch` construct:

```
try {
  throw new Error("Whoops!");
} catch (e) {
  console.error(`${e.name}: ${e.message}`);
}
```

Handling a specific error type

You can choose to handle only specific error types by testing the error type with the `instanceof` keyword:

```
try {
  foo.bar();
} catch (e) {
  if (e instanceof EvalError) {
    console.error(`${e.name}: ${e.message}`);
  } else if (e instanceof RangeError) {
    console.error(`${e.name}: ${e.message}`);
  }
  // etc.
  else {
    // If none of our cases matched leave the Error unhandled
    throw e;
  }
}
```

Differentiate between similar errors

Sometimes a block of code can fail for reasons that require different handling, but which throw very similar errors (i.e., with the same type and message).

If you don't have control over the original errors that are thrown, one option is to catch them and throw new `Error` objects that have more specific messages. The original error should be passed to the new `Error` in the constructor's `options` parameter as its `cause` property. This ensures that the original error and stack trace are available to higher-level try/catch blocks.

The example below shows this for two methods that would otherwise fail with similar errors (`doFailSomeWay()` and `doFailAnotherWay()`):

```
function doWork() {
  try {
    doFailSomeWay();
  } catch (err) {
    throw new Error("Failed in some way", { cause: err });
  }
  try {
    doFailAnotherWay();
  } catch (err) {
    throw new Error("Failed in another way", { cause: err });
  }
}

try {
  doWork();
} catch (err) {
  switch (err.message) {
    case "Failed in some way":
      handleFailSomeWay(err.cause);
      break;
    case "Failed in another way":
      handleFailAnotherWay(err.cause);
      break;
  }
}
```

> **Note:** If you are making a library, you should prefer to use error cause to discriminate between different errors emitted — rather than asking your consumers to parse the error message. See the error cause page for an example.

Custom error types can also use the `cause` property, provided the subclasses' constructor passes the `options` parameter when calling `super()`. The `Error()` base class constructor will read `options.cause` and define the `cause` property on the new error instance.

```
class MyError extends Error {
  constructor(message, options) {
    // Need to pass `options` as the second parameter to install the "cause" property.
    super(message, options);
  }
}

console.log(new MyError("test", { cause: new Error("cause") }).cause);
// Error: cause
```

Custom error types

You might want to define your own error types deriving from `Error` to be able to `throw new MyError()` and use `instanceof MyError` to check the kind of error in the exception handler. This results in cleaner and more consistent error handling code.

See "What's a good way to extend Error in JavaScript?" on Stack Overflow for an in-depth discussion.

> **Warning:** Builtin subclassing cannot be reliably transpiled to pre-ES6 code, because there's no way to construct the base class with a particular `new.target` without `Reflect.construct()`. You need additional configuration or manually call `Object.setPrototypeOf(this, CustomError.prototype)` at the end of the constructor; otherwise, the constructed instance will not be a `CustomError` instance. See the TypeScript FAQ for more information.

> **Note:** Some browsers include the `CustomError` constructor in the stack trace when using ES2015 classes.

```
class CustomError extends Error {
  constructor(foo = "bar", ...params) {
    // Pass remaining arguments (including vendor specific ones) to parent constructor
    super(...params);

    // Maintains proper stack trace for where our error was thrown (non-standard)
    if (Error.captureStackTrace) {
      Error.captureStackTrace(this, CustomError);
    }

    this.name = "CustomError";
    // Custom debugging information
    this.foo = foo;
    this.date = new Date();
  }
}

try {
  throw new CustomError("baz", "bazMessage");
} catch (e) {
  console.error(e.name); // CustomError
  console.error(e.foo); // baz
  console.error(e.message); // bazMessage
  console.error(e.stack); // stack trace
}
```

Error.captureStackTrace()

The **`Error.captureStackTrace()`** static method installs stack trace information on a provided object as the `stack` property.

Syntax

```
Error.captureStackTrace(object)
Error.captureStackTrace(object, constructor)
```

Parameters

`object`

The object on which to add the `stack` property.

`constructor` Optional

A function, typically the constructor where the `object` was created. When collecting the stack trace, all frames above the topmost call to this function, including that call, are left out of the stack trace.

Return value

None (`undefined`).

The `object` is modified in-place with an extra own property called `stack` defined, whose string value follows the same format as `Error.prototype.stack`. This property is non-enumerable and configurable. In V8, it is a getter-setter pair. In SpiderMonkey and JavaScriptCore, it is a data property that is writable.

Examples

Using Error.captureStackTrace()

The `getStack()` utility function returns the current stack trace at the point it is called, removing itself from the stack. This serves the same debugging purpose as `console.trace()`, but allows you to output the string elsewhere. Note that it does not construct an `Error` instance for this purpose, but installs `stack` on a plain object,

which would be more efficient for our purposes. Normally, you would call `Error.captureStackTrace` on objects intended to be thrown as errors, as shown in the next example.

```
function getStack() {
  const obj = {};
  if ("captureStackTrace" in Error) {
    // Avoid getStack itself in the stack trace
    Error.captureStackTrace(obj, getStack);
  }
  return obj.stack;
}

function foo() {
  console.log(getStack());
}

foo();
// Error
//     at foo (<anonymous>:8:15)
//     at <anonymous>:11:1
```

Installing stack trace on a custom error object

The main use case for `Error.captureStackTrace()` is to install a stack trace on a custom error object. Typically, you define custom errors by extending the `Error` class, which automatically makes the `stack` property available via inheritance. However, the problem with the default stack trace is that it includes the constructor call itself, which leaks implementation details. You can avoid this by using `Error.captureStackTrace()`, which allows the stack trace to be installed even for custom errors that do not inherit from `Error`.

```
class MyError extends Error {
  constructor(message, options) {
    super(message, options);
    if ("captureStackTrace" in Error) {
      // Avoid MyError itself in the stack trace
      Error.captureStackTrace(this, MyError);
    }
  }
}

const myError = new MyError("Something went wrong");
console.log(myError.stack);
// Error: Something went wrong
//     at <anonymous>:8:17
```

Note that even if you don't call `Error.captureStackTrace()` here, some engines are still smart enough to avoid `MyError` in the stack trace if the constructor inherits from `Error`. Calling `Error.captureStackTrace()` is more important for custom errors that, for some reason, do not inherit from `Error`.

```
class MyError {
  constructor(message) {
    this.message = message;
    if ("captureStackTrace" in Error) {
      // Avoid MyError itself in the stack trace
      Error.captureStackTrace(this, MyError);
    }
  }
}

const myError = new MyError("Something went wrong");
console.log(myError.stack);
// Error: Something went wrong
//     at <anonymous>:8:17
```

Error: cause

The **`cause`** data property of an `Error` instance indicates the specific original cause of the error.

It is used when catching and re-throwing an error with a more-specific or useful error message in order to still have access to the original error.

Value

The value that was passed to the `Error()` constructor in the `options.cause` argument. It may not be present.

Property attributes of `Error: cause`	
Writable	yes
Enumerable	no
Configurable	yes

Description

The value of `cause` can be of any type. You should not make assumptions that the error you caught has an `Error` as its `cause`, in the same way that you cannot be sure the variable bound in the `catch` statement is an `Error` either. The "Providing structured data as the error cause" example below shows a case where a non-error is deliberately provided as the cause.

The `SuppressedError` and `AggregateError` subclasses both serve the purpose of associating multiple errors. They both represent multiple failing sites: `SuppressedError` represents an error that occurred while handling another error, while `AggregateError` represents a collection of multiple, unrelated errors that occurred during the same operation. The `cause` property represents a single failing site, with the wrapper error only adding context to the cause and not representing an additional failure.

The following is typical usage of `cause`. There is a single failing site, which originates within `mainLogic()`. The `throw new Error()` statement merely wraps that original error to add context and does not constitute an additional failure.

```
try {
  mainLogic();
} catch (err) {
  throw new Error("Main logic failed", { cause: err });
}
```

The following is typical usage of `SuppressedError`. There are two failing sites: one within `mainLogic()` and one within `cleanup()`. The `SuppressedError` instance associates the two errors.

```
try {
  mainLogic();
} catch (primaryError) {
  try {
    cleanup();
  } catch (cleanupError) {
    throw new SuppressedError(
      cleanupError,
      primaryError,
      "Main logic failed; while handling that, cleanup also failed",
    );
  }
}
```

The following is typical usage of `AggregateError`. There are multiple failing sites within `mainLogic()`. The `AggregateError` instance associates all the errors.

```
function mainLogic() {
  const errors = [];
  try {
    operation1();
  } catch (e1) {
    errors.push(e1);
  }
  try {
    operation2();
  } catch (e2) {
    errors.push(e2);
  }
  if (errors.length > 0) {
    throw new AggregateError(errors, "Multiple operations failed");
  }
}
```

Examples

Rethrowing an error with a cause

It is sometimes useful to catch an error and re-throw it with a new message. In this case you should pass the original error into the constructor for the new `Error`, as shown.

```
try {
  connectToDatabase();
} catch (err) {
  throw new Error("Connecting to database failed.", { cause: err });
}
```

For a more detailed example see Error > Differentiate between similar errors.

Providing structured data as the error cause

Error messages written for human consumption may be inappropriate for machine parsing — since they're subject to rewording or punctuation changes that may break any existing parsing written to consume them. So when throwing an error from a function, as an alternative to a human-readable error message, you can instead provide the cause as structured data, for machine parsing.

```
function makeRSA(p, q) {
  if (!Number.isInteger(p) || !Number.isInteger(q)) {
    throw new Error("RSA key generation requires integer inputs.", {
      cause: { code: "NonInteger", values: [p, q] },
    });
  }
```

```
  if (!areCoprime(p, q)) {
    throw new Error("RSA key generation requires two co-prime integers.", {
      cause: { code: "NonCoprime", values: [p, q] },
    });
  }
  // rsa algorithm…
}
```

Error: columnNumber

> **Non-standard:** This feature is not standardized. We do not recommend using non-standard features in production, as they have limited browser support, and may change or be removed. However, they can be a suitable alternative in specific cases where no standard option exists.

The **`columnNumber`** data property of an `Error` instance contains the column number in the line of the file that raised this error.

Value

A positive integer.

Property attributes of `Error: columnNumber`	
Writable	yes
Enumerable	no
Configurable	yes

Examples

Using columnNumber

```
try {
  throw new Error("Could not parse input");
} catch (err) {
  console.log(err.columnNumber); // 9
}
```

Specifications

Not part of any standard.

See also

- `Error.prototype.stack`
- `Error.prototype.lineNumber`
- `Error.prototype.fileName`

Error() constructor

The **`Error()`** constructor creates `Error` objects.

Syntax

```
new Error()
new Error(message)
new Error(message, options)
new Error(message, fileName)
new Error(message, fileName, lineNumber)

Error()
Error(message)
Error(message, options)
Error(message, fileName)
Error(message, fileName, lineNumber)
```

> **Note:** `Error()` can be called with or without `new`. Both create a new `Error` instance.

Parameters

`message` Optional

A human-readable description of the error.

`options` Optional

An object that has the following properties:

`cause` Optional

A value indicating the specific cause of the error, reflected in the `cause` property. When catching and re-throwing an error with a more-specific or useful error message, this property can be used to pass the original error.

`fileName` Optional

The path to the file that raised this error, reflected in the `fileName` property. Defaults to the name of the file containing the code that called the `Error()` constructor.

`lineNumber` Optional

The line number within the file on which the error was raised, reflected in the `lineNumber` property. Defaults to the line number containing the `Error()` constructor invocation.

Examples

Function call or new construction

When `Error` is used like a function, that is without `new`, it will return an `Error` object. Therefore, a mere call to `Error` will produce the same output that constructing an `Error` object via the `new` keyword would.

```
const x = Error("I was created using a function call!");

// above has the same functionality as following
const y = new Error('I was constructed via the "new" keyword!');
```

Rethrowing an error with a cause

It is sometimes useful to catch an error and re-throw it with a new message. In this case you should pass the original error into the constructor for the new `Error`, as shown.

```
try {
  frameworkThatCanThrow();
} catch (err) {
  throw new Error("New error message", { cause: err });
}
```

For a more detailed example see Error > Differentiate between similar errors.

Omitting options argument

JavaScript only tries to read `options.cause` if `options` is an object — this avoids ambiguity with the other non-standard `Error(message, fileName, lineNumber)` signature, which requires the second parameter to be a string. If you omit `options`, pass a primitive value as `options`, or pass an object without the `cause` property, then the created `Error` object will have no `cause` property.

```
// Omitting options
const error1 = new Error("Error message");
console.log("cause" in error1); // false

// Passing a primitive value
const error2 = new Error("Error message", "");
console.log("cause" in error2); // false

// Passing an object without a cause property
const error3 = new Error("Error message", { details: "http error" });
console.log("cause" in error3); // false
```

Error: fileName

> **Non-standard:** This feature is not standardized. We do not recommend using non-standard features in production, as they have limited browser support, and may change or be removed. However, they can be a suitable alternative in specific cases where no standard option exists.

The **`fileName`** data property of an `Error` instance contains the path to the file that raised this error.

Value

A string.

Property attributes of `Error: fileName`	
Writable	yes

Property attributes of `Error: fileName`	
Enumerable	no
Configurable	yes

Description

This non-standard property contains the path to the file that raised this error. If called from a debugger context, the Firefox Developer Tools for example, "debugger eval code" is returned.

Examples

Using fileName

```
const e = new Error("Could not parse input");
throw e;
// e.fileName could look like "file:///C:/example.html"
```

Specifications

Not part of any standard.

See also

- `Error.prototype.stack`
- `Error.prototype.columnNumber`
- `Error.prototype.lineNumber`

Error.isError()

The **`Error.isError()`** static method determines whether the passed value is an `Error`.

Syntax

```
Error.isError(value)
```

Parameters

`value`

The value to be checked.

Return value

`true` if `value` is an `Error`; otherwise, `false`.

Description

`Error.isError()` checks if the passed value is an `Error`. It does so by performing a *branded check* for a private field initialized by the `Error()` constructor. This is the same mechanism used by `Array.isArray()`, which is in turn similar to the mechanism used by the `in` operator.

It is a more robust alternative to `instanceof Error` because it avoids false positives and false negatives:

- `Error.isError()` rejects values that aren't actual `Error` instances, even if they have `Error.prototype` in their prototype chain — `instanceof Error` would accept these as it does check the prototype chain.
- `Error.isError()` accepts `Error` objects constructed in another realm — `instanceof Error` returns `false` for these because the identity of the `Error` constructor is different across realms.

`Error.isError()` returns `true` for `DOMException` instances. This is because, although `DOMException` is not specified as a real subclass of `Error` (the `Error` constructor is not the prototype of the `DOMException` constructor), `DOMException` still behaves like `Error` for all branded checking purposes.

Examples

Using Error.isError()

```
// all following calls return true
Error.isError(new Error());
Error.isError(new TypeError());
Error.isError(new DOMException());
try {
  1 + 1n;
} catch (e) {
  console.log(Error.isError(e)); // The operation threw a TypeError, so this returns true
}

// all following calls return false
Error.isError();
Error.isError({});
Error.isError(null);
Error.isError(undefined);
Error.isError(17);
Error.isError("Error");
Error.isError(true);
```

```
Error.isError(false);
// This is not an error, because the object does not have the private field
// initialized by the Error constructor
Error.isError({ __proto__: Error.prototype });
```

instanceof vs. Error.isError()

When checking for `Error` instance, `Error.isError()` is preferred over `instanceof` because it works across realms.

```
const iframe = document.createElement("iframe");
document.body.appendChild(iframe);
const xError = window.frames[window.frames.length - 1].Error;
const error = new xError();

// Correctly checking for Error
Error.isError(error); // true
// The prototype of error is xError.prototype, which is a
// different object from Error.prototype
error instanceof Error; // false
```

Normalizing caught errors

You can use `Error.isError()` to detect if the caught value is an error and normalize it to an error object.

```
try {
  throw "Oops; this is not an Error object";
} catch (e) {
  if (!Error.isError(e)) {
    e = new Error(e);
  }
  console.error(e.message);
}
```

- Polyfill of `Error.isError` in `core-js`
- es-shims polyfill of `Error.isError`
- `Error`

Error: lineNumber

> **Non-standard:** This feature is not standardized. We do not recommend using non-standard features in production, as they have limited browser support, and may change or be removed. However, they can be a suitable alternative in specific cases where no standard option exists.

The **`lineNumber`** data property of an `Error` instance contains the line number in the file that raised this error.

Value

A positive integer.

Property attributes of `Error: lineNumber`	
Writable	yes
Enumerable	no
Configurable	yes

Examples

Using lineNumber

```
try {
  throw new Error("Could not parse input");
} catch (err) {
  console.log(err.lineNumber); // 2
}
```

Alternative example using error event

```
window.addEventListener("error", (e) => {
  console.log(e.lineNumber); // 5
});
const e = new Error("Could not parse input");
throw e;
```

This is not a standard feature and lacks widespread support. See the browser compatibility table below.

Specifications

Not part of any standard.

See also

- `Error.prototype.stack`
- `Error.prototype.columnNumber`
- `Error.prototype.fileName`

Error: message

The **`message`** data property of an `Error` instance is a human-readable description of the error.

Value

A string corresponding to the value passed to the `Error()` constructor as the first argument.

Property attributes of `Error: message`	
Writable	yes
Enumerable	no
Configurable	yes

Description

This property contains a brief description of the error if one is available or has been set. The `message` property combined with the `name` property is used by the `Error.prototype.toString()` method to create a string representation of the Error.

By default, the `message` property is an empty string, but this behavior can be overridden for an instance by specifying a message as the first argument to the `Error` constructor.

Examples

Throwing a custom error

```
const e = new Error("Could not parse input");
// e.message is 'Could not parse input'
throw e;
```

See also

- `Error.prototype.name`
- `Error.prototype.toString()`

Error.prototype.name

The **`name`** data property of `Error.prototype` is shared by all `Error` instances. It represents the name for the type of error. For `Error.prototype.name`, the initial value is `"Error"`. Subclasses like `TypeError` and `SyntaxError` provide their own `name` properties.

Value

A string. For `Error.prototype.name`, the initial value is `"Error"`.

Property attributes of `Error.prototype.name`	
Writable	yes
Enumerable	no
Configurable	yes

Description

By default, `Error` instances are given the name "Error". The `name` property, in addition to the `message` property, is used by the `Error.prototype.toString()` method to create a string representation of the error.

Examples

Throwing a custom error

```
const e = new Error("Malformed input"); // e.name is 'Error'

e.name = "ParseError";
throw e;
// e.toString() would return 'ParseError: Malformed input'
```

See also

- `Error.prototype.message`
- `Error.prototype.toString()`

Error.prototype.stack

> **Non-standard:** This feature is not standardized. We do not recommend using non-standard features in production, as they have limited browser support, and may

change or be removed. However, they can be a suitable alternative in specific cases where no standard option exists.

Note: The `stack` property is de facto implemented by all major JavaScript engines, and the JavaScript standards committee is looking to standardize it. You cannot rely on the precise content of the stack string due to implementation inconsistencies, but you can generally assume it exists and use it for debugging purposes.

The non-standard **`stack`** property of an `Error` instance offers a trace of which functions were called, in what order, from which line and file, and with what arguments. The stack string proceeds from the most recent calls to earlier ones, leading back to the original global scope call.

Value

A string.

Because the `stack` property is non-standard, implementations differ about where it's installed.

- In Firefox, it's an accessor property on `Error.prototype`.
- In Chrome and Safari, it's a data property on each `Error` instance, with the descriptor:

Property attributes of `Error.prototype.stack`	
Writable	yes
Enumerable	no
Configurable	yes

Description

Each JavaScript engine uses its own format for stack traces, but they are fairly consistent in their high-level structure. Every implementation uses a separate line in the stack to represent each function call. The call that directly caused the error is placed at the top, and the call that started the whole call chain is placed at the bottom. Below are some examples of stack traces:

```
function foo() {
  bar();
}

function bar() {
  baz();
}

function baz() {
  console.log(new Error().stack);
}

foo();
```

```
#### JavaScriptCore
baz@filename.js:10:24
bar@filename.js:6:6
foo@filename.js:2:6
global code@filename.js:13:4

#### SpiderMonkey
baz@filename.js:10:15
bar@filename.js:6:3
foo@filename.js:2:3
@filename.js:13:1

#### V8
Error
    at baz (filename.js:10:15)
    at bar (filename.js:6:3)
    at foo (filename.js:2:3)
    at filename.js:13:1
```

V8 provides the non-standard stack trace API for customizing the stack trace, including `Error.captureStackTrace()`, `Error.stackTraceLimit`, and `Error.prepareStackTrace()`. Other engines support this API to varying extents.

Different engines set this value at different times. Most modern engines set it when the `Error` object is created. This means you can get the full call stack information within a function using the following:

```
function foo() {
  console.log(new Error().stack);
}
```

Without having to throw an error and then catch it.

Stack frames can be things other than explicit function calls, too. For example, event listeners, timeout jobs, and promise handlers all begin their own call chain. Source code within `eval()` and `Function` constructor calls also appear in the stack:

```
console.log(new Function("return new Error('Function failed')")().stack);
console.log("====");
```

```
console.log(eval("new Error('eval failed')").stack);
```

```
#### JavaScriptCore
anonymous@
global code@filename.js:1:65
====
eval code@
eval@[native code]
global code@filename.js:3:17

#### SpiderMonkey
anonymous@filename.js line 1 > Function:1:8
@filename.js:1:65

====
@filename.js line 3 > eval:1:1
@filename.js:3:13

#### V8
Error: Function failed
    at eval (eval at <anonymous> (filename.js:1:13), <anonymous>:1:8)
    at filename.js:1:65
====
Error: eval failed
    at eval (eval at <anonymous> (filename.js:3:13), <anonymous>:1:1)
    at filename.js:3:13
```

In Firefox, you can use the `//# sourceURL` directive to name an eval source. See the Firefox Debug eval sources docs.

Examples

Using the stack property

The following script demonstrates how to use the `stack` property to output a stack trace into your browser window. You can use this to check what your browser's stack structure looks like.

```
function trace() {
  throw new Error("trace() failed");
}
function b() {
  trace();
}
function a() {
  b(3, 4, "\n\n", undefined, {});
}
try {
  a("first call, first arg");
} catch (e) {
  document.getElementById("output").textContent = e.stack;
}
```

Specifications

Not part of any standard.

Error.stackTraceLimit

> **Non-standard:** This feature is not standardized. We do not recommend using non-standard features in production, as they have limited browser support, and may change or be removed. However, they can be a suitable alternative in specific cases where no standard option exists.

> **Note:** This feature is part of the currently non-standard V8 stack trace API. However, for compatibility reasons, it is also implemented by JavaScriptCore.

The **`Error.stackTraceLimit`** static data property indicates the maximum number of stack frames captured by the stack trace of an error. It can be set by user code to change the engine's behavior.

Generally, *reading* this property is not very useful, but you can *set* it to a new value. Setting it to a larger value can be useful for debugging, as it allows you to see more of the call stack. Setting it to a smaller value can improve performance as it reduces the amount of stack captured.

Value

An integer representing the maximum number of stack frames captured by the stack trace of an error.

Property attributes of `Error.stackTraceLimit`	
Writable	yes
Enumerable	yes
Configurable	yes

Description

Because `stackTraceLimit` is a static property of `Error`, you always use it as `Error.stackTraceLimit`, rather than as a property of an `Error` object you created. If you want to customize the stack trace for a single error only, you may need to set the property, create the error, and then reset the property to its original value.

Examples

Setting Error.stackTraceLimit

This code is safe to run even in environments that don't support `Error.stackTraceLimit`, because it doesn't read the property, only sets it, and engines that don't support it will ignore the setting.

```
Error.stackTraceLimit = 2;
const a = () => b();
const b = () => c();
const c = () => d();
const d = () => e();
const e = () => {
  throw new Error("My error");
};
try {
  a();
} catch (e) {
  console.log(e.stack);
}
// Only two frames in supporting engines; all frames in others
```

See also

- `Error.prototype.stack`
- `Error.captureStackTrace()`
- Stack trace API in the V8 docs

Error.prototype.toString()

The **`toString()`** method of `Error` instances returns a string representing this error.

Syntax

```
toString()
```

Parameters

None.

Return value

A string representing the specified `Error` object.

Description

The `Error` object overrides the `Object.prototype.toString()` method inherited by all objects. Its semantics are as follows:

```
Error.prototype.toString = function () {
  if (
    this === null ||
    (typeof this !== "object" && typeof this !== "function")
  ) {
    throw new TypeError();
  }
  let name = this.name;
  name = name === undefined ? "Error" : `${name}`;
  let msg = this.message;
  msg = msg === undefined ? "" : `${msg}`;
  if (name === "") {
    return msg;
  }
  if (msg === "") {
    return name;
  }
  return `${name}: ${msg}`;
};
```

Examples

Using toString()

```
const e1 = new Error("fatal error");
console.log(e1.toString()); // "Error: fatal error"

const e2 = new Error("fatal error");
e2.name = undefined;
console.log(e2.toString()); // "Error: fatal error"

const e3 = new Error("fatal error");
e3.name = "";
console.log(e3.toString()); // "fatal error"

const e4 = new Error("fatal error");
e4.name = "";
e4.message = undefined;
console.log(e4.toString()); // ""

const e5 = new Error("fatal error");
e5.name = "hello";
e5.message = undefined;
console.log(e5.toString()); // "hello"
```

See also

- Polyfill of `Error.prototype.toString` with many bug fixes in `core-js`

escape()

> **Note:** `escape()` is a non-standard function implemented by browsers and was only standardized for cross-engine compatibility. It is not required to be implemented by all JavaScript engines and may not work everywhere. Use `encodeURIComponent()` or `encodeURI()` if possible.

The **`escape()`** function computes a new string in which certain characters have been replaced by hexadecimal escape sequences.

Syntax

```
escape(str)
```

Parameters

`str`

A string to be encoded.

Return value

A new string in which certain characters have been escaped.

Description

`escape()` is a function property of the global object.

The `escape()` function replaces all characters with escape sequences, with the exception of ASCII word characters (A–Z, a–z, 0–9, _) and `@\*_+-./`. Characters are escaped by UTF-16 code units. If the code unit's value is less than 256, it is represented by a two-digit hexadecimal number in the format `%xx`, left-padded with 0 if necessary. Otherwise, it is represented by a four-digit hexadecimal number in the format `%uxxxx`, left-padded with 0 if necessary.

> **Note:** This function was used mostly for percent-encoding and is partly based on the escape format in RFC 1738. The escape format is *not* an escape sequence in string literals. You can replace `%xx` with `\xxx` and `%uxxxx` with `\uxxxx` to get a string containing actual string-literal escape sequences.

Examples

Using escape()

```
escape("abc123"); // "abc123"
escape("äöü"); // "%E4%F6%FC"
escape("ć"); // "%u0107"

// special characters
escape("@*_+-./"); // "@*_+-./"
```

eval()

> **Warning:** The argument passed to this function is dynamically parsed and executed as JavaScript. APIs like this are known as injection sinks, and are potentially a vector for cross-site-scripting (XSS) attacks.
>
> You can mitigate this risk by always passing `TrustedScript` objects instead of strings and enforcing trusted types.
>
> See Security considerations for more information.

The **`eval()`** function evaluates JavaScript code represented as a string and returns its completion value. The source is parsed as a script.

Try it

```
console.log(eval("2 + 2"));
// Expected output: 4

console.log(eval(new String("2 + 2")));
// Expected output: 2 + 2

console.log(eval("2 + 2") === eval("4"));
// Expected output: true

console.log(eval("2 + 2") === eval(new String("2 + 2")));
// Expected output: false
```

Syntax

```
eval(script)
```

Parameters

`script`

A `TrustedScript` instance or string representing a JavaScript expression, statement, or sequence of statements. The expression can include variables and properties of existing objects. It will be parsed as a script, so `import` declarations (which can only exist in modules) are not allowed.

Return value

The completion value of evaluating the given code. If the completion value is empty, `undefined` is returned. If `script` is not a `TrustedScript` or string primitive, `eval()` returns the argument unchanged.

Exceptions

`SyntaxError`

The `script` parameter cannot be parsed as a script.

`TypeError`

`script` is a string when Trusted Types are enforced by a CSP and no default policy is defined.

The method also throws any exception that occurs during evaluation of the code.

Description

`eval()` is a function property of the global object.

The argument of the `eval()` function is a string. It will evaluate the source string as a script body, which means both statements and expressions are allowed. It returns the completion value of the code. For expressions, it's the value the expression evaluates to. Many statements and declarations have completion values as well, but the result may be surprising (for example, the completion value of an assignment is the assigned value, but the completion value of `let` is undefined), so it's recommended to not rely on statements' completion values.

In strict mode, declaring a variable named `eval` or re-assigning `eval` is a `SyntaxError`.

```
"use strict";

const eval = 1; // SyntaxError: Unexpected eval or arguments in strict mode
```

If the argument of `eval()` is not a `TrustedScript` or string, `eval()` returns the argument unchanged. In the following example, passing a `String` object instead of a primitive causes `eval()` to return the `String` object rather than evaluating the string.

```
eval(new String("2 + 2")); // returns a String object containing "2 + 2"
eval("2 + 2"); // returns 4
```

To work around the issue in a generic fashion, you can coerce the argument to a string yourself before passing it to `eval()`.

```
const expression = new String("2 + 2");
eval(String(expression)); // returns 4
```

Direct and indirect eval

There are two modes of `eval()` calls: *direct* eval and *indirect* eval. Direct eval, as the name implies, refers to *directly* calling the global `eval` function with `eval(...)`. Everything else, including invoking it via an aliased variable, via a member access or other expression, or through the optional chaining `?.` operator, is indirect.

```
// Direct call
eval("x + y");

// Indirect call using the comma operator to return eval
(0, eval)("x + y");

// Indirect call through optional chaining
eval?.("x + y");

// Indirect call using a variable to store and return eval
const myEval = eval;
myEval("x + y");

// Indirect call through member access
const obj = { eval };
obj.eval("x + y");
```

Indirect eval can be seen as if the code is evaluated within a separate `<script>` tag. This means:

- Indirect eval works in the global scope rather than the local scope, and the code being evaluated doesn't have access to local variables within the scope where it's being called.

  ```
  function test() {
    const x = 2;
    const y = 4;
    // Direct call, uses local scope
    console.log(eval("x + y")); // Result is 6
    // Indirect call, uses global scope
    console.log(eval?.("x + y")); // Throws because x is not defined in global scope
  }
  ```

- Indirect `eval` does not inherit the strictness of the surrounding context, and is only in strict mode if the source string itself has a `"use strict"` directive.

  ```
  function nonStrictContext() {
    eval?.(`with (Math) console.log(PI);`);
  }
  function strictContext() {
    "use strict";
    eval?.(`with (Math) console.log(PI);`);
  }
  function strictContextStrictEval() {
    "use strict";
    eval?.(`"use strict"; with (Math) console.log(PI);`);
  }
  nonStrictContext(); // Logs 3.141592653589793
  strictContext(); // Logs 3.141592653589793
  strictContextStrictEval(); // Uncaught SyntaxError: Strict mode code may not include a with statement
  ```

  On the other hand, direct eval inherits the strictness of the invoking context.

  ```
  function nonStrictContext() {
    eval(`with (Math) console.log(PI);`);
  }
  function strictContext() {
    "use strict";
    eval(`with (Math) console.log(PI);`);
  }
  function strictContextStrictEval() {
    "use strict";
    eval(`"use strict"; with (Math) console.log(PI);`);
  }
  nonStrictContext(); // Logs 3.141592653589793
  strictContext(); // Uncaught SyntaxError: Strict mode code may not include a with statement
  strictContextStrictEval(); // Uncaught SyntaxError: Strict mode code may not include a with statement
  ```

- `var`-declared variables and function declarations would go into the surrounding scope if the source string is not interpreted in strict mode — for indirect eval, they become global variables. If it's a direct eval in a strict mode context, or if the `eval` source string itself is in strict mode, then `var` and function declarations do not "leak" into the surrounding scope.

  ```
  // Neither context nor source string is strict,
  // so var creates a variable in the surrounding scope
  eval("var a = 1;");
  console.log(a); // 1
  // Context is not strict, but eval source is strict,
  // so b is scoped to the evaluated script
  eval("'use strict'; var b = 1;");
  console.log(b); // ReferenceError: b is not defined

  function strictContext() {
    "use strict";
  ```

```
  // Context is strict, but this is indirect and the source
  // string is not strict, so c is still global
  eval?.("var c = 1;");
  // Direct eval in a strict context, so d is scoped
  eval("var d = 1;");
}
strictContext();
console.log(c); // 1
console.log(d); // ReferenceError: d is not defined
```

`let` and `const` declarations within the evaluated string are always scoped to that script.

- Direct eval may have access to additional contextual expressions. For example, in a function's body, one can use `new.target`:

```
function Ctor() {
  eval("console.log(new.target)");
}
new Ctor(); // [Function: Ctor]
```

Never use direct eval()!

Using direct `eval()` suffers from multiple problems:

- `eval()` executes the code it's passed with the privileges of the caller. If you run `eval()` with a string that could be affected by a malicious party, you may end up running malicious code on the user's machine with the permissions of your webpage / extension. More importantly, allowing third-party code to access the scope in which `eval()` was invoked (if it's a direct eval) can lead to possible attacks that reads or changes local variables. See Security considerations for approaches that mitigate these risks.
- `eval()` is slower than the alternatives, since it has to invoke the JavaScript interpreter, while many other constructs are optimized by modern JS engines.
- Modern JavaScript interpreters convert JavaScript to machine code. This means that any concept of variable naming gets obliterated. Thus, any use of `eval()` will force the browser to do long expensive variable name lookups to figure out where the variable exists in the machine code and set its value. Additionally, new things can be introduced to that variable through `eval()`, such as changing the type of that variable, forcing the browser to re-evaluate all of the generated machine code to compensate.
- Minifiers give up on any minification if the scope is transitively depended on by `eval()`, because otherwise `eval()` cannot read the correct variable at runtime.

There are many cases where the use of `eval()` or related methods can be optimized or avoided altogether.

Using indirect eval()

Consider this code:

```
function looseJsonParse(obj) {
  return eval(`(${obj})`);
}
console.log(looseJsonParse("{ a: 4 - 1, b: function () {}, c: new Map() }"));
```

Simply using indirect eval and forcing strict mode can make the code much better:

```
function looseJsonParse(obj) {
  return eval?.(`"use strict";(${obj})`);
}
console.log(looseJsonParse("{ a: 4 - 1, b: function () {}, c: new Map() }"));
```

The two code snippets above may seem to work the same way, but they do not; the first one using direct eval suffers from multiple problems.

- It is a great deal slower, due to more scope inspections. Notice `c: new Map()` in the evaluated string. In the indirect eval version, the object is being evaluated in the global scope, so it is safe for the interpreter to assume that `Map` refers to the global `Map()` constructor instead of a local variable called `Map`. However, in the code using direct eval, the interpreter cannot assume this. For example, in the following code, `Map` in the evaluated string doesn't refer to `window.Map()`.

  ```
  function looseJsonParse(obj) {
    class Map {}
    return eval(`(${obj})`);
  }
  console.log(looseJsonParse(`{ a: 4 - 1, b: function () {}, c: new Map() }`));
  ```

  Thus, in the `eval()` version of the code, the browser is forced to make the expensive lookup call to check to see if there are any local variables called `Map()`.

- If not using strict mode, `var` declarations within the `eval()` source becomes variables in the surrounding scope. This leads to hard-to-debug issues if the string is acquired from external input, especially if there's an existing variable with the same name.
- Direct eval can read and mutate bindings in the surrounding scope, which may lead to external input corrupting local data.
- When using direct `eval`, especially when the eval source cannot be proven to be in strict mode, the engine — and build tools — have to disable all optimizations related to inlining, because the `eval()` source can depend on any variable name in its surrounding scope.

However, using indirect `eval()` does not allow passing extra bindings other than existing global variables for the evaluated source to read. If you need to specify additional variables that the evaluated source should have access to, consider using the `Function()` constructor.

Using the Function() constructor

The `Function()` constructor is very similar to the indirect eval example above: it also evaluates the JavaScript source passed to it in the global scope without reading or mutating any local bindings, and therefore allows engines to do more optimizations than direct `eval()`.

The difference between `eval()` and `Function()` is that the source string passed to `Function()` is parsed as a function body, not as a script. There are a few nuances — for example, you can use `return` statements at the top level of a function body, but not in a script.

The `Function()` constructor is useful if you wish to create local bindings within your eval source, by passing the variables as parameter bindings.

```
function add(a, b) {
  return a + b;
}
function runCodeWithAddFunction(obj) {
  return Function("add", `"use strict";return (${obj});`)(add);
}
console.log(runCodeWithAddFunction("add(5, 7)")); // 12
```

Both `eval()` and `Function()` implicitly evaluate arbitrary code, and are forbidden in strict CSP settings. There are also additional safer (and faster!) alternatives to `eval()` or `Function()` for common use-cases.

Using bracket accessors

You should not use `eval()` to access properties dynamically. Consider the following example where the property of the object to be accessed is not known until the code is executed. This can be done with `eval()`:

```
const obj = { a: 20, b: 30 };
const propName = getPropName(); // returns "a" or "b"

const result = eval(`obj.${propName}`);
```

However, `eval()` is not necessary here — in fact, it's more error-prone, because if `propName` is not a valid identifier, it leads to a syntax error. Moreover, if `getPropName` is not a function you control, this may lead to execution of arbitrary code. Instead, use the property accessors, which are much faster and safer:

```
const obj = { a: 20, b: 30 };
const propName = getPropName(); // returns "a" or "b"
const result = obj[propName]; // obj["a"] is the same as obj.a
```

You can even use this method to access descendant properties. Using `eval()`, this would look like:

```
const obj = { a: { b: { c: 0 } } };
const propPath = getPropPath(); // suppose it returns "a.b.c"

const result = eval(`obj.${propPath}`); // 0
```

Avoiding `eval()` here could be done by splitting the property path and looping through the different properties:

```
function getDescendantProp(obj, desc) {
  const arr = desc.split(".");
  while (arr.length) {
    obj = obj[arr.shift()];
  }
  return obj;
}

const obj = { a: { b: { c: 0 } } };
const propPath = getPropPath(); // suppose it returns "a.b.c"
const result = getDescendantProp(obj, propPath); // 0
```

Setting a property that way works similarly:

```
function setDescendantProp(obj, desc, value) {
  const arr = desc.split(".");
  while (arr.length > 1) {
    obj = obj[arr.shift()];
  }
  return (obj[arr[0]] = value);
}

const obj = { a: { b: { c: 0 } } };
const propPath = getPropPath(); // suppose it returns "a.b.c"
const result = setDescendantProp(obj, propPath, 1); // obj.a.b.c is now 1
```

However, beware that using bracket accessors with unconstrained input is not safe either — it may lead to object injection attacks.

Using callbacks

JavaScript has first-class functions, which means you can pass functions as arguments to other APIs, store them in variables and objects' properties, and so on. Many DOM APIs are designed with this in mind, so you can (and should) write:

```
// Instead of setTimeout("…", 1000) use:
setTimeout(() => {
  // …
}, 1000);

// Instead of elt.setAttribute("onclick", "…") use:
elt.addEventListener("click", () => {
```

```
  // …
});
```

Closures are also helpful as a way to create parameterized functions without concatenating strings.

Using JSON

If the string you're calling `eval()` on contains data (for example, an array: `"[1, 2, 3]"`), as opposed to code, you should consider switching to JSON, which allows the string to use a subset of JavaScript syntax to represent data.

Note that since JSON syntax is limited compared to JavaScript syntax, many valid JavaScript literals will not parse as JSON. For example, trailing commas are not allowed in JSON, and property names (keys) in object literals must be enclosed in quotes. Be sure to use a JSON serializer to generate strings that will be later parsed as JSON.

Passing carefully constrained data instead of arbitrary code is a good idea in general. For example, an extension designed to scrape contents of web-pages could have the scraping rules defined in XPath instead of JavaScript code.

Security considerations

The method can be used to execute arbitrary input with the privileges of the caller. If the input is a potentially unsafe string provided by a user, this is a possible vector for Cross-site-scripting (XSS) attacks.

For example, the following code shows how `eval()` might execute `untrustedCode` provided by a user:

```
const untrustedCode = "alert('Potentially evil code!');";
const adder = eval(untrustedCode);
```

Websites with a Content Security Policy (CSP) that specifies `script-src` or `default-src` will prevent such code running by default. If you must allow the scripts to run via `eval()`, you can mitigate the risks by always assigning a `TrustedScript` instance instead of a string, and enforcing trusted types using the `require-trusted-types-for` CSP directive. This ensures that the input is passed through a transformation function.

To allow `eval()` to run, you additionally need to specify the `trusted-types-eval` keyword in your CSP `script-src` directive. The `unsafe-eval` keyword also allows `eval()`, but is much less safe than `trusted-types-eval` because it would allow execution even on browsers that do not support trusted types.

For example, the required CSP for your site might look like this:

```
Content-Security-Policy: require-trusted-types-for 'script'; script-src '<your_allowlist>' 'trusted-types-eval'
```

The behavior of the transformation function implemented in your trusted types policy depends on the specific use case that requires a user-provided script. If possible, you should lock the allowed scripts to exactly the code that you trust to run. If that is not possible, you might allow or block the use of certain functions within the provided input.

Examples

Note that the first example shows how to use the method with trusted types. The other examples omit this step for brevity.

Using TrustedScript

To mitigate the risk of XSS, we should always assign `TrustedScript` instances to the `script` parameter. We also need to do this if we're enforcing trusted types for other reasons and we want to allow some script sources that have been permitted (by `CSP: script-src`).

Trusted types are not yet supported on all browsers, so first we define the trusted types tinyfill. This acts as a transparent replacement for the Trusted Types JavaScript API:

```
if (typeof trustedTypes === "undefined")
  trustedTypes = { createPolicy: (n, rules) => rules };
```

Next we create a `TrustedTypePolicy` that defines a `createScript()` method for transforming input strings into `TrustedScript` instances.

For the purpose of this example, we'll assume that we have a function `transformedScript()` that defines our transformation/filtering logic.

```
const policy = trustedTypes.createPolicy("script-policy", {
  createScript(input) {
    const transformed = transformedScript(input); // Our filter method
    return transformed;
  },
});
```

Then we use the `policy` object to create a `TrustedScript` object from a potentially unsafe input string:

```
// The potentially malicious string
const untrustedScript = "alert('Potentially evil code!');";

// Create a TrustedScriptURL instance using the policy
const trustedScript = policy.createScript(untrustedScript);
```

The `TrustedScript` object can now be passed to `eval()`:

```
eval(trustedScript);
```

Using eval()

In the following code, both of the statements containing `eval()` return 42. The first evaluates the string `"x + y + 1"`; the second evaluates the string `"42"`.

```
const x = 2;
const y = 39;
const z = "42";
eval("x + y + 1"); // 42
eval(z); // 42
```

eval() returns the completion value of statements

`eval()` returns the completion value of statements. For `if`, it would be the last expression or statement evaluated.

```
const str = "if (a) { 1 + 1 } else { 1 + 2 }";
let a = true;
let b = eval(str);

console.log(`b is: ${b}`); // b is: 2

a = false;
b = eval(str);

console.log(`b is: ${b}`); // b is: 3
```

The following example uses `eval()` to evaluate the string `str`. This string consists of JavaScript statements that assign `z` a value of 42 if `x` is five, and assign 0 to `z` otherwise. When the second statement is executed, `eval()` will cause these statements to be performed, and it will also evaluate the set of statements and return the value that is assigned to `z`, because the completion value of an assignment is the assigned value.

```
const x = 5;
const str = `if (x === 5) {
  console.log("z is 42");
  z = 42;
} else {
  z = 0;
}`;

console.log("z is ", eval(str)); // z is 42  z is 42
```

If you assign multiple values then the last value is returned.

```
let x = 5;
const str = `if (x === 5) {
  console.log("z is 42");
  z = 42;
  x = 420;
} else {
  z = 0;
}`;

console.log("x is", eval(str)); // z is 42  x is 420
```

eval() as a string defining function requires "(" and ")" as prefix and suffix

```
// This is a function declaration
const fctStr1 = "function a() {}";
// This is a function expression
const fctStr2 = "(function b() {})";
const fct1 = eval(fctStr1); // return undefined, but `a` is available as a global function now
const fct2 = eval(fctStr2); // return the function `b`
```

EvalError

The **`EvalError`** object indicates an error regarding the global `eval()` function. This exception is not thrown by JavaScript anymore, however the `EvalError` object remains for compatibility.

`EvalError` is a serializable object, so it can be cloned with `structuredClone()` or copied between Workers using `postMessage()`.

`EvalError` is a subclass of `Error`.

Constructor

`EvalError()`

Creates a new `EvalError` object.

Instance properties

Also inherits instance properties from its parent `Error`.

These properties are defined on `EvalError.prototype` and shared by all `EvalError` instances.

`EvalError.prototype.constructor`

The constructor function that created the instance object. For `EvalError` instances, the initial value is the `EvalError` constructor.

`EvalError.prototype.name`

Represents the name for the type of error. For `EvalError.prototype.name`, the initial value is `"EvalError"`.

Instance methods

Inherits instance methods from its parent `Error`.

Examples

Creating an EvalError

```
try {
  throw new EvalError("Hello");
} catch (e) {
  console.log(e instanceof EvalError); // true
  console.log(e.message); // "Hello"
  console.log(e.name); // "EvalError"
  console.log(e.stack); // Stack of the error
}
```

- `Error`
- `eval()`

EvalError() constructor

The **`EvalError()`** constructor creates `EvalError` objects.

Syntax

```
new EvalError()
new EvalError(message)
new EvalError(message, options)
new EvalError(message, fileName)
new EvalError(message, fileName, lineNumber)

EvalError()
EvalError(message)
EvalError(message, options)
EvalError(message, fileName)
EvalError(message, fileName, lineNumber)
```

> **Note:** `EvalError()` can be called with or without `new`. Both create a new `EvalError` instance.

Parameters

`message` Optional

Human-readable description of the error.

`options` Optional

An object that has the following properties:

`cause` Optional

A property indicating the specific cause of the error. When catching and re-throwing an error with a more-specific or useful error message, this property can be used to pass the original error.

`fileName` Optional

The name of the file containing the code that caused the exception

`lineNumber` Optional

The line number of the code that caused the exception

Examples

`EvalError` is not used in the current ECMAScript specification and will thus not be thrown by the runtime. However, the object itself remains for backwards compatibility with earlier versions of the specification.

Creating an EvalError

```
try {
  throw new EvalError("Hello");
} catch (e) {
  console.log(e instanceof EvalError); // true
  console.log(e.message); // "Hello"
  console.log(e.name); // "EvalError"
  console.log(e.stack); // Stack of the error
}
```

FinalizationRegistry

A **`FinalizationRegistry`** object lets you request a callback when a value is garbage-collected.

Description

`FinalizationRegistry` provides a way to request that a *cleanup callback* get called at some point when a value registered with the registry has been *reclaimed* (garbage-collected). (Cleanup callbacks are sometimes called *finalizers*.)

> **Note:** Cleanup callbacks should not be used for essential program logic. See Notes on cleanup callbacks for details.

You create the registry passing in the callback:

```
const registry = new FinalizationRegistry((heldValue) => {
  // …
});
```

Then you register any value you want a cleanup callback for by calling the `register` method, passing in the value and a *held value* for it:

```
registry.register(target, "some value");
```

The registry does not keep a strong reference to the value, as that would defeat the purpose (if the registry held it strongly, the value would never be reclaimed). In JavaScript, objects and non-registered symbols are garbage collectable, so they can be registered in a `FinalizationRegistry` object as the target or the token.

If `target` is reclaimed, your cleanup callback may be called at some point with the *held value* you provided for it (`"some value"` in the above). The held value can be any value you like: a primitive or an object, even `undefined`. If the held value is an object, the registry keeps a *strong* reference to it (so it can pass it to your cleanup callback later).

If you might want to unregister a registered target value later, you pass a third value, which is the *unregistration token* you'll use later when calling the registry's `unregister` function to unregister the value. The registry only keeps a weak reference to the unregister token.

It's common to use the target value itself as the unregister token, which is just fine:

```
registry.register(target, "some value", target);
// …

// some time later, if you don't care about `target` anymore, unregister it
registry.unregister(target);
```

It doesn't have to be the same value, though; it can be a different one:

```
registry.register(target, "some value", token);
// …

// some time later
registry.unregister(token);
```

Avoid where possible

Correct use of `FinalizationRegistry` takes careful thought, and it's best avoided if possible. It's also important to avoid relying on any specific behaviors not guaranteed by the specification. When, how, and whether garbage collection occurs is down to the implementation of any given JavaScript engine. Any behavior you observe in one engine may be different in another engine, in another version of the same engine, or even in a slightly different situation with the same version of the same engine. Garbage collection is a hard problem that JavaScript engine implementers are constantly refining and improving their solutions to.

Here are some specific points included by the authors in the proposal that introduced `FinalizationRegistry`:

> Garbage collectors are complicated. If an application or library depends on GC cleaning up a WeakRef or calling a finalizer [cleanup callback] in a timely, predictable manner, it's likely to be disappointed: the cleanup may happen much later than expected, or not at all. Sources of variability include:
>
> - One object might be garbage-collected much sooner than another object, even if they become unreachable at the same time, e.g., due to generational collection.
> - Garbage collection work can be split up over time using incremental and concurrent techniques.
> - Various runtime heuristics can be used to balance memory usage, responsiveness.
> - The JavaScript engine may hold references to things which look like they are unreachable (e.g., in closures, or inline caches).

> - Different JavaScript engines may do these things differently, or the same engine may change its algorithms across versions.
> - Complex factors may lead to objects being held alive for unexpected amounts of time, such as use with certain APIs.

Notes on cleanup callbacks

- Developers shouldn't rely on cleanup callbacks for essential program logic. Cleanup callbacks may be useful for reducing memory usage across the course of a program, but are unlikely to be useful otherwise.
- If your code has just registered a value to the registry, that target will not be reclaimed until the end of the current JavaScript job. See notes on WeakRefs for details.
- A conforming JavaScript implementation, even one that does garbage collection, is not required to call cleanup callbacks. When and whether it does so is entirely down to the implementation of the JavaScript engine. When a registered object is reclaimed, any cleanup callbacks for it may be called then, or some time later, or not at all.
- It's likely that major implementations will call cleanup callbacks at some point during execution, but those calls may be substantially after the related object was reclaimed. Furthermore, if there is an object registered in two registries, there is no guarantee that the two callbacks are called next to each other — one may be called and the other never called, or the other may be called much later.
- There are also situations where even implementations that normally call cleanup callbacks are unlikely to call them:
  - When the JavaScript program shuts down entirely (for instance, closing a tab in a browser).
  - When the `FinalizationRegistry` instance itself is no longer reachable by JavaScript code.
- If the target of a `WeakRef` is also in a `FinalizationRegistry`, the `WeakRef`'s target is cleared at the same time or before any cleanup callback associated with the registry is called; if your cleanup callback calls `deref` on a `WeakRef` for the object, it will receive `undefined`.

Constructor

`FinalizationRegistry()`

Creates a new `FinalizationRegistry` object.

Instance properties

These properties are defined on `FinalizationRegistry.prototype` and shared by all `FinalizationRegistry` instances.

`FinalizationRegistry.prototype.constructor`

The constructor function that created the instance object. For `FinalizationRegistry` instances, the initial value is the `FinalizationRegistry` constructor.

`FinalizationRegistry.prototype[Symbol.toStringTag]`

The initial value of the `[Symbol.toStringTag]` property is the string `"FinalizationRegistry"`. This property is used in `Object.prototype.toString()`.

Instance methods

`FinalizationRegistry.prototype.register()`

Registers an object with the registry in order to get a cleanup callback when/if the object is garbage-collected.

`FinalizationRegistry.prototype.unregister()`

Unregisters an object from the registry.

Examples

Creating a new registry

You create the registry passing in the callback:

```
const registry = new FinalizationRegistry((heldValue) => {
  // …
});
```

Registering objects for cleanup

Then you register any objects you want a cleanup callback for by calling the `register` method, passing in the object and a *held value* for it:

```
registry.register(theObject, "some value");
```

Callbacks never called synchronously

No matter how much pressure you put on the garbage collector, the cleanup callback will never be called synchronously. The object may be reclaimed synchronously, but the callback will always be called sometime after the current job finishes:

```
let counter = 0;
const registry = new FinalizationRegistry(() => {
  console.log(`Array gets garbage collected at ${counter}`);
});

registry.register(["foo"]);

(function allocateMemory() {
  // Allocate 50000 functions — a lot of memory!
  Array.from({ length: 50000 }, () => () => {});
  if (counter > 5000) return;
```

```
  counter++;
  allocateMemory();
})();

console.log("Main job ends");
// Logs:
// Main job ends
// Array gets garbage collected at 5001
```

However, if you allow a little break between each allocation, the callback may be called sooner:

```
let arrayCollected = false;
let counter = 0;
const registry = new FinalizationRegistry(() => {
  console.log(`Array gets garbage collected at ${counter}`);
  arrayCollected = true;
});

registry.register(["foo"]);

(function allocateMemory() {
  // Allocate 50000 functions — a lot of memory!
  Array.from({ length: 50000 }, () => () => {});
  if (counter > 5000 || arrayCollected) return;
  counter++;
  // Use setTimeout to make each allocateMemory a different job
  setTimeout(allocateMemory);
})();

console.log("Main job ends");
```

There's no guarantee that the callback will be called sooner or if it will be called at all, but there's a possibility that the logged message has a counter value smaller than 5000.

FinalizationRegistry() constructor

The **`FinalizationRegistry()`** constructor creates `FinalizationRegistry` objects.

Syntax

```
new FinalizationRegistry(callbackFn)
```

> **Note:** `FinalizationRegistry()` can only be constructed with `new`. Attempting to call it without `new` throws a `TypeError`.

Parameters

`callback`

A function to be invoked each time a registered target value is garbage collected. Its return value is ignored. The function is called with the following arguments:

`heldValue`

The value that was passed to the second parameter of the `register()` method when the `target` object was registered.

Examples

Creating a new registry

You create the registry passing in the callback:

```
const registry = new FinalizationRegistry((heldValue) => {
  // …
});
```

See also

- `FinalizationRegistry`

FinalizationRegistry.prototype.register()

The **`register()`** method of `FinalizationRegistry` instances registers a value with this `FinalizationRegistry` so that if the value is garbage-collected, the registry's callback may get called.

Syntax

```
register(target, heldValue)
register(target, heldValue, unregisterToken)
```

Parameters

`target`

The target value to register.

`heldValue`

The value to pass to the finalizer for this `target`. This cannot be the `target` itself but can be anything else, including functions and primitives.

`unregisterToken` Optional

A token that may be used with the `unregister` method later to unregister the target value. If provided (and not `undefined`), this must be an object or a non-registered symbol. If not provided, the target cannot be unregistered.

Return value

None (`undefined`).

Exceptions

`TypeError`

Thrown in one of the following cases:

- `target` is not an object or a non-registered symbol (object as opposed to primitives; functions are objects as well)
- `target` is the same as `heldValue` (`target === heldValue`)
- `unregisterToken` is not an object or a non-registered symbol

Description

See the Avoid where possible and Notes on cleanup callbacks sections of the `FinalizationRegistry` page for important caveats.

Examples

Using register

The following registers the value referenced by `target`, passing in the held value `"some value"` and passing the target itself as the unregistration token:

```
registry.register(target, "some value", target);
```

The following registers the value referenced by `target`, passing in another object as the held value, and not passing in any unregistration token (which means `target` can't be unregistered):

```
registry.register(target, { useful: "info about target" });
```

See also

- `FinalizationRegistry`

FinalizationRegistry.prototype.unregister()

The **`unregister()`** method of `FinalizationRegistry` instances unregisters a target value from this `FinalizationRegistry`.

Syntax

```
unregister(unregisterToken)
```

Parameters

`unregisterToken`

The token used with the `register()` method when registering the target value. Multiple cells registered with the same `unregisterToken` will be unregistered together.

Return value

A boolean value that is `true` if at least one cell was unregistered and `false` if no cell was unregistered.

Exceptions

`TypeError`

Thrown if `unregisterToken` is not an object or a non-registered symbol.

Description

When a target value has been reclaimed, it is no longer registered in the registry. There is no need to call `unregister` in your cleanup callback. Only call `unregister` if you haven't received a cleanup callback and no longer need to receive one.

Examples

Using unregister

This example shows registering a target object using that same object as the unregister token, then later unregistering it via `unregister`:

```
class Thingy {
  static #cleanup = (label) => {
    //              ^^^^^----- held value
    console.error(
      `The "release" method was never called for the object with the label "${label}"`,
    );
  };
  #registry = new FinalizationRegistry(Thingy.#cleanup);

  /**
   * Constructs a `Thingy` instance.
   * Be sure to call `release` when you're done with it.
   *
   * @param label A label for the `Thingy`.
   */
  constructor(label) {
    //                            vvvvv----- held value
    this.#registry.register(this, label, this);
    //          target -----^^^^         ^^^^----- unregister token
  }

  /**
   * Releases resources held by this `Thingy` instance.
   */
  release() {
    this.#registry.unregister(this);
    //                       ^^^^----- unregister token
  }
}
```

This example shows registering a target object using a different object as its unregister token:

```
class Thingy {
  static #cleanup = (file) => {
    //              ^^^^----- held value
    console.error(
      `The "release" method was never called for the "Thingy" for the file "${file.name}"`,
    );
  };
  #registry = new FinalizationRegistry(Thingy.#cleanup);
  #file;

  /**
   * Constructs a `Thingy` instance for the given file.
   * Be sure to call `release` when you're done with it.
   *
   * @param filename The name of the file.
   */
  constructor(filename) {
    this.#file = File.open(filename);
    //                            vvvvv----- held value
    this.#registry.register(this, label, this.#file);
    //          target -----^^^^         ^^^^^^^^^^----- unregister token
  }

  /**
   * Releases resources held by this `Thingy` instance.
   */
  release() {
    if (this.#file) {
      this.#registry.unregister(this.#file);
      //                       ^^^^^^^^^^----- unregister token
      File.close(this.#file);
      this.#file = null;
    }
  }
}
```

Float16Array

The **`Float16Array`** typed array represents an array of 16-bit floating point numbers in the platform byte order. If control over byte order is needed, use `DataView` instead. The contents are initialized to `0` unless initialization data is explicitly provided. Once established, you can reference elements in the array using the object's methods, or using standard array index syntax (that is, using bracket notation).

`Float16Array` is a subclass of the hidden `TypedArray` class.

> **Note:** Float16 support is not universal, both in the JavaScript API and the underlying CPU architecture. Using it may result in slower performance on some platforms. It is intended for interacting with highly optimized and performance-sensitive systems such as float-backed canvases, WebGPU, WebGL, and deep learning models including stable diffusion.

Constructor

`Float16Array()`

Creates a new `Float16Array` object.

Static properties

Also inherits static properties from its parent `TypedArray`.

`Float16Array.BYTES_PER_ELEMENT`

Returns a number value of the element size. `2` in the case of `Float16Array`.

Static methods

Inherits static methods from its parent `TypedArray`.

Instance properties

Also inherits instance properties from its parent `TypedArray`.

These properties are defined on `Float16Array.prototype` and shared by all `Float16Array` instances.

`Float16Array.prototype.BYTES_PER_ELEMENT`

Returns a number value of the element size. `2` in the case of a `Float16Array`.

`Float16Array.prototype.constructor`

The constructor function that created the instance object. For `Float16Array` instances, the initial value is the `Float16Array` constructor.

Instance methods

Inherits instance methods from its parent `TypedArray`.

Examples

Different ways to create a Float16Array

```
// From a length
const float16 = new Float16Array(2);
float16[0] = 42;
console.log(float16[0]); // 42
console.log(float16.length); // 2
console.log(float16.BYTES_PER_ELEMENT); // 2

// From an array
const x = new Float16Array([21, 31]);
console.log(x[1]); // 31

// From another TypedArray
const y = new Float16Array(x);
console.log(y[0]); // 21

// From an ArrayBuffer
const buffer = new ArrayBuffer(32);
const z = new Float16Array(buffer, 4, 4);
console.log(z.byteOffset); // 4

// From an iterable
const iterable = (function* () {
  yield* [1, 2, 3];
})();
const float16FromIterable = new Float16Array(iterable);
console.log(float16FromIterable);
// Float16Array [1, 2, 3]
```

Float16Array() constructor

The **`Float16Array()`** constructor creates `Float16Array` objects. The contents are initialized to `0` unless initialization data is explicitly provided.

Syntax

```
new Float16Array()
new Float16Array(length)
new Float16Array(typedArray)
new Float16Array(object)

new Float16Array(buffer)
new Float16Array(buffer, byteOffset)
new Float16Array(buffer, byteOffset, length)
```

> **Note:** `Float16Array()` can only be constructed with `new`. Attempting to call it without `new` throws a `TypeError`.

Parameters

See `TypedArray`.

Exceptions

See `TypedArray`.

Examples

Different ways to create a Float16Array

```
// From a length
const float16 = new Float16Array(2);
float16[0] = 42;
console.log(float16[0]); // 42
console.log(float16.length); // 2
console.log(float16.BYTES_PER_ELEMENT); // 2

// From an array
const x = new Float16Array([21, 31]);
console.log(x[1]); // 31

// From another TypedArray
const y = new Float16Array(x);
console.log(y[0]); // 21

// From an ArrayBuffer
const buffer = new ArrayBuffer(32);
const z = new Float16Array(buffer, 4, 4);
console.log(z.byteOffset); // 4

// From an iterable
const iterable = (function* () {
  yield* [1, 2, 3];
})();
const float16FromIterable = new Float16Array(iterable);
console.log(float16FromIterable);
// Float16Array [1, 2, 3]
```

Float32Array

The **`Float32Array`** typed array represents an array of 32-bit floating point numbers in the platform byte order. If control over byte order is needed, use `DataView` instead. The contents are initialized to `0` unless initialization data is explicitly provided. Once established, you can reference elements in the array using the object's methods, or using standard array index syntax (that is, using bracket notation).

`Float32Array` is a subclass of the hidden `TypedArray` class.

Constructor

`Float32Array()`

Creates a new `Float32Array` object.

Static properties

Also inherits static properties from its parent `TypedArray`.

`Float32Array.BYTES_PER_ELEMENT`

Returns a number value of the element size. `4` in the case of `Float32Array`.

Static methods

Inherits static methods from its parent `TypedArray`.

Instance properties

Also inherits instance properties from its parent `TypedArray`.

These properties are defined on `Float32Array.prototype` and shared by all `Float32Array` instances.

`Float32Array.prototype.BYTES_PER_ELEMENT`

Returns a number value of the element size. `4` in the case of a `Float32Array`.

`Float32Array.prototype.constructor`

The constructor function that created the instance object. For `Float32Array` instances, the initial value is the `Float32Array` constructor.

Instance methods

Inherits instance methods from its parent `TypedArray`.

Examples

Different ways to create a Float32Array

```
// From a length
const float32 = new Float32Array(2);
float32[0] = 42;
console.log(float32[0]); // 42
console.log(float32.length); // 2
console.log(float32.BYTES_PER_ELEMENT); // 4

// From an array
const x = new Float32Array([21, 31]);
console.log(x[1]); // 31

// From another TypedArray
const y = new Float32Array(x);
console.log(y[0]); // 21

// From an ArrayBuffer
const buffer = new ArrayBuffer(32);
const z = new Float32Array(buffer, 4, 4);
console.log(z.byteOffset); // 4

// From an iterable
const iterable = (function* () {
  yield* [1, 2, 3];
})();
const float32FromIterable = new Float32Array(iterable);
console.log(float32FromIterable);
// Float32Array [1, 2, 3]
```

Float32Array() constructor

The **`Float32Array()`** constructor creates `Float32Array` objects. The contents are initialized to `0` unless initialization data is explicitly provided.

Syntax

```
new Float32Array()
new Float32Array(length)
new Float32Array(typedArray)
new Float32Array(object)

new Float32Array(buffer)
new Float32Array(buffer, byteOffset)
new Float32Array(buffer, byteOffset, length)
```

> **Note:** `Float32Array()` can only be constructed with `new`. Attempting to call it without `new` throws a `TypeError`.

Parameters

See `TypedArray`.

Exceptions

See `TypedArray`.

Examples

Different ways to create a Float32Array

```
// From a length
const float32 = new Float32Array(2);
float32[0] = 42;
console.log(float32[0]); // 42
console.log(float32.length); // 2
console.log(float32.BYTES_PER_ELEMENT); // 4

// From an array
const x = new Float32Array([21, 31]);
console.log(x[1]); // 31

// From another TypedArray
const y = new Float32Array(x);
console.log(y[0]); // 21

// From an ArrayBuffer
const buffer = new ArrayBuffer(32);
const z = new Float32Array(buffer, 4, 4);
console.log(z.byteOffset); // 4

// From an iterable
const iterable = (function* () {
  yield* [1, 2, 3];
})();
const float32FromIterable = new Float32Array(iterable);
console.log(float32FromIterable);
// Float32Array [1, 2, 3]
```

Float64Array

The **`Float64Array`** typed array represents an array of 64-bit floating point numbers in the platform byte order. If control over byte order is needed, use `DataView` instead. The contents are initialized to `0` unless initialization data is explicitly provided. Once established, you can reference elements in the array using the object's methods, or using standard array index syntax (that is, using bracket notation).

`Float64Array` is a subclass of the hidden `TypedArray` class.

Constructor

`Float64Array()`

Creates a new `Float64Array` object.

Static properties

Also inherits static properties from its parent `TypedArray`.

`Float64Array.BYTES_PER_ELEMENT`

Returns a number value of the element size. `8` in the case of `Float64Array`.

Static methods

Inherits static methods from its parent `TypedArray`.

Instance properties

Also inherits instance properties from its parent `TypedArray`.

These properties are defined on `Float64Array.prototype` and shared by all `Float64Array` instances.

`Float64Array.prototype.BYTES_PER_ELEMENT`

Returns a number value of the element size. `8` in the case of a `Float64Array`.

`Float64Array.prototype.constructor`

The constructor function that created the instance object. For `Float64Array` instances, the initial value is the `Float64Array` constructor.

Instance methods

Inherits instance methods from its parent `TypedArray`.

Examples

Different ways to create a Float64Array

```
// From a length
const float64 = new Float64Array(2);
float64[0] = 42;
console.log(float64[0]); // 42
console.log(float64.length); // 2
console.log(float64.BYTES_PER_ELEMENT); // 8

// From an array
const x = new Float64Array([21, 31]);
console.log(x[1]); // 31

// From another TypedArray
const y = new Float64Array(x);
console.log(y[0]); // 21

// From an ArrayBuffer
const buffer = new ArrayBuffer(64);
const z = new Float64Array(buffer, 8, 4);
console.log(z.byteOffset); // 8

// From an iterable
const iterable = (function* () {
  yield* [1, 2, 3];
})();
const float64FromIterable = new Float64Array(iterable);
console.log(float64FromIterable);
// Float64Array [1, 2, 3]
```

Float64Array() constructor

The **`Float64Array()`** constructor creates `Float64Array` objects. The contents are initialized to `0` unless initialization data is explicitly provided.

Syntax

```
new Float64Array()
new Float64Array(length)
new Float64Array(typedArray)
new Float64Array(object)

new Float64Array(buffer)
new Float64Array(buffer, byteOffset)
new Float64Array(buffer, byteOffset, length)
```

> **Note:** `Float64Array()` can only be constructed with `new`. Attempting to call it without `new` throws a `TypeError`.

Parameters

See `TypedArray`.

Exceptions

See `TypedArray`.

Examples

Different ways to create a Float64Array

```
// From a length
const float64 = new Float64Array(2);
float64[0] = 42;
console.log(float64[0]); // 42
console.log(float64.length); // 2
console.log(float64.BYTES_PER_ELEMENT); // 8

// From an array
const x = new Float64Array([21, 31]);
```

```
console.log(x[1]); // 31

// From another TypedArray
const y = new Float64Array(x);
console.log(y[0]); // 21

// From an ArrayBuffer
const buffer = new ArrayBuffer(64);
const z = new Float64Array(buffer, 8, 4);
console.log(z.byteOffset); // 8

// From an iterable
const iterable = (function* () {
  yield* [1, 2, 3];
})();
const float64FromIterable = new Float64Array(iterable);
console.log(float64FromIterable);
// Float64Array [1, 2, 3]
```

Function

The **`Function`** object provides methods for functions. In JavaScript, every function is actually a `Function` object.

Constructor

`Function()`

Creates a new `Function` object. Calling the constructor directly can create functions dynamically but suffers from security and similar (but far less significant) performance issues to `eval()`. However, unlike `eval()`, the `Function` constructor creates functions that execute in the global scope only.

Instance properties

These properties are defined on `Function.prototype` and shared by all `Function` instances.

`Function.prototype.arguments`

Represents the arguments passed to this function. For strict, arrow, async, and generator functions, accessing the `arguments` property throws a `TypeError`. Use the `arguments` object inside function closures instead.

`Function.prototype.caller`

Represents the function that invoked this function. For strict, arrow, async, and generator functions, accessing the `caller` property throws a `TypeError`.

`Function.prototype.constructor`

The constructor function that created the instance object. For `Function` instances, the initial value is the `Function` constructor.

These properties are own properties of each `Function` instance.

`displayName` Optional

The display name of the function.

`length`

Specifies the number of arguments expected by the function.

`name`

The name of the function.

`prototype`

Used when the function is used as a constructor with the `new` operator. It will become the new object's prototype.

Instance methods

`Function.prototype.apply()`

Calls a function with a given `this` value and optional arguments provided as an array (or an array-like object).

`Function.prototype.bind()`

Creates a new function that, when called, has its `this` keyword set to a provided value, optionally with a given sequence of arguments preceding any provided when the new function is called.

`Function.prototype.call()`

Calls a function with a given `this` value and optional arguments.

`Function.prototype.toString()`

Returns a string representing the source code of the function. Overrides the `Object.prototype.toString` method.

`Function.prototype[Symbol.hasInstance]()`

Specifies the default procedure for determining if a constructor function recognizes an object as one of the constructor's instances. Called by the `instanceof` operator.

Examples

Difference between Function constructor and function declaration

Functions created with the `Function` constructor do not create closures to their creation contexts; they always are created in the global scope. When running them, they will only be able to access their own local variables and global ones, not the ones from the scope in which the `Function` constructor was created. This is different from using `eval()` with code for a function expression.

```
// Create a global property with `var`
var x = 10;

function createFunction1() {
  const x = 20;
  return new Function("return x;"); // this `x` refers to global `x`
}

function createFunction2() {
  const x = 20;
  function f() {
    return x; // this `x` refers to the local `x` above
  }
  return f;
}

const f1 = createFunction1();
console.log(f1()); // 10
const f2 = createFunction2();
console.log(f2()); // 20
```

While this code works in web browsers, `f1()` will produce a `ReferenceError` in Node.js, as `x` will not be found. This is because the top-level scope in Node is not the global scope, and `x` will be local to the module.

- Functions

Function.prototype.apply()

The **`apply()`** method of `Function` instances calls this function with a given `this` value, and `arguments` provided as an array (or an array-like object).

Try it

```
const numbers = [5, 6, 2, 3, 7];

const max = Math.max.apply(null, numbers);

console.log(max);
// Expected output: 7

const min = Math.min.apply(null, numbers);

console.log(min);
// Expected output: 2
```

Syntax

```
apply(thisArg)
apply(thisArg, argsArray)
```

Parameters

`thisArg`

The value of `this` provided for the call to `func`. If the function is not in strict mode, `null` and `undefined` will be replaced with the global object, and primitive values will be converted to objects.

`argsArray` Optional

An array-like object, specifying the arguments with which `func` should be called, or `null` or `undefined` if no arguments should be provided to the function.

Return value

The result of calling the function with the specified `this` value and arguments.

Description

> **Note:** This function is almost identical to `call()`, except that the function arguments are passed to `call()` individually as a list, while for `apply()` they are combined in one object, typically an array — for example, `func.call(this, "eat", "bananas")` vs. `func.apply(this, ["eat", "bananas"])`.

Normally, when calling a function, the value of `this` inside the function is the object that the function was accessed on. With `apply()`, you can assign an arbitrary value as `this` when calling an existing function, without first attaching the function to the object as a property. This allows you to use methods of one object as generic utility functions.

You can also use any kind of object which is array-like as the second parameter. In practice, this means that it needs to have a `length` property, and integer ("index") properties in the range `(0..length - 1)`. For example, you could use a `NodeList`, or a custom object like `{ 'length': 2, '0': 'eat', '1': 'bananas' }`. You can also use `arguments`, for example:

```
function wrapper() {
  return anotherFn.apply(null, arguments);
}
```

With the rest parameters and parameter spread syntax, this can be rewritten as:

```
function wrapper(...args) {
  return anotherFn(...args);
}
```

In general, `fn.apply(null, args)` is equivalent to `fn(...args)` with the parameter spread syntax, except `args` is expected to be an array-like object in the former case with `apply()`, and an iterable object in the latter case with spread syntax.

> **Warning:** Do not use `apply()` to chain constructors (for example, to implement inheritance). This invokes the constructor function as a plain function, which means `new.target` is `undefined`, and classes throw an error because they can't be called without `new`. Use `Reflect.construct()` or `extends` instead.

Examples

Using apply() to append an array to another

You can use `Array.prototype.push()` to append an element to an array. Because `push()` accepts a variable number of arguments, you can also push multiple elements at once. But if you pass an array to `push()`, it will actually add that array as a single element, instead of adding the elements individually, ending up with an array inside an array. On the other hand, `Array.prototype.concat()` does have the desired behavior in this case, but it does not append to the *existing* array — it creates and returns a new array.

In this case, you can use `apply` to implicitly "spread" an array as a series of arguments.

```
const array = ["a", "b"];
const elements = [0, 1, 2];
array.push.apply(array, elements);
console.info(array); // ["a", "b", 0, 1, 2]
```

The same effect can be achieved with the spread syntax.

```
const array = ["a", "b"];
const elements = [0, 1, 2];
array.push(...elements);
console.info(array); // ["a", "b", 0, 1, 2]
```

Using apply() and built-in functions

Clever usage of `apply()` allows you to use built-in functions for some tasks that would probably otherwise require manually looping over a collection (or using the spread syntax).

For example, we can use `Math.max()` and `Math.min()` to find out the maximum and minimum value in an array.

```
// min/max number in an array
const numbers = [5, 6, 2, 3, 7];

// using Math.min/Math.max apply
let max = Math.max.apply(null, numbers);
// This about equal to Math.max(numbers[0], …)
// or Math.max(5, 6, …)

let min = Math.min.apply(null, numbers);

// vs. loop based algorithm
max = -Infinity;
min = Infinity;
```

```
for (const n of numbers) {
  if (n > max) {
    max = n;
  }
  if (n < min) {
    min = n;
  }
}
```

But beware: by using `apply()` (or the spread syntax) with an arbitrarily long arguments list, you run the risk of exceeding the JavaScript engine's argument length limit.

The consequences of calling a function with too many arguments (that is, more than tens of thousands of arguments) is unspecified and varies across engines. (The JavaScriptCore engine has a hard-coded argument limit of 65536.) Most engines throw an exception; but there's no normative specification preventing other behaviors, such as arbitrarily limiting the number of arguments actually passed to the applied function. To illustrate this latter case: if such an engine had a limit of four arguments (actual limits are of course significantly higher), it would be as if the arguments `5, 6, 2, 3` had been passed to `apply` in the examples above, rather than the full array.

If your value array might grow into the tens of thousands, use a hybrid strategy: apply your function to chunks of the array at a time:

```
function minOfArray(arr) {
  let min = Infinity;
  const QUANTUM = 32768;

  for (let i = 0; i < arr.length; i += QUANTUM) {
    const subMin = Math.min.apply(
      null,
      arr.slice(i, Math.min(i + QUANTUM, arr.length)),
    );
    min = Math.min(subMin, min);
  }

  return min;
}

const min = minOfArray([5, 6, 2, 3, 7]);
```

Function.prototype.arguments

> **Non-standard:** This feature is not standardized. We do not recommend using non-standard features in production, as they have limited browser support, and may change or be removed. However, they can be a suitable alternative in specific cases where no standard option exists.

> **Note:** The `arguments` property of `Function` objects is deprecated. The recommended way to access the `arguments` object is to refer to the variable `arguments` available within functions.

The **`arguments`** accessor property of `Function` instances returns the arguments passed to this function. For strict, arrow, async, and generator functions, accessing the `arguments` property throws a `TypeError`.

Description

The value of `arguments` is an array-like object corresponding to the arguments passed to a function.

In the case of recursion, i.e., if function `f` appears several times on the call stack, the value of `f.arguments` represents the arguments corresponding to the most recent invocation of the function.

The value of the `arguments` property is normally `null` if there is no outstanding invocation of the function in progress (that is, the function has been called but has not yet returned).

Note that the only behavior specified by the ECMAScript specification is that `Function.prototype` has an initial `arguments` accessor that unconditionally throws a `TypeError` for any `get` or `set` request (known as a "poison pill accessor"), and that implementations are not allowed to change this semantic for any function except non-strict plain functions. The actual behavior of the `arguments` property, if it's anything other than throwing an error, is implementation-defined. For example, Chrome defines it as an own data property, while Firefox and Safari extend the initial poison-pill `Function.prototype.arguments` accessor to specially handle `this` values that are non-strict functions.

```
(function f() {
  if (Object.hasOwn(f, "arguments")) {
    console.log(
      "arguments is an own property with descriptor",
      Object.getOwnPropertyDescriptor(f, "arguments"),
    );
```

```
  } else {
    console.log(
      "f doesn't have an own property named arguments. Trying to get f.[[Prototype]].arguments",
    );
    console.log(
      Object.getOwnPropertyDescriptor(
        Object.getPrototypeOf(f),
        "arguments",
      ).get.call(f),
    );
  }
})();

// In Chrome:
// arguments is an own property with descriptor {value: Arguments(0), writable: false, enumerable: false, configurable: false}

// In Firefox:
// f doesn't have an own property named arguments. Trying to get f.[[Prototype]].arguments
// Arguments { … }
```

Examples

Using the arguments property

```
function f(n) {
  g(n - 1);
}

function g(n) {
  console.log(`before: ${g.arguments[0]}`);
  if (n > 0) {
    f(n);
  }
  console.log(`after: ${g.arguments[0]}`);
}

f(2);

console.log(`returned: ${g.arguments}`);

// Logs:
// before: 1
// before: 0
// after: 0
// after: 1
// returned: null
```

Function.prototype.bind()

The **`bind()`** method of `Function` instances creates a new function that, when called, calls this function with its `this` keyword set to the provided value, and a given sequence of arguments preceding any provided when the new function is called.

Try it

```
const module = {
  x: 42,
  getX() {
    return this.x;
  },
};

const unboundGetX = module.getX;
console.log(unboundGetX()); // The function gets invoked at the global scope
// Expected output: undefined

const boundGetX = unboundGetX.bind(module);
console.log(boundGetX());
// Expected output: 42
```

Syntax

```
bind(thisArg)
bind(thisArg, arg1)
bind(thisArg, arg1, arg2)
bind(thisArg, arg1, arg2, /* …, */ argN)
```

Parameters

`thisArg`

> The value to be passed as the `this` parameter to the target function `func` when the bound function is called. If the function is not in strict mode, `null` and `undefined` will be replaced with the global object, and primitive values will be converted to objects. The value is ignored if the bound function is constructed using the `new` operator.

`arg1, ..., argN` Optional

> Arguments to prepend to arguments provided to the bound function when invoking `func`.

Return value

A copy of the given function with the specified `this` value, and initial arguments (if provided).

Description

The `bind()` function creates a new *bound function*. Calling the bound function generally results in the execution of the function it wraps, which is also called the *target function*. The bound function will store the parameters passed — which include the value of `this` and the first few arguments — as its internal state. These values are stored in advance, instead of being passed at call time. You can generally see `const boundFn = fn.bind(thisArg, arg1, arg2)` as being equivalent to `const boundFn = (...restArgs) => fn.call(thisArg, arg1, arg2, ...restArgs)` for the effect when it's called (but not when `boundFn` is constructed).

A bound function can be further bound by calling `boundFn.bind(thisArg, /* more args */)`, which creates another bound function `boundFn2`. The newly bound `thisArg` value is ignored, because the target function of `boundFn2`, which is `boundFn`, already has a bound `this`. When `boundFn2` is called, it would call `boundFn`, which in turn calls `fn`. The arguments that `fn` ultimately receives are, in order: the arguments bound by `boundFn`, arguments bound by `boundFn2`, and the arguments received by `boundFn2`.

```
"use strict"; // prevent `this` from being boxed into the wrapper object

function log(...args) {
  console.log(this, ...args);
}
const boundLog = log.bind("this value", 1, 2);
const boundLog2 = boundLog.bind("new this value", 3, 4);
boundLog2(5, 6); // "this value", 1, 2, 3, 4, 5, 6
```

A bound function may also be constructed using the `new` operator if its target function is constructable. Doing so acts as though the target function had instead been constructed. The prepended arguments are provided to the target function as usual, while the provided `this` value is ignored (because construction prepares its own `this`, as seen by the parameters of `Reflect.construct`). If the bound function is directly constructed, `new.target` will be the target function instead. (That is, the bound function is transparent to `new.target`.)

```
class Base {
  constructor(...args) {
    console.log(new.target === Base);
    console.log(args);
  }
}

const BoundBase = Base.bind(null, 1, 2);

new BoundBase(3, 4); // true, [1, 2, 3, 4]
```

However, because a bound function does not have the `prototype` property, it cannot be used as a base class for `extends`.

```
class Derived extends class {}.bind(null) {}
// TypeError: Class extends value does not have valid prototype property undefined
```

When using a bound function as the right-hand side of `instanceof`, `instanceof` would reach for the target function (which is stored internally in the bound function) and read its `prototype` instead.

```
class Base {}
const BoundBase = Base.bind(null, 1, 2);
console.log(new Base() instanceof BoundBase); // true
```

The bound function has the following properties:

`length`

> The `length` of the target function minus the number of arguments being bound (not counting the `thisArg` parameter), with 0 being the minimum value.

`name`

> The `name` of the target function plus a `"bound "` prefix.

The bound function also inherits the prototype chain of the target function. However, it doesn't have other own properties of the target function (such as static properties if the target function is a class).

Examples

Creating a bound function

The most common use of `bind()` is to make a function that, no matter how it is called, is called with a particular `this` value.

A common mistake for new JavaScript programmers is to extract a method from an object, then to later call that function and expect it to use the original object as its `this` (e.g., by using the method in callback-based code).

Without special care, however, the original object is usually lost. Creating a bound function from the function, using the original object, neatly solves this problem:

```
// Top-level 'this' is bound to 'globalThis' in scripts.
this.x = 9;
const module = {
  x: 81,
  getX() {
    return this.x;
  },
};

// The 'this' parameter of 'getX' is bound to 'module'.
console.log(module.getX()); // 81

const retrieveX = module.getX;
// The 'this' parameter of 'retrieveX' is bound to 'globalThis' in non-strict mode.
console.log(retrieveX()); // 9

// Create a new function 'boundGetX' with the 'this' parameter bound to 'module'.
const boundGetX = retrieveX.bind(module);
console.log(boundGetX()); // 81
```

> **Note:** If you run this example in strict mode, the `this` parameter of `retrieveX` will be bound to `undefined` instead of `globalThis`, causing the `retrieveX()` call to fail.
>
> If you run this example in an ECMAScript module, top-level `this` will be bound to `undefined` instead of `globalThis`, causing the `this.x = 9` assignment to fail.
>
> If you run this example in a Node CommonJS module, top-level `this` will be bound to `module.exports` instead of `globalThis`. However, the `this` parameter of `retrieveX` will still be bound to `globalThis` in non-strict mode and to `undefined` in strict mode. Therefore, in non-strict mode (the default), the `retrieveX()` call will return `undefined` because `this.x = 9` is writing to a different object (`module.exports`) from what `getX` is reading from (`globalThis`).

In fact, some built-in "methods" are also getters that return bound functions — one notable example being `Intl.NumberFormat.prototype.format()`, which, when accessed, returns a bound function that you can directly pass as a callback.

Partially applied functions

Another use of `bind()` is to make a function with pre-specified initial arguments.

These arguments (if any) follow the provided `this` value and are then inserted at the start of the arguments passed to the target function, followed by whatever arguments are passed to the bound function at the time it is called.

```
function list(...args) {
  return args;
}

function addArguments(arg1, arg2) {
  return arg1 + arg2;
}

console.log(list(1, 2, 3)); // [1, 2, 3]

console.log(addArguments(1, 2)); // 3

// Create a function with a preset leading argument
const leadingThirtySevenList = list.bind(null, 37);

// Create a function with a preset first argument.
const addThirtySeven = addArguments.bind(null, 37);

console.log(leadingThirtySevenList()); // [37]
console.log(leadingThirtySevenList(1, 2, 3)); // [37, 1, 2, 3]
console.log(addThirtySeven(5)); // 42
console.log(addThirtySeven(5, 10)); // 42
// (the last argument 10 is ignored)
```

With setTimeout()

By default, within `setTimeout()`, the `this` keyword will be set to `globalThis`, which is `window` in browsers. When working with class methods that require `this` to refer to class instances, you may explicitly bind `this` to the callback function, in order to maintain the instance.

```
class LateBloomer {
  constructor() {
    this.petalCount = Math.floor(Math.random() * 12) + 1;
  }
  bloom() {
    // Declare bloom after a delay of 1 second
    setTimeout(this.declare.bind(this), 1000);
  }
  declare() {
    console.log(`I am a beautiful flower with ${this.petalCount} petals!`);
```

```
  }
}

const flower = new LateBloomer();
flower.bloom();
// After 1 second, calls 'flower.declare()'
```

You can also use arrow functions for this purpose.

```
class LateBloomer {
  bloom() {
    // Declare bloom after a delay of 1 second
    setTimeout(() => this.declare(), 1000);
  }
}
```

Bound functions used as constructors

Bound functions are automatically suitable for use with the `new` operator to construct new instances created by the target function. When a bound function is used to construct a value, the provided `this` is ignored. However, provided arguments are still prepended to the constructor call.

```
function Point(x, y) {
  this.x = x;
  this.y = y;
}

Point.prototype.toString = function () {
  return `${this.x},${this.y}`;
};

const p = new Point(1, 2);
p.toString();
// '1,2'

// The thisArg's value doesn't matter because it's ignored
const YAxisPoint = Point.bind(null, 0 /* x */);

const axisPoint = new YAxisPoint(5);
axisPoint.toString(); // '0,5'

axisPoint instanceof Point; // true
axisPoint instanceof YAxisPoint; // true
new YAxisPoint(17, 42) instanceof Point; // true
```

Note that you need not do anything special to create a bound function for use with `new`. `new.target`, `instanceof`, `this` etc. all work as expected, as if the constructor was never bound. The only difference is that it can no longer be used for `extends`.

The corollary is that you need not do anything special to create a bound function to be called plainly, even if you would rather require the bound function to only be called using `new`. If you call it without `new`, the bound `this` is suddenly not ignored.

```
const emptyObj = {};
const YAxisPoint = Point.bind(emptyObj, 0 /* x */);

// Can still be called as a normal function
// (although usually this is undesirable)
YAxisPoint(13);

// The modifications to `this` is now observable from the outside
console.log(emptyObj); // { x: 0, y: 13 }
```

If you wish to restrict a bound function to only be callable with `new`, or only be callable without `new`, the target function must enforce that restriction, such as by checking `new.target !== undefined` or using a class instead.

Binding classes

Using `bind()` on classes preserves most of the class's semantics, except that all static own properties of the current class are lost. However, because the prototype chain is preserved, you can still access static properties inherited from the parent class.

```
class Base {
  static baseProp = "base";
}

class Derived extends Base {
  static derivedProp = "derived";
}

const BoundDerived = Derived.bind(null);
console.log(BoundDerived.baseProp); // "base"
console.log(BoundDerived.derivedProp); // undefined
console.log(new BoundDerived() instanceof Derived); // true
```

Transforming methods to utility functions

`bind()` is also helpful in cases where you want to transform a method which requires a specific `this` value to a plain utility function that accepts the previous `this` parameter as a normal parameter. This is similar to how general-purpose utility functions work: instead of calling `array.map(callback)`, you use `map(array, callback)`, which allows you to use `map` with array-like objects that are not arrays (for example, `arguments`) without mutating `Object.prototype`.

Take `Array.prototype.slice()`, for example, which you want to use for converting an array-like object to a real array. You could create a shortcut like this:

```
const slice = Array.prototype.slice;

// …

slice.call(arguments);
```

Note that you can't save `slice.call` and call it as a plain function, because the `call()` method also reads its `this` value, which is the function it should call. In this case, you can use `bind()` to bind the value of `this` for `call()`. In the following piece of code, `slice()` is a bound version of `Function.prototype.call()`, with the `this` value bound to `Array.prototype.slice()`. This means that additional `call()` calls can be eliminated:

```
// Same as "slice" in the previous example
const unboundSlice = Array.prototype.slice;
const slice = Function.prototype.call.bind(unboundSlice);

// …

slice(arguments);
```

- Polyfill of `Function.prototype.bind` in `core-js`
- `Function.prototype.apply()`
- `Function.prototype.call()`
- Functions

Function.prototype.call()

The **`call()`** method of `Function` instances calls this function with a given `this` value and arguments provided individually.

Try it

```
function Product(name, price) {
  this.name = name;
  this.price = price;
}

function Food(name, price) {
  Product.call(this, name, price);
  this.category = "food";
}

console.log(new Food("cheese", 5).name);
// Expected output: "cheese"
```

Syntax

```
call(thisArg)
call(thisArg, arg1)
call(thisArg, arg1, arg2)
call(thisArg, arg1, arg2, /* …, */ argN)
```

Parameters

`thisArg`

> The value to use as `this` when calling `func`. If the function is not in strict mode, `null` and `undefined` will be replaced with the global object, and primitive values will be converted to objects.

`arg1, ..., argN` Optional

> Arguments for the function.

Return value

The result of calling the function with the specified `this` value and arguments.

Description

> **Note:** This function is almost identical to `apply()`, except that the function arguments are passed to `call()` individually as a list, while for `apply()` they are combined in one object, typically an array — for example, `func.call(this, "eat", "bananas")` vs. `func.apply(this, ["eat", "bananas"])`.

Normally, when calling a function, the value of `this` inside the function is the object that the function was accessed on. With `call()`, you can assign an arbitrary value as `this` when calling an existing function, without first attaching the function to the object as a property. This allows you to use methods of one object as generic utility functions.

> **Warning:** Do not use `call()` to chain constructors (for example, to implement inheritance). This invokes the constructor function as a plain function, which means `new.target` is `undefined`, and classes throw an error because they can't be called without `new`. Use `Reflect.construct()` or `extends` instead.

Examples

Using call() to invoke a function and specifying the this value

In the example below, when we call `greet`, the value of `this` will be bound to object `obj`, even when `greet` is not a method of `obj`.

```
function greet() {
  console.log(this.animal, "typically sleep between", this.sleepDuration);
}

const obj = {
  animal: "cats",
  sleepDuration: "12 and 16 hours",
};

greet.call(obj); // cats typically sleep between 12 and 16 hours
```

Using call() to invoke a function without specifying the first argument

If the first `thisArg` parameter is omitted, it defaults to `undefined`. In non-strict mode, the `this` value is then substituted with `globalThis` (which is akin to the global object).

```
globalThis.globProp = "foo";

function display() {
  console.log(`globProp value is ${this.globProp}`);
}

display.call(); // Logs "globProp value is foo"
```

In strict mode, the value of `this` is not substituted, so it stays as `undefined`.

```
"use strict";

globalThis.globProp = "foo";

function display() {
  console.log(`globProp value is ${this.globProp}`);
}

display.call(); // throws TypeError: Cannot read the property of 'globProp' of undefined
```

Transforming methods to utility functions

`call()` is almost equivalent to a normal function call, except that `this` is passed as a normal parameter instead of as the value that the function was accessed on. This is similar to how general-purpose utility functions work: instead of calling `array.map(callback)`, you use `map(array, callback)`, which allows you to use `map` with array-like objects that are not arrays (for example, `arguments`) without mutating `Object.prototype`.

Take `Array.prototype.slice()`, for example, which you want to use for converting an array-like object to a real array. You could create a shortcut like this:

```
const slice = Array.prototype.slice;

// …

slice.call(arguments);
```

Note that you can't save `slice.call` and call it as a plain function, because the `call()` method also reads its `this` value, which is the function it should call. In this case, you can use `bind()` to bind the value of `this` for `call()`. In the following piece of code, `slice()` is a bound version of `Function.prototype.call()`, with the `this` value bound to `Array.prototype.slice()`. This means that additional `call()` calls can be eliminated:

```
// Same as "slice" in the previous example
const unboundSlice = Array.prototype.slice;
const slice = Function.prototype.call.bind(unboundSlice);

// …

slice(arguments);
```

Function.prototype.caller

> **Non-standard:** This feature is not standardized. We do not recommend using non-standard features in production, as they have limited browser support, and may change or be removed. However, they can be a suitable alternative in specific cases where no standard option exists.

> **Note:** In strict mode, accessing `caller` of a function throws an error — the API is removed with no replacement. This is to prevent code from being able to "walk the stack", which both poses security risks and severely limits the possibility of optimizations like inlining and tail-call optimization. For more explanation, you can read the rationale for the deprecation of `arguments.callee`.

The **`caller`** accessor property of `Function` instances returns the function that invoked this function. For strict, arrow, async, and generator functions, accessing the `caller` property throws a `TypeError`.

Description

If the function `f` was invoked by the top-level code, the value of `f.caller` is `null`; otherwise it's the function that called `f`. If the function that called `f` is a strict mode function, the value of `f.caller` is also `null`.

Note that the only behavior specified by the ECMAScript specification is that `Function.prototype` has an initial `caller` accessor that unconditionally throws a `TypeError` for any `get` or `set` request (known as a "poison pill accessor"), and that implementations are not allowed to change this semantic for any function except non-strict plain functions, in which case it must not have the value of a strict mode function. The actual behavior of the `caller` property, if it's anything other than throwing an error, is implementation-defined. For example, Chrome defines it as an own data property, while Firefox and Safari extend the initial poison-pill `Function.prototype.caller` accessor to specially handle `this` values that are non-strict functions.

```
(function f() {
  if (Object.hasOwn(f, "caller")) {
    console.log(
      "caller is an own property with descriptor",
      Object.getOwnPropertyDescriptor(f, "caller"),
    );
  } else {
    console.log(
      "f doesn't have an own property named caller. Trying to get f.[[Prototype]].caller",
    );
    console.log(
      Object.getOwnPropertyDescriptor(
        Object.getPrototypeOf(f),
        "caller",
      ).get.call(f),
    );
  }
})();

// In Chrome:
// caller is an own property with descriptor {value: null, writable: false, enumerable: false, configurable: false}

// In Firefox:
// f doesn't have an own property named caller. Trying to get f.[[Prototype]].caller
// null
```

This property replaces the obsolete `arguments.caller` property of the `arguments` object.

The special property `__caller__`, which returned the activation object of the caller thus allowing you to reconstruct the stack, was removed for security reasons.

Examples

Checking the value of a function's caller property

The following code checks the value a function's `caller` property.

```
function myFunc() {
  if (myFunc.caller === null) {
    return "The function was called from the top!";
  }
  return `This function's caller was ${myFunc.caller}`;
}
```

Reconstructing the stack and recursion

Note that in case of recursion, you can't reconstruct the call stack using this property. Consider:

```
function f(n) {
  g(n - 1);
}
function g(n) {
  if (n > 0) {
    f(n);
  } else {
    stop();
  }
```

```
}
f(2);
```

At the moment `stop()` is called the call stack will be:

```
f(2) -> g(1) -> f(1) -> g(0) -> stop()
```

The following is true:

```
stop.caller === g && f.caller === g && g.caller === f;
```

so if you tried to get the stack trace in the `stop()` function like this:

```
let f = stop;
let stack = "Stack trace:";
while (f) {
  stack += `\n${f.name}`;
  f = f.caller;
}
```

the loop would never stop.

Strict mode caller

If the caller is a strict mode function, the value of `caller` is `null`.

```
function callerFunc() {
  calleeFunc();
}

function strictCallerFunc() {
  "use strict";
  calleeFunc();
}

function calleeFunc() {
  console.log(calleeFunc.caller);
}

(function () {
  callerFunc();
})();
// Logs [Function: callerFunc]

(function () {
  strictCallerFunc();
})();
// Logs null
```

- `arguments`

Function: displayName

> **Non-standard:** This feature is not standardized. We do not recommend using non-standard features in production, as they have limited browser support, and may change or be removed. However, they can be a suitable alternative in specific cases where no standard option exists.

The optional **`displayName`** property of a `Function` instance specifies the display name of the function.

Value

The `displayName` property is not initially present on any function — it's added by the code authors. For the purpose of display, it should be a string.

Description

The `displayName` property, if present, may be preferred by consoles and profilers over the `name` property to be displayed as the name of a function.

Among browsers, only the Firefox console utilizes this property. React devtools also use the `displayName` property when displaying the component tree.

Firefox does some basic attempts to decode the `displayName` that's possibly generated by the anonymous JavaScript functions naming convention algorithm. The following patterns are detected:

- If `displayName` ends with a sequence of alphanumeric characters, `_`, and `$`, the longest such suffix is displayed.
- If `displayName` ends with a sequence of `[]`-enclosed characters, that sequence is displayed without the square brackets.

- If `displayName` ends with a sequence of alphanumeric characters and _ followed by some `/`, `.`, or `<`, the sequence is returned without the trailing `/`, `.`, or `<` characters.
- If `displayName` ends with a sequence of alphanumeric characters and _ followed by `(^)`, the sequence is displayed without the `(^)`.

If none of the above patterns match, the entire `displayName` is displayed.

Examples

Setting a displayName

By entering the following in a Firefox console, it should display as something like `function MyFunction()`:

```
function a() {}
a.displayName = "MyFunction";

a; // function MyFunction()
```

Changing displayName dynamically

You can dynamically change the `displayName` of a function:

```
const object = {
  // anonymous
  someMethod: function someMethod(value) {
    someMethod.displayName = `someMethod (${value})`;
  },
};

console.log(object.someMethod.displayName); // undefined

object.someMethod("123");
console.log(object.someMethod.displayName); // "someMethod (123)"
```

Cleaning of displayName

Firefox devtools would clean up a few common patterns in the `displayName` property before displaying it.

```
function foo() {}

function testName(name) {
  foo.displayName = name;
  console.log(foo);
}

testName("$foo$"); // function $foo$()
testName("foo bar"); // function bar()
testName("Foo.prototype.add"); // function add()
testName("foo ."); // function foo .()
testName("foo <"); // function foo <()
testName("foo?"); // function foo?()
testName("foo()"); // function foo()()

testName("[...]"); // function ...()
testName("foo<"); // function foo()
testName("foo..."); // function foo()
testName("foo(^)"); // function foo()
```

Specifications

Not part of any standard.

Function() constructor

> **Warning:** The arguments passed to this constructor are dynamically parsed and executed as JavaScript. APIs like this are known as injection sinks, and are potentially a vector for cross-site-scripting (XSS) attacks.
>
> You can mitigate this risk by always passing `TrustedScript` objects instead of strings and enforcing trusted types.
>
> See Security considerations for more information.

The **`Function()`** constructor creates `Function` objects. Calling the constructor directly can create functions dynamically, but suffers from security and similar (but far less significant) performance issues as `eval()`. However, unlike `eval` (which may have access to the local scope), the `Function` constructor creates functions which execute in the global scope only.

Try it

```
const sum = new Function("a", "b", "return a + b");
```

```
console.log(sum(2, 6));
// Expected output: 8
```

Syntax

```
new Function(functionBody)
new Function(arg1, functionBody)
new Function(arg1, arg2, functionBody)
new Function(arg1, arg2, /* …, */ argN, functionBody)

Function(functionBody)
Function(arg1, functionBody)
Function(arg1, arg2, functionBody)
Function(arg1, arg2, /* …, */ argN, functionBody)
```

> **Note:** `Function()` can be called with or without `new`. Both create a new `Function` instance.

Parameters

`arg1, ..., argN` Optional

> `TrustedScript` instances or strings specifying names to be used by the function as formal argument names. The value must correspond to a valid JavaScript parameter (any of plain identifier, rest parameter, or destructured parameter, optionally with a default), or a list of such strings separated with commas.
>
> As the parameters are parsed in the same way as function expressions, whitespace and comments are accepted. For example: `"x", "theValue = 42", "[a, b] /* numbers */"` — or `"x, theValue = 42, [a, b] /* numbers */"`. (`"x, theValue = 42", "[a, b]"` is also correct, though very confusing to read.)

`functionBody`

> A `TrustedScript` or a string containing the JavaScript statements comprising the function definition.

Exceptions

`SyntaxError`

> Function parameter arguments can't be parsed as a valid parameter list, or the `functionBody` can't be parsed as valid JavaScript statements.

`TypeError`

> Any parameter is a string when Trusted Types are enforced by a CSP and no default policy is defined.

Description

`Function` objects created with the `Function` constructor are parsed when the function is created. This is less efficient than creating a function with a function expression or function declaration and calling it within your code, because such functions are parsed with the rest of the code.

All arguments passed to the function, except the last, are treated as the names of the identifiers of the parameters in the function to be created, in the order in which they are passed. The function will be dynamically compiled as a function expression, with the source assembled in the following fashion:

```
`function anonymous(${args.join(",")}
) {
${functionBody}
}`;
```

This is observable by calling the function's `toString()` method.

However, unlike normal function expressions, the name `anonymous` is not added to the `functionBody`'s scope, since `functionBody` only has access the global scope. If `functionBody` is not in strict mode (the body itself needs to have the `"use strict"` directive since it doesn't inherit the strictness from the context), you may use `arguments.callee` to refer to the function itself. Alternatively, you can define the recursive part as an inner function:

```
const recursiveFn = new Function(
  "count",
  `
(function recursiveFn(count) {
  if (count < 0) {
    return;
  }
  console.log(count);
  recursiveFn(count - 1);
})(count);
`,
);
```

Note that the two dynamic parts of the assembled source — the parameters list `args.join(",")` and `functionBody` — will first be parsed separately to ensure they are each syntactically valid. This prevents injection-like attempts.

```
new Function("/*", "*/) {");
// SyntaxError: Unexpected end of arg string
// Doesn't become "function anonymous(/*) {*/) {}"
```

Security considerations

The method can be used to execute arbitrary input passed to any parameter. If the input is a potentially unsafe string provided by a user, this is a possible vector for Cross-site-scripting (XSS) attacks. For example, the following example assumes the `untrustedCode` was provided by a user:

```
const untrustedCode = "alert('Potentially evil code!');";
const adder = new Function("a", "b", untrustedCode);
```

Websites with a Content Security Policy (CSP) that specifies `script-src` or `default-src` will prevent such code running by default. If you must allow the scripts to run via `Function()`, you can mitigate these issues by always assigning `TrustedScript` objects instead of strings, and enforcing trusted types using the `require-trusted-types-for` CSP directive. This ensures that the input is passed through a transformation function.

To allow `Function()` to run, you additionally need to specify the `trusted-types-eval` keyword in your CSP `script-src` directive. The `unsafe-eval` keyword also allows `Function()`, but is much less safe than `trusted-types-eval` because it would allow execution even on browsers that do not support trusted types.

For example, the required CSP for your site might look like this:

```
Content-Security-Policy: require-trusted-types-for 'script'; script-src '<your_allowlist>' 'trusted-types-eval'
```

The behavior of the transformation function depends on the specific use case that requires a user-provided script. If possible, you should lock the allowed scripts to exactly the code that you trust to run. If that is not possible, you might allow or block the use of certain functions within the provided string.

Examples

Note that these examples omit the use of trusted types for brevity. For code showing the recommended approach, see Using `TrustedScript` in `eval()`.

Specifying arguments with the Function constructor

The following code creates a `Function` object that takes two arguments.

```
// Example can be run directly in your JavaScript console

// Create a function that takes two arguments, and returns the sum of those arguments
const adder = new Function("a", "b", "return a + b");

// Call the function
adder(2, 6);
// 8
```

The arguments `a` and `b` are formal argument names that are used in the function body, `return a + b`.

Creating a function object from a function declaration or function expression

```
// The function constructor can take in multiple statements separated by a semicolon. Function expressions require a return statement with the function's
name

// Observe that new Function is called. This is so we can call the function we created directly afterwards
const sumOfArray = new Function(
  "const sumArray = (arr) => arr.reduce((previousValue, currentValue) => previousValue + currentValue); return sumArray",
)();

// call the function
sumOfArray([1, 2, 3, 4]);
// 10

// If you don't call new Function at the point of creation, you can use the Function.call() method to call it
const findLargestNumber = new Function(
  "function findLargestNumber (arr) { return Math.max(...arr) }; return findLargestNumber",
);

// call the function
findLargestNumber.call({}).call({}, [2, 4, 1, 8, 5]);
// 8

// Function declarations do not require a return statement
const sayHello = new Function(
  "return function (name) { return `Hello, ${name}` }",
)();

// call the function
sayHello("world");
// Hello, world
```

Function: length

The **`length`** data property of a `Function` instance indicates the number of parameters expected by the function.

Try it

```
function func1() {}

function func2(a, b) {}

console.log(func1.length);
// Expected output: 0

console.log(func2.length);
// Expected output: 2
```

Value

A number.

Property attributes of `Function: length`	
Writable	no
Enumerable	no
Configurable	yes

Description

A `Function` object's `length` property indicates how many arguments the function expects, i.e., the number of formal parameters:

- Only parameters before the first one with a default value are counted.
- A destructuring pattern counts as a single parameter.
- The rest parameter is excluded.

By contrast, `arguments.length` is local to a function and provides the number of arguments actually passed to the function.

The `Function` constructor is itself a `Function` object. Its `length` data property has a value of `1`.

Due to historical reasons, `Function.prototype` is a callable itself. The `length` property of `Function.prototype` has a value of `0`.

Examples

Using function length

```
console.log(Function.length); // 1

console.log((() => {}).length); // 0
console.log(((a) => {}).length); // 1
console.log(((a, b) => {}).length); // 2 etc.

console.log(((...args) => {}).length);
// 0, rest parameter is not counted

console.log(((a, b = 1, c) => {}).length);
// 1, only parameters before the first one with
// a default value are counted

console.log((({ a, b }, [c, d]) => {}).length);
// 2, destructuring patterns each count as
// a single parameter
```

Function: name

The **`name`** data property of a `Function` instance indicates the function's name as specified when it was created, or it may be either `anonymous` or `''` (an empty string) for functions created anonymously.

Try it

```
const func1 = function () {};

const object = {
  func2: function () {},
};

console.log(func1.name);
// Expected output: "func1"

console.log(object.func2.name);
// Expected output: "func2"
```

Value

A string.

Property attributes of `Function: name`	
Writable	no
Enumerable	no
Configurable	yes

> **Note:** In non-standard, pre-ES2015 implementations the `configurable` attribute was `false` as well.

Description

The function's `name` property can be used to identify the function in debugging tools or error messages. It has no semantic significance to the language itself.

The `name` property is read-only and cannot be changed by the assignment operator:

```
function someFunction() {}

someFunction.name = "otherFunction";
console.log(someFunction.name); // someFunction
```

To change it, use `Object.defineProperty()`.

The `name` property is typically inferred from how the function is defined. In the following sections, we will describe the various ways in which it can be inferred.

Function declaration

The `name` property returns the name of a function declaration.

```
function doSomething() {}
doSomething.name; // "doSomething"
```

Default-exported function declaration

An `export default` declaration exports the function as a declaration instead of an expression. If the declaration is anonymous, the name is `"default"`.

```
// -- someModule.js --
export default function () {}

// -- main.js --
import someModule from "./someModule.js";

someModule.name; // "default"
```

Function constructor

Functions created with the `Function()` constructor have name "anonymous".

```
new Function().name; // "anonymous"
```

Function expression

If the function expression is named, that name is used as the `name` property.

```
const someFunction = function someFunctionName() {};
someFunction.name; // "someFunctionName"
```

Anonymous function expressions, created using either the `function` keyword or the arrow function syntax, have `""` (an empty string) as their name by default.

```
(function () {}).name; // ""
(() => {}).name; // ""
```

However, such cases are rare — usually, in order to call the function elsewhere, the function expression is associated with an identifier. The name of an anonymous function expression can be inferred within certain syntactic contexts, including: variable declaration, method, initializer, and default value.

One practical case where the name cannot be inferred is a function returned from another function:

```
function getFoo() {
  return () => {};
}
getFoo().name; // ""
```

Variable declaration and method

Variables and methods can infer the name of an anonymous function from its syntactic position.

```
const f = function () {};
const object = {
  someMethod: function () {},
};
```

```
console.log(f.name); // "f"
console.log(object.someMethod.name); // "someMethod"
```

The same applies to assignment:

```
let f;
f = () => {};
f.name; // "f"
```

Initializer and default value

Functions in initializers (default values) of destructuring, default parameters, class fields, etc., will inherit the name of the bound identifier as their `name`.

```
const [f = () => {}] = [];
f.name; // "f"

const { someMethod: m = () => {} } = {};
m.name; // "m"

function foo(f = () => {}) {
  console.log(f.name);
}
foo(); // "f"

class Foo {
  static someMethod = () => {};
}
Foo.someMethod.name; // someMethod
```

Shorthand method

```
const o = {
  foo() {},
};
o.foo.name; // "foo";
```

Bound function

`Function.prototype.bind()` produces a function whose name is "bound " plus the function name.

```
function foo() {}
foo.bind({}).name; // "bound foo"
```

Getter and setter

When using `get` and `set` accessor properties, "get" or "set" will appear in the function name.

```
const o = {
  get foo() {
    return 1;
  },
  set foo(x) {},
};

const descriptor = Object.getOwnPropertyDescriptor(o, "foo");
descriptor.get.name; // "get foo"
descriptor.set.name; // "set foo";
```

Class

A class's name follows the same algorithm as function declarations and expressions.

```
class Foo {}
Foo.name; // "Foo"
```

> **Warning:** JavaScript will set the function's `name` property only if a function does not have an own property called `name`. However, classes' static members will be set as own properties of the class constructor function, and thus prevent the built-in `name` from being applied. See an example below.

Symbol as function name

If a `Symbol` is used a function name and the symbol has a description, the method's name is the description in square brackets.

```
const sym1 = Symbol("foo");
const sym2 = Symbol();

const o = {
  [sym1]() {},
  [sym2]() {},
};
```

```
o[sym1].name; // "[foo]"
o[sym2].name; // "[]"
```

Private fields and methods

Private fields and private methods have the hash (`#`) as part of their names.

```
class Foo {
  #field = () => {};
  #method() {}
  getNames() {
    console.log(this.#field.name);
    console.log(this.#method.name);
  }
}

new Foo().getNames();
// "#field"
// "#method"
```

Examples

Telling the constructor name of an object

You can use `obj.constructor.name` to check the "class" of an object.

```
function Foo() {} // Or: class Foo {}

const fooInstance = new Foo();
console.log(fooInstance.constructor.name); // "Foo"
```

However, because static members will become own properties of the class, we can't obtain the class name for virtually any class with a static method property `name()`:

```
class Foo {
  constructor() {}
  static name() {}
}
```

With a `static name()` method `Foo.name` no longer holds the actual class name but a reference to the `name()` function object. Trying to obtain the class of `fooInstance` via `fooInstance.constructor.name` won't give us the class name at all, but instead a reference to the static class method. Example:

```
const fooInstance = new Foo();
console.log(fooInstance.constructor.name); // ƒ name() {}
```

Due to the existence of static fields, `name` may not be a function either.

```
class Foo {
  static name = 123;
}
console.log(new Foo().constructor.name); // 123
```

If a class has a static property called `name`, it will also become *writable*. The built-in definition in the absence of a custom static definition is *read-only*.

```
Foo.name = "Hello";
console.log(Foo.name); // "Hello" if class Foo has a static "name" property, but "Foo" if not.
```

Therefore you may not rely on the built-in `name` property to always hold a class's name.

JavaScript compressors and minifiers

> **Warning:** Be careful when using the `name` property with source-code transformations, such as those carried out by JavaScript compressors (minifiers) or obfuscators. These tools are often used as part of a JavaScript build pipeline to reduce the size of a program prior to deploying it to production. Such transformations often change a function's name at build time.

Source code such as:

```
function Foo() {}
const foo = new Foo();

if (foo.constructor.name === "Foo") {
  console.log("'foo' is an instance of 'Foo'");
} else {
  console.log("Oops!");
}
```

may be compressed to:

```
function a() {}
const b = new a();
if (b.constructor.name === "Foo") {
  console.log("'foo' is an instance of 'Foo'");
} else {
  console.log("Oops!");
}
```

In the uncompressed version, the program runs into the truthy branch and logs "'foo' is an instance of 'Foo'" — whereas, in the compressed version it behaves differently, and runs into the else branch. If you rely on the `name` property, like in the example above, make sure your build pipeline doesn't change function names, or don't assume a function has a particular name.

Function: prototype

The **`prototype`** data property of a `Function` instance is used when the function is used as a constructor with the `new` operator. It will become the new object's prototype.

> **Note:** Not all `Function` objects have the `prototype` property — see description.

Value

An object.

Property attributes of `Function: prototype`	
Writable	yes
Enumerable	no
Configurable	no

> **Note:** Classes are a type of function, so most of the description here applies to the `prototype` property of classes too. The only salient difference is that the `prototype` property of a class is not writable.

Description

When a function is called with `new`, the constructor's `prototype` property will become the resulting object's prototype.

```
function Ctor() {}
const inst = new Ctor();
console.log(Object.getPrototypeOf(inst) === Ctor.prototype); // true
```

You can read Inheritance and the prototype chain for more information about the interactions between a constructor function's `prototype` property and the resulting object's prototype.

A function having a `prototype` property is not sufficient for it to be eligible as a constructor. Generator functions have a `prototype` property, but cannot be called with `new`:

```
async function* asyncGeneratorFunction() {}
function* generatorFunction() {}
```

Instead, generator functions' `prototype` property is used when they are called *without* `new`. The `prototype` property will become the returned `Generator` object's prototype.

In addition, some functions may have a `prototype` but throw unconditionally when called with `new`. For example, the `Symbol()` and `BigInt()` functions throw when called with `new`, because `Symbol.prototype` and `BigInt.prototype` are only intended to provide methods for the primitive values, but the wrapper objects should not be directly constructed.

The following functions do not have `prototype`, and are therefore ineligible as constructors, even if a `prototype` property is later manually assigned:

```
const method = { foo() {} }.foo;
const arrowFunction = () => {};
async function asyncFunction() {}
```

The following are valid constructors that have `prototype`:

```
class Class {}
function fn() {}
```

A bound function does not have a `prototype` property, but may be constructable. When it's constructed, the target function is constructed instead, and if the target function is constructable, it would return a normal instance.

```
const boundFunction = function () {}.bind(null);
```

A function's `prototype` property, by default, is a plain object with one property: `constructor`, which is a reference to the function itself. The `constructor` property is writable, non-enumerable, and configurable.

If the `prototype` of a function is reassigned with something other than an `Object`, when the function is called with `new`, the returned object's prototype would be `Object.prototype` instead. (In other words, `new` ignores the `prototype` property and constructs a plain object.)

```
function Ctor() {}
Ctor.prototype = 3;
console.log(Object.getPrototypeOf(new Ctor()) === Object.prototype); // true
```

Examples

Changing the prototype of all instances by mutating the prototype property

```
function Ctor() {}
const p1 = new Ctor();
const p2 = new Ctor();
Ctor.prototype.prop = 1;
console.log(p1.prop); // 1
console.log(p2.prop); // 1
```

Adding a non-method property to a class's prototype property

Class fields add properties to each instance. Class methods declare *function* properties on the prototype. However, there's no way to add a non-function property to the prototype. In case you want to share static data between all instances (for example, `Error.prototype.name` is the same between all error instances), you can manually assign it on the `prototype` of a class.

```
class Dog {
  constructor(name) {
    this.name = name;
  }
}

Dog.prototype.species = "dog";

console.log(new Dog("Jack").species); // "dog"
```

This can be made more ergonomic using static initialization blocks, which are called when the class is initialized.

```
class Dog {
  static {
    Dog.prototype.species = "dog";
  }
  constructor(name) {
    this.name = name;
  }
}

console.log(new Dog("Jack").species); // "dog"
```

- Inheritance and the prototype chain

Function.prototype[Symbol.hasInstance]()

The **`[Symbol.hasInstance]()`** method of `Function` instances specifies the default procedure for determining if a constructor function recognizes an object as one of the constructor's instances. It is called by the `instanceof` operator.

Syntax

```
func[Symbol.hasInstance](value)
```

Parameters

`value`

The object to test. Primitive values always return `false`.

Return value

`true` if `func.prototype` is in the prototype chain of `value`; otherwise, `false`. Always returns `false` if `value` is not an object or `this` is not a function. If `this` is a bound function, returns the result of an `instanceof` test on `value` and the underlying target function.

Exceptions

`TypeError`

Thrown if `this` is not a bound function and `this.prototype` is not an object.

Description

The `instanceof` operator calls the `[Symbol.hasInstance]()` method of the right-hand side whenever such a method exists. Because all functions inherit from `Function.prototype` by default, they would all have the `[Symbol.hasInstance]()` method, so most of the time, the `Function.prototype[Symbol.hasInstance]()` method specifies the behavior of `instanceof` when the right-hand side is a function. This method implements the default behavior of the `instanceof` operator (the same algorithm when `constructor` has no `[Symbol.hasInstance]()` method).

Unlike most methods, the `Function.prototype[Symbol.hasInstance]()` property is non-configurable and non-writable. This is a security feature to prevent the underlying target function of a bound function from being obtainable. See this Stack Overflow answer for an example.

Examples

Reverting to default instanceof behavior

You would rarely need to call this method directly. Instead, this method is called by the `instanceof` operator. You should expect the two results to usually be equivalent.

```
class Foo {}
const foo = new Foo();
console.log(foo instanceof Foo === Foo[Symbol.hasInstance](foo)); // true
```

You may want to use this method if you want to invoke the default `instanceof` behavior, but you don't know if a constructor has an overridden `[Symbol.hasInstance]()` method.

```
class Foo {
  static [Symbol.hasInstance](value) {
    // A custom implementation
    return false;
  }
}

const foo = new Foo();
console.log(foo instanceof Foo); // false
console.log(Function.prototype[Symbol.hasInstance].call(Foo, foo)); // true
```

See also

- `instanceof`
- `Symbol.hasInstance`

Function.prototype.toString()

The **`toString()`** method of `Function` instances returns a string representing the source code of this function.

Try it

```
function sum(a, b) {
  return a + b;
}

console.log(sum.toString());
// Expected output: "function sum(a, b) {
//                     return a + b;
//                   }"

console.log(Math.abs.toString());
// Expected output: "function abs() { [native code] }"
```

Syntax

```
toString()
```

Parameters

None.

Return value

A string representing the source code of the function.

Description

The `Function` object overrides the `toString()` method inherited from `Object`; it does not inherit `Object.prototype.toString`. For user-defined `Function` objects, the `toString` method returns a string containing the source text segment which was used to define the function.

JavaScript calls the `toString` method automatically when a `Function` is to be represented as a text value, e.g., when a function is concatenated with a string.

The `toString()` method will throw a `TypeError` exception ("Function.prototype.toString called on incompatible object"), if its `this` value object is not a `Function` object.

```
Function.prototype.toString.call("foo"); // throws TypeError
```

If the `toString()` method is called on built-in function objects, a function created by `Function.prototype.bind()`, or other non-JavaScript functions, then `toString()` returns a *native function string* which looks like

```
function someName() { [native code] }
```

For intrinsic object methods and functions, `someName` is the initial name of the function; otherwise its content may be implementation-defined, but will always be in property name syntax, like `[1 + 1]`, `someName`, or `1`.

> **Note:** This means using `eval()` on native function strings is a guaranteed syntax error.

If the `toString()` method is called on a function created by the `Function` constructor, `toString()` returns the source code of a synthesized function declaration named "anonymous" using the provided parameters and function body. For example, `Function("a", "b", "return a + b").toString()` will return:

```
function anonymous(a,b
) {
return a + b
}
```

Since ES2018, the spec requires the return value of `toString()` to be the exact same source code as it was declared, including any whitespace and/or comments — or, if the host doesn't have the source code available for some reason, requires returning a native function string. Support for this revised behavior can be found in the compatibility table.

Examples

Comparing actual source code and toString results

```
function test(fn) {
  console.log(fn.toString());
}

function f() {}
class A {
  a() {}
}
function* g() {}

test(f); // "function f() {}"
test(A); // "class A { a() {} }"
test(g); // "function* g() {}"
test((a) => a); // "(a) => a"
test({ a() {} }.a); // "a() {}"
test({ *a() {} }.a); // "*a() {}"
test({ [0]() {} }[0]); // "[0]() {}"
test(Object.getOwnPropertyDescriptor({ get a() {} }, "a").get); // "get a() {}"
test(Object.getOwnPropertyDescriptor({ set a(x) {} }, "a").set); // "set a(x) {}"
test(Function.prototype.toString); // "function toString() { [native code] }"
test(function f() {}.bind(0)); // "function () { [native code] }"
test(Function("a", "b")); // function anonymous(a\n) {\nb\n}
```

Note that after the `Function.prototype.toString()` revision, when `toString()` is called, implementations are never allowed to synthesize a function's source that is not a native function string. The method always returns the exact source code used to create the function — including the getter and setter examples above. The `Function` constructor itself has the capability of synthesizing the source code for the function (and is therefore a form of implicit `eval()`).

Getting source text of a function

It is possible to get the source text of a function by coercing it to a string — for example, by wrapping it in a template literal:

```
function foo() {
  return "bar";
}
console.log(`${foo}`);
// function foo() {
//   return "bar";
// }
```

This source text is *exact*, including any interspersed comments (which won't be stored by the engine's internal representation otherwise).

```
function foo /* a comment */() {
  return "bar";
}
console.log(foo.toString());
// function foo /* a comment */() {
//   return "bar";
// }
```

- `Object.prototype.toString()`

Generator

The **`Generator`** object is returned by a generator function and it conforms to both the iterable protocol and the iterator protocol.

`Generator` is a subclass of the `Iterator` class.

Constructor

There's no JavaScript entity that corresponds to the `Generator` constructor. Instances of `Generator` must be returned from generator functions:

```
function* generator() {
  yield 1;
  yield 2;
  yield 3;
}

const gen = generator(); // "Generator { }"

console.log(gen.next().value); // 1
console.log(gen.next().value); // 2
console.log(gen.next().value); // 3
```

There's only a hidden object which is the prototype object shared by all objects created by generator functions. This object is often stylized as `Generator.prototype` to make it look like a class, but it should be more appropriately called `GeneratorFunction.prototype.prototype`, because `GeneratorFunction` is an actual JavaScript entity. To understand the prototype chain of `Generator` instances, see `GeneratorFunction.prototype.prototype`.

Instance properties

These properties are defined on `Generator.prototype` and shared by all `Generator` instances.

`Generator.prototype.constructor`

> The constructor function that created the instance object. For `Generator` instances, the initial value is `GeneratorFunction.prototype`.
>
> > **Note:** `Generator` objects do not store a reference to the generator function that created them.

`Generator.prototype[Symbol.toStringTag]`

> The initial value of the `[Symbol.toStringTag]` property is the string `"Generator"`. This property is used in `Object.prototype.toString()`.

Instance methods

Also inherits instance methods from its parent `Iterator`.

`Generator.prototype.next()`

> Returns a value yielded by the `yield` expression.

`Generator.prototype.return()`

> Acts as if a `return` statement is inserted in the generator's body at the current suspended position, which finishes the generator and allows the generator to perform any cleanup tasks when combined with a `try...finally` block.

`Generator.prototype.throw()`

> Acts as if a `throw` statement is inserted in the generator's body at the current suspended position, which informs the generator of an error condition and allows it to handle the error, or perform cleanup and close itself.

Examples

An infinite iterator

With a generator function, values are not evaluated until they are needed. Therefore a generator allows us to define a potentially infinite data structure.

```
function* infinite() {
  let index = 0;

  while (true) {
    yield index++;
  }
}

const generator = infinite(); // "Generator { }"

console.log(generator.next().value); // 0
console.log(generator.next().value); // 1
console.log(generator.next().value); // 2
// …
```

- Iteration protocols

Generator.prototype.next()

The **`next()`** method of `Generator` instances returns an object with two properties `done` and `value`. You can also provide a parameter to the `next` method to send a value to the generator.

Syntax

```
next()
next(value)
```

Parameters

`value` Optional

The value to send to the generator.

The value will be assigned as a result of a `yield` expression. For example, in `variable = yield expression`, the value passed to the `.next()` function will be assigned to `variable`.

Return value

An `Object` with two properties:

`done`

A boolean value:

- `true` if the generator is past the end of its control flow. In this case `value` specifies the *return value* of the generator (which may be undefined).
- `false` if the generator is able to produce more values.

`value`

Any JavaScript value yielded or returned by the generator.

Exceptions

`TypeError`

Thrown if the generator is already running.

Examples

Using next()

The following example shows a generator and the object that the `next` method returns:

```
function* gen() {
  yield 1;
  yield 2;
  yield 3;
}

const g = gen(); // Generator { }
g.next(); // { value: 1, done: false }
g.next(); // { value: 2, done: false }
g.next(); // { value: 3, done: false }
g.next(); // { value: undefined, done: true }
```

Using next() with a list

In this example, `getPage` takes a list and "paginates" it into chunks of size `pageSize`. Each call to `next` will yield one such chunk.

```
function* getPage(list, pageSize = 1) {
  for (let index = 0; index < list.length; index += pageSize) {
    yield list.slice(index, index + pageSize);
  }
}

const list = [1, 2, 3, 4, 5, 6, 7, 8];
const page = getPage(list, 3); // Generator { }

page.next(); // { value: [1, 2, 3], done: false }
page.next(); // { value: [4, 5, 6], done: false }
page.next(); // { value: [7, 8], done: false }
page.next(); // { value: undefined, done: true }
```

Sending values to the generator

In this example, `next` is called with a value.

> **Note:** The first call does not log anything, because the generator was not yielding anything initially.

```
function* gen() {
  while (true) {
    const value = yield;
    console.log(value);
  }
}

const g = gen();
g.next(1); // Returns { value: undefined, done: false }
// No log at this step: the first value sent through `next` is lost
g.next(2); // Returns { value: undefined, done: false }
// Logs 2
```

- `function*`
- Iterators and generators guide

Generator.prototype.return()

The **`return()`** method of `Generator` instances acts as if a `return` statement is inserted in the generator's body at the current suspended position, which finishes the generator and allows the generator to perform any cleanup tasks when combined with a `try...finally` block.

Syntax

```
generatorInstance.return()
generatorInstance.return(value)
```

Parameters

`value` Optional

The value to return.

Return value

An `Object` with two properties:

`done`

A boolean value:

- `true` if the generator function's control flow has reached the end.
- `false` if the generator function's control flow hasn't reached the end and can produce more values. This can only happen if the `return` is captured in a `try...finally` and there are more `yield` expressions in the `finally` block.

`value`

The value that is given as an argument, or, if the `yield` expression is wrapped in a `try...finally`, the value yielded/returned from the `finally` block.

Exceptions

`TypeError`

Thrown if the generator is already running.

Description

The `return()` method, when called, can be seen as if a `return value;` statement is inserted in the generator's body at the current suspended position, where `value` is the value passed to the `return()` method. Therefore, in a typical flow, calling `return(value)` will return `{ done: true, value: value }`. However, if the `yield` expression is wrapped in a `try...finally` block, the control flow doesn't exit the function body, but proceeds to the `finally` block instead. In this case, the value returned may be different, and `done` may even be `false`, if there are more `yield` expressions within the `finally` block.

Examples

Using return()

The following example shows a generator and the `return` method.

```
function* gen() {
  yield 1;
  yield 2;
  yield 3;
}

const g = gen();

g.next(); // { value: 1, done: false }
g.return("foo"); // { value: "foo", done: true }
g.next(); // { value: undefined, done: true }
```

If `return(value)` is called on a generator that is already in "completed" state, the generator will remain in "completed" state.

If no argument is provided, the `value` property of the returned object will be `undefined`. If an argument is provided, it will become the value of the `value` property of the returned object, unless the `yield` expression is wrapped in a `try...finally`.

```
function* gen() {
  yield 1;
  yield 2;
  yield 3;
}

const g = gen();
g.next(); // { value: 1, done: false }
g.next(); // { value: 2, done: false }
g.next(); // { value: 3, done: false }
g.next(); // { value: undefined, done: true }
g.return(); // { value: undefined, done: true }
g.return(1); // { value: 1, done: true }
```

Using return() with try...finally

The fact that the `return` method has been called can only be made known to the generator itself if the `yield` expression is wrapped in a `try...finally` block.

When the `return` method is called on a generator that is suspended within a `try` block, execution in the generator proceeds to the `finally` block — since the `finally` block of `try...finally` statements always executes.

```
function* gen() {
  yield 1;
  try {
    yield 2;
    yield 3;
  } finally {
    yield "cleanup";
  }
}

const g1 = gen();
g1.next(); // { value: 1, done: false }

// Execution is suspended before the try...finally.
g1.return("early return"); // { value: 'early return', done: true }

const g2 = gen();
g2.next(); // { value: 1, done: false }
g2.next(); // { value: 2, done: false }

// Execution is suspended within the try...finally.
g2.return("early return"); // { value: 'cleanup', done: false }

// The completion value is preserved
g2.next(); // { value: 'early return', done: true }

// Generator is in the completed state
g2.return("not so early return"); // { value: 'not so early return', done: true }
```

The return value of the finally block can also become the `value` of the result returned from the `return` call.

```
function* gen() {
  try {
    yield 1;
  } finally {
    return "cleanup";
  }
}

const generator = gen();
generator.next(); // { value: 1, done: false }
generator.return("early return"); // { value: 'cleanup', done: true }
```

See also

- `function*`

Generator.prototype.throw()

The **`throw()`** method of `Generator` instances acts as if a `throw` statement is inserted in the generator's body at the current suspended position, which informs the generator of an error condition and allows it to handle the error, or perform cleanup and close itself.

Syntax

```
generatorInstance.throw(exception)
```

Parameters

`exception`

The exception to throw. For debugging purposes, it is useful to make it an `instanceof` `Error`.

Return value

If the thrown exception is caught by a `try...catch` and the generator resumes to yield more values, it will return an `Object` with two properties:

`done`

A boolean value:

- `true` if the generator function's control flow has reached the end.
- `false` if the generator function is able to produce more values.

`value`

The value yielded from the next `yield` expression.

Exceptions

`TypeError`

Thrown if the generator is already running.

If the `exception` is not caught by a `try...catch` within the generator function, it is also thrown to the caller of `throw()`.

Description

The `throw()` method, when called, can be seen as if a `throw exception;` statement is inserted in the generator's body at the current suspended position, where `exception` is the exception passed to the `throw()` method. Therefore, in a typical flow, calling `throw(exception)` will cause the generator to throw. However, if the `yield` expression is wrapped in a `try...catch` block, the error may be caught and control flow can either resume after error handling, or exit gracefully.

Examples

Using throw()

The following example shows a generator and an error that is thrown using the `throw` method. An error can be caught by a `try...catch` block as usual.

```
function* gen() {
  while (true) {
    try {
      yield 42;
    } catch (e) {
      console.log("Error caught!");
    }
  }
}

const g = gen();
g.next();
// { value: 42, done: false }
g.throw(new Error("Something went wrong"));
// "Error caught!"
// { value: 42, done: false }
```

- `function*`

GeneratorFunction

The **`GeneratorFunction`** object provides methods for generator functions. In JavaScript, every generator function is actually a `GeneratorFunction` object.

Note that `GeneratorFunction` is *not* a global object. It can be obtained with the following code:

```
const GeneratorFunction = function* () {}.constructor;
```

`GeneratorFunction` is a subclass of `Function`.

Try it

```
const GeneratorFunction = function* () {}.constructor;

const foo = new GeneratorFunction(`
  yield 'a';
  yield 'b';
  yield 'c';
`);

let str = "";
for (const val of foo()) {
  str += val;
}

console.log(str);
// Expected output: "abc"
```

Constructor

`GeneratorFunction()`

> Creates a new `GeneratorFunction` object.

Instance properties

Also inherits instance properties from its parent `Function`.

These properties are defined on `GeneratorFunction.prototype` and shared by all `GeneratorFunction` instances.

`GeneratorFunction.prototype.constructor`

> The constructor function that created the instance object. For `GeneratorFunction` instances, the initial value is the `GeneratorFunction` constructor.

`GeneratorFunction.prototype.prototype`

> All generator functions share the same `prototype` property, which is `Generator.prototype`. Each generator function created with the `function*` syntax or the `GeneratorFunction()` constructor also has its own `prototype` property, whose prototype is `GeneratorFunction.prototype.prototype`. When the generator function is called, its `prototype` property becomes the prototype of the returned generator object.

`GeneratorFunction.prototype[Symbol.toStringTag]`

> The initial value of the `[Symbol.toStringTag]` property is the string `"GeneratorFunction"`. This property is used in `Object.prototype.toString()`.

These properties are own properties of each `GeneratorFunction` instance.

`prototype`

> Used when the function is used as a constructor with the `new` operator. It will become the new object's prototype.

Instance methods

Inherits instance methods from its parent `Function`.

GeneratorFunction() constructor

> **Warning:** The arguments passed to this constructor are dynamically parsed and executed as JavaScript. APIs like this are known as injection sinks, and are potentially a vector for cross-site-scripting (XSS) attacks.
>
> You can mitigate this risk by always passing `TrustedScript` objects instead of strings and enforcing trusted types.
>
> See Security considerations in the `Function()` constructor reference for more information.

The **`GeneratorFunction()`** constructor creates `GeneratorFunction` objects.

Note that `GeneratorFunction` is *not* a global object. It can be obtained with the following code:

```
const GeneratorFunction = function* () {}.constructor;
```

The `GeneratorFunction()` constructor is not intended to be used directly, and all caveats mentioned in the `Function()` description apply to `GeneratorFunction()`.

Syntax

```
new GeneratorFunction(functionBody)
new GeneratorFunction(arg1, functionBody)
new GeneratorFunction(arg1, arg2, functionBody)
new GeneratorFunction(arg1, arg2, /* …, */ argN, functionBody)

GeneratorFunction(functionBody)
GeneratorFunction(arg1, functionBody)
GeneratorFunction(arg1, arg2, functionBody)
GeneratorFunction(arg1, arg2, /* …, */ argN, functionBody)
```

> **Note:** `GeneratorFunction()` can be called with or without `new`. Both create a new `GeneratorFunction` instance.

Parameters

See `Function()`.

Examples

Note that these examples omit the use of trusted types for brevity. For code showing the recommended approach, see Using `TrustedScript` in `eval()`.

Creating and using a GeneratorFunction() constructor

```
const GeneratorFunction = function* () {}.constructor;
const g = new GeneratorFunction("a", "yield a * 2");
const iterator = g(10);
console.log(iterator.next().value); // 20
```

- Functions

GeneratorFunction.prototype.prototype

The **`prototype`** property of `GeneratorFunction.prototype` is shared by all generator functions. Its value is `Generator.prototype`. Each generator function created with the `function*` syntax or the `GeneratorFunction()` constructor also has its own `prototype` property, whose prototype is `GeneratorFunction.prototype.prototype`. When the generator function is called, its `prototype` property becomes the prototype of the returned generator object.

Value

The same object as `Generator.prototype`. `GeneratorFunction.prototype.prototype` is the technically more accurate name, but `Generator.prototype` appeals to the intuition that it's the prototype of generator objects.

Property attributes of `GeneratorFunction.prototype.prototype`	
Writable	yes
Enumerable	no
Configurable	no

The `prototype` property of each `GeneratorFunction` instance is an empty object with no properties, whose prototype is `GeneratorFunction.prototype.prototype`. It has the following property attributes:

Property attributes of `GeneratorFunction.prototype.prototype`	
Writable	no
Enumerable	no
Configurable	yes

Description

A generator function instance has two `prototype` properties. The first one is its own `prototype` property. The second one is the `prototype` property on its prototype, which is `GeneratorFunction.prototype`. (Remember that every generator function is an instance of `GeneratorFunction`, so it has `GeneratorFunction.prototype` as its prototype.)

```
function* genFunc() {}
const GeneratorFunctionPrototype = Object.getPrototypeOf(genFunc);
console.log(Object.hasOwn(genFunc, "prototype")); // true
console.log(Object.hasOwn(GeneratorFunctionPrototype, "prototype")); // true
```

When a generator function is called, the generator function's `prototype` property becomes the prototype of the returned generator object.

```
const gen = genFunc();
const proto = Object.getPrototypeOf;
console.log(proto(gen) === genFunc.prototype); // true
console.log(proto(proto(gen)) === GeneratorFunctionPrototype.prototype); // true
```

The following diagram illustrates the prototype chain of a generator function and its instances. Each hollow arrow indicates an inheritance relationship (i.e., a prototype link), and each solid arrow indicates a property relationship. Note that there's no way to access `genFunc` from `gen` — they only have an `instanceof` relationship.

globalThis

The **`globalThis`** global property contains the global `this` value, which is usually akin to the global object.

Try it

```
function canMakeHTTPRequest() {
  return typeof globalThis.XMLHttpRequest === "function";
}

console.log(canMakeHTTPRequest());
// Expected output (in a browser): true
```

Value

The global `this` object.

Property attributes of `globalThis`	
Writable	yes
Enumerable	no
Configurable	yes

> **Note:** The `globalThis` property is configurable and writable so that code authors can hide it when executing untrusted code and prevent exposing the global object.

Description

Historically, accessing the global object has required different syntax in different JavaScript environments. On the web you can use `window`, `self`, or `frames` - but in Web Workers only `self` will work. In Node.js none of these work, and you must instead use `global`. The `this` keyword could be used inside functions running in non–strict mode, but `this` will be `undefined` in modules and inside functions running in strict mode. You can also use `Function('return this')()`, but environments that disable `eval()`, like CSP in browsers, prevent use of `Function` in this way.

The `globalThis` property provides a standard way of accessing the global `this` value (and hence the global object itself) across environments. Unlike similar properties such as `window` and `self`, it's guaranteed to work in window and non-window contexts. In this way, you can access the global object in a consistent manner without having to know which environment the code is being run in. To help you remember the name, just remember that in global scope the `this` value is `globalThis`.

> **Note:** `globalThis` is generally the same concept as the global object (i.e., adding properties to `globalThis` makes them global variables) — this is the case for browsers and Node — but hosts are allowed to provide a different value for `globalThis` that's unrelated to the global object.

HTML and the WindowProxy

In many engines `globalThis` will be a reference to the actual global object, but in web browsers, due to iframe and cross-window security considerations, it references a `Proxy` around the actual global object (which you can't directly access). This distinction is rarely relevant in common usage, but important to be aware of.

Naming

Several other popular name choices such as `self` and `global` were removed from consideration because of their potential to break compatibility with existing code. See the language proposal's "naming" document for more details.

`globalThis` is, quite literally, the global `this` value. It's the same value as the `this` value in a non-strict function called without an object. It's also the value of `this` in the global scope of a script.

Examples

Search for the global across environments

Usually, the global object does not need to be explicitly specified — its properties are automatically accessible as global variables.

```
console.log(window.Math === Math); // true
```

However, one case where one needs to explicitly access the global object is when *writing* to it, usually for the purpose of polyfills.

Prior to `globalThis`, the only reliable cross-platform way to get the global object for an environment was `Function('return this')()`. However, this causes CSP violations in some settings, so authors would use a piecewise definition like this (slightly adapted from the original core-js source):

```
function check(it) {
  // Math is known to exist as a global in every environment.
  return it && it.Math === Math && it;
}

const globalObject =
  check(typeof window === "object" && window) ||
  check(typeof self === "object" && self) ||
  check(typeof global === "object" && global) ||
  // This returns undefined when running in strict mode
  (function () {
    return this;
```

```
  })() ||
  Function("return this")();
```

After obtaining the global object, we can define new globals on it. For example, adding an implementation for `Intl`:

```
if (typeof globalObject.Intl === "undefined") {
  // No Intl in this environment; define our own on the global scope
  Object.defineProperty(globalObject, "Intl", {
    value: {
      // Our Intl implementation
    },
    enumerable: false,
    configurable: true,
    writable: true,
  });
}
```

With `globalThis` available, the additional search for the global across environments is not necessary anymore:

```
if (typeof globalThis.Intl === "undefined") {
  Object.defineProperty(globalThis, "Intl", {
    value: {
      // Our Intl implementation
    },
    enumerable: false,
    configurable: true,
    writable: true,
  });
}
```

- `this`

Infinity

The **`Infinity`** global property is a numeric value representing infinity.

Try it

```
const maxNumber = 10 ** 1000; // Max positive number

if (maxNumber === Infinity) {
  console.log("Let's call it Infinity!");
  // Expected output: "Let's call it Infinity!"
}

console.log(1 / maxNumber);
// Expected output: 0
```

Value

The same number value as `Number.POSITIVE_INFINITY`.

Property attributes of `Infinity`	
Writable	no
Enumerable	no
Configurable	no

Description

`Infinity` is a property of the *global object*. In other words, it is a variable in global scope.

The value `Infinity` (positive infinity) is greater than any other number.

This value behaves slightly differently than mathematical infinity; see `Number.POSITIVE_INFINITY` for details.

Examples

Using Infinity

```
console.log(Infinity); /* Infinity */
console.log(Infinity + 1); /* Infinity */
console.log(10 ** 1000); /* Infinity */
console.log(Math.log(0)); /* -Infinity */
console.log(1 / Infinity); /* 0 */
console.log(1 / 0); /* Infinity */
```

Int16Array

The **`Int16Array`** typed array represents an array of 16-bit signed integers in the platform byte order. If control over byte order is needed, use `DataView` instead. The contents are initialized to `0` unless initialization data is explicitly provided. Once established, you can reference elements in the array using the object's methods, or using standard array index syntax (that is, using bracket notation).

`Int16Array` is a subclass of the hidden `TypedArray` class.

Constructor

`Int16Array()`

Creates a new `Int16Array` object.

Static properties

Also inherits static properties from its parent `TypedArray`.

`Int16Array.BYTES_PER_ELEMENT`

Returns a number value of the element size. `2` in the case of `Int16Array`.

Static methods

Inherits static methods from its parent `TypedArray`.

Instance properties

Also inherits instance properties from its parent `TypedArray`.

These properties are defined on `Int16Array.prototype` and shared by all `Int16Array` instances.

`Int16Array.prototype.BYTES_PER_ELEMENT`

Returns a number value of the element size. `2` in the case of an `Int16Array`.

`Int16Array.prototype.constructor`

The constructor function that created the instance object. For `Int16Array` instances, the initial value is the `Int16Array` constructor.

Instance methods

Inherits instance methods from its parent `TypedArray`.

Examples

Different ways to create an Int16Array

```
// From a length
const int16 = new Int16Array(2);
int16[0] = 42;
console.log(int16[0]); // 42
console.log(int16.length); // 2
console.log(int16.BYTES_PER_ELEMENT); // 2

// From an array
const x = new Int16Array([21, 31]);
console.log(x[1]); // 31

// From another TypedArray
const y = new Int16Array(x);
console.log(y[0]); // 21

// From an ArrayBuffer
const buffer = new ArrayBuffer(16);
const z = new Int16Array(buffer, 2, 4);
console.log(z.byteOffset); // 2

// From an iterable
const iterable = (function* () {
  yield* [1, 2, 3];
})();
const int16FromIterable = new Int16Array(iterable);
console.log(int16FromIterable);
// Int16Array [1, 2, 3]
```

- `ArrayBuffer`
- `DataView`

Int16Array() constructor

The **`Int16Array()`** constructor creates `Int16Array` objects. The contents are initialized to `0` unless initialization data is explicitly provided.

Syntax

```
new Int16Array()
new Int16Array(length)
new Int16Array(typedArray)
new Int16Array(object)

new Int16Array(buffer)
new Int16Array(buffer, byteOffset)
new Int16Array(buffer, byteOffset, length)
```

> **Note:** `Int16Array()` can only be constructed with `new`. Attempting to call it without `new` throws a `TypeError`.

Parameters

See `TypedArray`.

Exceptions

See `TypedArray`.

Examples

Different ways to create an Int16Array

```
// From a length
const int16 = new Int16Array(2);
int16[0] = 42;
console.log(int16[0]); // 42
console.log(int16.length); // 2
console.log(int16.BYTES_PER_ELEMENT); // 2

// From an array
const x = new Int16Array([21, 31]);
console.log(x[1]); // 31

// From another TypedArray
const y = new Int16Array(x);
console.log(y[0]); // 21

// From an ArrayBuffer
const buffer = new ArrayBuffer(16);
const z = new Int16Array(buffer, 2, 4);
console.log(z.byteOffset); // 2

// From an iterable
const iterable = (function* () {
  yield* [1, 2, 3];
})();
const int16FromIterable = new Int16Array(iterable);
console.log(int16FromIterable);
// Int16Array [1, 2, 3]
```

Int32Array

The **`Int32Array`** typed array represents an array of 32-bit signed integers in the platform byte order. If control over byte order is needed, use `DataView` instead. The contents are initialized to `0` unless initialization data is explicitly provided. Once established, you can reference elements in the array using the object's methods, or using standard array index syntax (that is, using bracket notation).

`Int32Array` is a subclass of the hidden `TypedArray` class.

Constructor

`Int32Array()`

Creates a new `Int32Array` object.

Static properties

Also inherits static properties from its parent `TypedArray`.

`Int32Array.BYTES_PER_ELEMENT`

> Returns a number value of the element size. `4` in the case of `Int32Array`.

Static methods

Inherits static methods from its parent `TypedArray`.

Instance properties

Also inherits instance properties from its parent `TypedArray`.

These properties are defined on `Int32Array.prototype` and shared by all `Int32Array` instances.

`Int32Array.prototype.BYTES_PER_ELEMENT`

> Returns a number value of the element size. `4` in the case of an `Int32Array`.

`Int32Array.prototype.constructor`

> The constructor function that created the instance object. For `Int32Array` instances, the initial value is the `Int32Array` constructor.

Instance methods

Inherits instance methods from its parent `TypedArray`.

Examples

Different ways to create an Int32Array

```
// From a length
const int32 = new Int32Array(2);
int32[0] = 42;
console.log(int32[0]); // 42
console.log(int32.length); // 2
console.log(int32.BYTES_PER_ELEMENT); // 4

// From an array
const x = new Int32Array([21, 31]);
console.log(x[1]); // 31

// From another TypedArray
const y = new Int32Array(x);
console.log(y[0]); // 21

// From an ArrayBuffer
const buffer = new ArrayBuffer(32);
const z = new Int32Array(buffer, 4, 4);
console.log(z.byteOffset); // 4

// From an iterable
const iterable = (function* () {
  yield* [1, 2, 3];
})();
const int32FromIterable = new Int32Array(iterable);
console.log(int32FromIterable);
// Int32Array [1, 2, 3]
```

- `DataView`

Int32Array() constructor

The **`Int32Array()`** constructor creates `Int32Array` objects. The contents are initialized to `0` unless initialization data is explicitly provided.

Syntax

```
new Int32Array()
new Int32Array(length)
new Int32Array(typedArray)
new Int32Array(object)

new Int32Array(buffer)
new Int32Array(buffer, byteOffset)
new Int32Array(buffer, byteOffset, length)
```

> **Note:** `Int32Array()` can only be constructed with `new`. Attempting to call it without `new` throws a `TypeError`.

Parameters

See `TypedArray`.

Exceptions

See `TypedArray`.

Examples

Different ways to create an Int32Array

```
// From a length
const int32 = new Int32Array(2);
int32[0] = 42;
console.log(int32[0]); // 42
console.log(int32.length); // 2
console.log(int32.BYTES_PER_ELEMENT); // 4

// From an array
const x = new Int32Array([21, 31]);
console.log(x[1]); // 31

// From another TypedArray
const y = new Int32Array(x);
console.log(y[0]); // 21

// From an ArrayBuffer
const buffer = new ArrayBuffer(32);
const z = new Int32Array(buffer, 4, 4);
console.log(z.byteOffset); // 4

// From an iterable
const iterable = (function* () {
  yield* [1, 2, 3];
})();
const int32FromIterable = new Int32Array(iterable);
console.log(int32FromIterable);
// Int32Array [1, 2, 3]
```

Int8Array

The **`Int8Array`** typed array represents an array of 8-bit signed integers. The contents are initialized to `0` unless initialization data is explicitly provided. Once established, you can reference elements in the array using the object's methods, or using standard array index syntax (that is, using bracket notation).

`Int8Array` is a subclass of the hidden `TypedArray` class.

Constructor

`Int8Array()`

Creates a new `Int8Array` object.

Static properties

Also inherits static properties from its parent `TypedArray`.

`Int8Array.BYTES_PER_ELEMENT`

Returns a number value of the element size. `1` in the case of `Int8Array`.

Static methods

Inherits static methods from its parent `TypedArray`.

Instance properties

Also inherits instance properties from its parent `TypedArray`.

These properties are defined on `Int8Array.prototype` and shared by all `Int8Array` instances.

`Int8Array.prototype.BYTES_PER_ELEMENT`

Returns a number value of the element size. `1` in the case of an `Int8Array`.

`Int8Array.prototype.constructor`

The constructor function that created the instance object. For `Int8Array` instances, the initial value is the `Int8Array` constructor.

Instance methods

Inherits instance methods from its parent `TypedArray`.

Examples

Different ways to create an Int8Array

```
// From a length
const int8 = new Int8Array(2);
int8[0] = 42;
console.log(int8[0]); // 42
console.log(int8.length); // 2
console.log(int8.BYTES_PER_ELEMENT); // 1

// From an array
const x = new Int8Array([21, 31]);
console.log(x[1]); // 31

// From another TypedArray
const y = new Int8Array(x);
console.log(y[0]); // 21

// From an ArrayBuffer
const buffer = new ArrayBuffer(8);
const z = new Int8Array(buffer, 1, 4);
console.log(z.byteOffset); // 1

// From an iterable
const iterable = (function* () {
  yield* [1, 2, 3];
})();
const int8FromIterable = new Int8Array(iterable);
console.log(int8FromIterable);
// Int8Array [1, 2, 3]
```

Int8Array() constructor

The **`Int8Array()`** constructor creates `Int8Array` objects. The contents are initialized to `0` unless initialization data is explicitly provided.

Syntax

```
new Int8Array()
new Int8Array(length)
new Int8Array(typedArray)
new Int8Array(object)

new Int8Array(buffer)
new Int8Array(buffer, byteOffset)
new Int8Array(buffer, byteOffset, length)
```

> **Note:** `Int8Array()` can only be constructed with `new`. Attempting to call it without `new` throws a `TypeError`.

Parameters

See `TypedArray`.

Exceptions

See `TypedArray`.

Examples

Different ways to create an Int8Array

```
// From a length
const int8 = new Int8Array(2);
int8[0] = 42;
```

```
console.log(int8[0]); // 42
console.log(int8.length); // 2
console.log(int8.BYTES_PER_ELEMENT); // 1

// From an array
const x = new Int8Array([21, 31]);
console.log(x[1]); // 31

// From another TypedArray
const y = new Int8Array(x);
console.log(y[0]); // 21

// From an ArrayBuffer
const buffer = new ArrayBuffer(8);
const z = new Int8Array(buffer, 1, 4);
console.log(z.byteOffset); // 1

// From an iterable
const iterable = (function* () {
  yield* [1, 2, 3];
})();
const int8FromIterable = new Int8Array(iterable);
console.log(int8FromIterable);
// Int8Array [1, 2, 3]
```

InternalError

> **Non-standard:** This feature is not standardized. We do not recommend using non-standard features in production, as they have limited browser support, and may change or be removed. However, they can be a suitable alternative in specific cases where no standard option exists.

The **`InternalError`** object indicates an error that occurred internally in the JavaScript engine.

Example cases are mostly when something is too large, e.g.:

- "too many switch cases",
- "too many parentheses in regular expression",
- "array initializer too large",
- "too much recursion".

`InternalError` is a subclass of `Error`.

Constructor

`InternalError()`

Creates a new `InternalError` object.

Instance properties

Also inherits instance properties from its parent `Error`.

These properties are defined on `InternalError.prototype` and shared by all `InternalError` instances.

`InternalError.prototype.constructor`

The constructor function that created the instance object. For `InternalError` instances, the initial value is the `InternalError` constructor.

`InternalError.prototype.name`

Represents the name for the type of error. For `InternalError.prototype.name`, the initial value is `"InternalError"`.

Instance methods

Inherits instance methods from its parent `Error`.

Examples

Too much recursion

This recursive function runs 10 times, as per the exit condition.

```
function loop(x) {
  // "x >= 10" is the exit condition
  if (x >= 10) return;
```

```
  // do stuff
  loop(x + 1); // the recursive call
}
loop(0);
```

Setting this condition to an extremely high value, may not work:

```
function loop(x) {
  if (x >= 1000000000000) return;

  // do stuff
  loop(x + 1);
}
loop(0);

// InternalError: too much recursion
```

For more information, see InternalError: too much recursion.

Specifications

Not part of any standard.

See also

- `Error`

InternalError() constructor

> **Non-standard:** This feature is not standardized. We do not recommend using non-standard features in production, as they have limited browser support, and may change or be removed. However, they can be a suitable alternative in specific cases where no standard option exists.

The **`InternalError()`** constructor creates `InternalError` objects.

Syntax

```
new InternalError()
new InternalError(message)
new InternalError(message, options)
new InternalError(message, fileName)
new InternalError(message, fileName, lineNumber)

InternalError()
InternalError(message)
InternalError(message, options)
InternalError(message, fileName)
InternalError(message, fileName, lineNumber)
```

> **Note:** `InternalError()` can be called with or without `new`. Both create a new `InternalError` instance.

Parameters

`message` Optional

Human-readable description of the error.

`options` Optional

An object that has the following properties:

`cause` Optional

A property indicating the specific cause of the error. When catching and re-throwing an error with a more-specific or useful error message, this property can be used to pass the original error.

`fileName` Optional

The name of the file containing the code that caused the exception

`lineNumber` Optional

The line number of the code that caused the exception

Examples

Creating a new InternalError

```
new InternalError("Engine failure");
```

Specifications

Not part of any standard.

- `Error`

Intl

The **`Intl`** namespace object contains several constructors as well as functionality common to the internationalization constructors and other language sensitive functions. Collectively, they comprise the ECMAScript Internationalization API, which provides language sensitive string comparison, number formatting, date and time formatting, and more.

Description

Unlike most global objects, `Intl` is not a constructor. You cannot use it with the `new` operator or invoke the `Intl` object as a function. All properties and methods of `Intl` are static (just like the `Math` object).

The internationalization constructors as well as several language sensitive methods of other constructors (listed under See also) use a common pattern for identifying locales and determining the one they will actually use: they all accept `locales` and `options` arguments, and negotiate the requested locale(s) against the locales they support using an algorithm specified in the `options.localeMatcher` property.

locales argument

The `locales` argument is used to determine the locale used in a given operation. The JavaScript implementation examines `locales`, and then computes a locale it understands that comes closest to satisfying the expressed preference. `locales` may be:

- `undefined` (or omitted): The implementation's default locale will be used.
- A locale: A locale identifier or an `Intl.Locale` object that wraps a locale identifier.
- A list of locales: Any other value, that will be converted into an object and then treated as an array of locales.

In the latter two cases, the actual locale used is the best-supported locale determined by locale negotiation. If a locale identifier is not a string or an object, a `TypeError` is thrown. If a locale identifier is a string that's syntactically invalid, a `RangeError` is thrown. If a locale identifier is well-formed but the implementation doesn't recognize it, it is ignored and the next locale in the list is considered, eventually falling back to the system's locale. However, you shouldn't rely on a particular locale name being ignored, because the implementation may add data for any locale in the future. For example, `new Intl.DateTimeFormat("default")` uses the implementation's default locale only because `"default"` is syntactically valid but not recognized as any locale.

A locale identifier is a string that consists of:

1. A language subtag with 2–3 or 5–8 letters
2. A script subtag with 4 letters Optional
3. A region subtag with either 2 letters or 3 digits Optional
4. One or more variant subtags (all of which must be unique), each with either 5–8 alphanumerals or a digit followed by 3 alphanumerals Optional
5. One or more BCP 47 extension sequences Optional
6. A private-use extension sequence Optional

Each subtag and sequence are separated by hyphens. Locale identifiers are case-insensitive ASCII. However, it's conventional to use title case (the first letter is capitalized, successive letters are lower case) for script subtags, upper case for region subtags, and lower case for everything else. For example:

- `"hi"`: Hindi (language)
- `"de-AT"`: German (language) as used in Austria (region)
- `"zh-Hans-CN"`: Chinese (language) written in simplified characters (script) as used in China (region)
- `"en-emodeng"`: English (language) in the "Early modern English" dialect (variant)

Subtags identifying languages, scripts, regions (including countries), and (rarely used) variants are registered in the IANA Language Subtag Registry. This registry is periodically updated over time, and implementations may not always be up to date, so don't rely too much on subtags being universally supported.

BCP 47 extension sequences consist of a single digit or letter (other than `"x"`) and one or more two- to eight-letter or digit subtags separated by hyphens. Only one sequence is permitted for each digit or letter: `"de-a-foo-a-foo"` is invalid. BCP 47 extension subtags are defined in the Unicode CLDR Project. Currently only two extensions have defined semantics:

- The `"u"` (Unicode) extension can be used to request additional customization of `Intl` API objects. Examples:
  - `"de-DE-u-co-phonebk"`: Use the phonebook variant of the German sort order, which interprets umlauted vowels as corresponding character pairs: ä → ae, ö → oe, ü → ue.
  - `"th-TH-u-nu-thai"`: Use Thai digits (๐, ๑, ๒, ๓, ๔, ๕, ๖, ๗, ๘, ๙) in number formatting.
  - `"ja-JP-u-ca-japanese"`: Use the Japanese calendar in date and time formatting, so that 2013 is expressed as the year 25 of the Heisei period, or 平成 25.
  - `"en-GB-u-ca-islamic-umalqura"`: use British English with the Umm al-Qura (Hijri) calendar, where the Gregorian date 14 October, 2017 is the Hijri date 24 Muharram, 1439.
- The `"t"` (transformed) extension indicates transformed content: for example, text that was translated from another locale. No `Intl` functionality currently considers the `"t"` extension. However, this extension sometimes contains a nested locale (with no extensions): for example, the transformed extension in `"de-t-en"` contains the locale identifier for English. If a nested locale is present, it must be a valid locale identifier. For example, because `"en-emodeng-emodeng"` is invalid (because it contains a duplicate `emodeng` variant subtag), `"de-t-en-emodeng-emodeng"` is also invalid.

Finally, a private-use extension sequence using the letter `"x"` may appear, followed by one or more one- to eight-letter or digit subtags separated by hyphens. This allows applications to encode information for their own private use, that will be ignored by all `Intl` operations.

options argument

The `options` argument must be an object with properties that vary between constructors and functions. If the `options` argument is not provided or is undefined, default values are used for all properties.

One property is supported by all language sensitive constructors and functions: The `localeMatcher` property, whose value must be a string `"lookup"` or `"best fit"` and which selects one of the locale matching algorithms described below.

Locale identification and negotiation

The list of locales specified by the `locales` argument, after Unicode extensions have been removed from them, is interpreted as a prioritized request from the application. The runtime compares it against the locales it has available and picks the best one available. Two matching algorithms exist: the `"lookup"` matcher follows the Lookup algorithm specified in BCP 47; the `"best fit"` matcher lets the runtime provide a locale that's at least, but possibly more, suited for the request than the result of the Lookup algorithm. If the application doesn't provide a `locales` argument, or the runtime doesn't have a locale that matches the request, then the runtime's default locale is used. The matcher can be selected using a property of the `options` argument (see below).

If the selected locale identifier had a Unicode extension sequence, that extension is now used to customize the constructed object or the behavior of the function. Each constructor or function supports only a subset of the keys defined for the Unicode extension, and the supported values often depend on the locale identifier. For example, the `"co"` key (collation) is only supported by `Intl.Collator`, and its `"phonebk"` value is only supported for German.

Static properties

`Intl.Collator`

: Constructor for collators, which are objects that enable language-sensitive string comparison.

`Intl.DateTimeFormat`

: Constructor for objects that enable language-sensitive date and time formatting.

`Intl.DisplayNames`

: Constructor for objects that enable the consistent translation of language, region and script display names.

`Intl.DurationFormat`

: Constructor for objects that enable locale-sensitive duration formatting.

`Intl.ListFormat`

: Constructor for objects that enable language-sensitive list formatting.

`Intl.Locale`

: Constructor for objects that represents a Unicode locale identifier.

`Intl.NumberFormat`

: Constructor for objects that enable language-sensitive number formatting.

`Intl.PluralRules`

: Constructor for objects that enable plural-sensitive formatting and language-specific rules for plurals.

`Intl.RelativeTimeFormat`

: Constructor for objects that enable language-sensitive relative time formatting.

`Intl.Segmenter`

: Constructor for objects that enable locale-sensitive text segmentation.

`Intl[Symbol.toStringTag]`

: The initial value of the `[Symbol.toStringTag]` property is the string `"Intl"`. This property is used in `Object.prototype.toString()`.

Static methods

`Intl.getCanonicalLocales()`

: Returns canonical locale names.

`Intl.supportedValuesOf()`

: Returns a sorted array containing the supported unique calendar, collation, currency, numbering systems, or unit values supported by the implementation.

Examples

Formatting dates and numbers

You can use `Intl` to format dates and numbers in a form that's conventional for a specific language and region:

```
const count = 26254.39;
const date = new Date("2012-05-24");

function log(locale) {
  console.log(
```

```
    `${new Intl.DateTimeFormat(locale).format(date)} ${new Intl.NumberFormat(
      locale,
    ).format(count)}`,
  );
}

log("en-US"); // 5/24/2012 26,254.39

log("de-DE"); // 24.5.2012 26.254,39
```

Using the browser's preferred language

Instead of passing a hardcoded locale name to the `Intl` methods, you can use the user's preferred language provided by `navigator.language`:

```
const date = new Date("2012-05-24");

const formattedDate = new Intl.DateTimeFormat(navigator.language).format(date);
```

Alternatively, the `navigator.languages` property provides a sorted list of the user's preferred languages. This list can be passed directly to the `Intl` constructors to implement preference-based fallback selection of locales. The locale negotiation process is used to pick the most appropriate locale available:

```
const count = 26254.39;

const formattedCount = new Intl.NumberFormat(navigator.languages).format(count);
```

See also

- `Keyboard.getLayoutMap()`
- `navigator.language`
- `navigator.languages`
- The ECMAScript Internationalization API by Norbert Lindenberg (2012)

Intl.Collator

The **`Intl.Collator`** object enables language-sensitive string comparison.

Try it

```
console.log(["Z", "a", "z", "ä"].sort(new Intl.Collator("de").compare));
// Expected output: Array ["a", "ä", "z", "Z"]

console.log(["Z", "a", "z", "ä"].sort(new Intl.Collator("sv").compare));
// Expected output: Array ["a", "z", "Z", "ä"]

console.log(
  ["Z", "a", "z", "ä"].sort(
    new Intl.Collator("de", { caseFirst: "upper" }).compare,
  ),
);
// Expected output: Array ["a", "ä", "Z", "z"]
```

Constructor

`Intl.Collator()`

Creates a new `Collator` object.

Static methods

`Intl.Collator.supportedLocalesOf()`

Returns an array containing those of the provided locales that are supported without having to fall back to the runtime's default locale.

Instance properties

These properties are defined on `Intl.Collator.prototype` and shared by all `Intl.Collator` instances.

`Intl.Collator.prototype.constructor`

The constructor function that created the instance object. For `Intl.Collator` instances, the initial value is the `Intl.Collator` constructor.

`Intl.Collator.prototype[Symbol.toStringTag]`

The initial value of the `[Symbol.toStringTag]` property is the string `"Intl.Collator"`. This property is used in `Object.prototype.toString()`.

Instance methods

`Intl.Collator.prototype.compare()`

Getter function that compares two strings according to the sort order of this `Intl.Collator` object.

`Intl.Collator.prototype.resolvedOptions()`

Returns a new object with properties reflecting the locale and collation options computed during initialization of the object.

Examples

Using Collator

The following example demonstrates the different potential results for a string occurring before, after, or at the same level as another:

```
console.log(new Intl.Collator().compare("a", "c")); // -1, or some other negative value
console.log(new Intl.Collator().compare("c", "a")); // 1, or some other positive value
console.log(new Intl.Collator().compare("a", "a")); // 0
```

Note that the results shown in the code above can vary between browsers and browser versions. This is because the values are implementation-specific. That is, the specification requires only that the before and after values are negative and positive.

Using locales

The results provided by `Intl.Collator.prototype.compare()` vary between languages. In order to get the sort order of the language used in the user interface of your application, make sure to specify that language (and possibly some fallback languages) using the `locales` argument:

```
// in German, ä sorts with a
console.log(new Intl.Collator("de").compare("ä", "z"));
// -1, or some other negative value

// in Swedish, ä sorts after z
console.log(new Intl.Collator("sv").compare("ä", "z"));
// 1, or some other positive value
```

Using options

The results provided by `Intl.Collator.prototype.compare()` can be customized using the `options` argument:

```
// in German, ä has a as the base letter
console.log(new Intl.Collator("de", { sensitivity: "base" }).compare("ä", "a"));
// 0

// in Swedish, ä and a are separate base letters
console.log(new Intl.Collator("sv", { sensitivity: "base" }).compare("ä", "a"));
// 1, or some other positive value
```

See also

- `Intl`
- `String.prototype.localeCompare()`

Intl.Collator() constructor

The **`Intl.Collator()`** constructor creates `Intl.Collator` objects.

Try it

```
console.log(["Z", "a", "z", "ä"].sort(new Intl.Collator("de").compare));
// Expected output: Array ["a", "ä", "z", "Z"]

console.log(["Z", "a", "z", "ä"].sort(new Intl.Collator("sv").compare));
// Expected output: Array ["a", "z", "Z", "ä"]

console.log(
  ["Z", "a", "z", "ä"].sort(
    new Intl.Collator("de", { caseFirst: "upper" }).compare,
  ),
);
// Expected output: Array ["a", "ä", "Z", "z"]
```

Syntax

```
new Intl.Collator()
new Intl.Collator(locales)
new Intl.Collator(locales, options)

Intl.Collator()
Intl.Collator(locales)
Intl.Collator(locales, options)
```

> **Note:** `Intl.Collator()` can be called with or without `new`. Both create a new `Intl.Collator` instance.

Parameters

`locales` Optional

A string with a BCP 47 language tag or an `Intl.Locale` instance, or an array of such locale identifiers. The runtime's default locale is used when `undefined` is passed or when none of the specified locale identifiers is supported. For the general form and interpretation of the `locales` argument, see the parameter

description on the `Intl` main page.

The following Unicode extension keys are allowed:

`co`

See `collation`.

`kn`

See `numeric`.

`kf`

See `caseFirst`.

These keys can also be set with `options` (as listed below). When both are set, the `options` property takes precedence.

`options` Optional

An object containing the following properties, in the order they are retrieved (all of them are optional):

`usage`

Whether the comparison is for sorting a list of strings or fuzzy (for the Latin script diacritic-insensitive and case-insensitive) filtering a list of strings by key. Possible values are:

`"sort"` (default)

For sorting a list of strings.

`"search"`

For filtering a list of strings by testing each list item for a full-string match against a key. With `"search"`, the caller should only pay attention to whether `compare()` returns zero or non-zero and should not distinguish the non-zero return values from each other. That is, it is inappropriate to use `"search"` for sorting/ordering.

`localeMatcher`

The locale matching algorithm to use. Possible values are `"lookup"` and `"best fit"`; the default is `"best fit"`. For information about this option, see Locale identification and negotiation.

`collation`

Variant collations for certain locales, such as `"emoji"`, `"pinyin"`, `"stroke"`, and so on. Only has an effect when `usage` is `"sort"` (because `"search"` is underlyingly its own collation type). For a list of supported collation types, see `Intl.supportedValuesOf()`; the default is `"default"`. This option can also be set through the `co` Unicode extension key; if both are provided, this `options` property takes precedence.

`numeric`

Whether numeric collation should be used, such that "1" < "2" < "10". Possible values are `true` and `false`; the default is `false`. This option can also be set through the `kn` Unicode extension key; if both are provided, this `options` property takes precedence.

`caseFirst`

Whether upper case or lower case should sort first. Possible values are `"upper"`, `"lower"`, and `"false"` (use the locale's default); the default is `"false"`. This option can also be set through the `kf` Unicode extension key; if both are provided, this `options` property takes precedence.

`sensitivity`

Which differences in the strings should lead to non-zero result values. Possible values are:

`"base"`

Only strings that differ in base letters compare as unequal. Examples: a ≠ b, a = á, a = A. In the Unicode collation algorithm, this is equivalent to the primary strength level.

`"accent"`

Only strings that differ in base letters or accents and other diacritic marks compare as unequal. Examples: a ≠ b, a ≠ á, a = A. In the Unicode collation algorithm, this is equivalent to the secondary strength level.

`"case"`

Only strings that differ in base letters or case compare as unequal. Examples: a ≠ b, a = á, a ≠ A. In the Unicode collation algorithm, this is equivalent to the primary strength level with case level handling.

`"variant"`

Strings that differ in base letters, accents and other diacritic marks, or case compare as unequal. Other differences may also be taken into consideration. Examples: a ≠ b, a ≠ á, a ≠ A. In the Unicode collation algorithm, this is equivalent to the tertiary strength level.

The default is `"variant"` for usage `"sort"`; it's locale dependent for usage `"search"` per spec, but is usually also `"variant"`. Because the core functionality of `"search"` is accent-insensitive and case-insensitive filtering, setting it to `"base"` makes the most sense (and perhaps `"case"`).

`ignorePunctuation`

Whether punctuation should be ignored. Possible values are `true` and `false`. The default is `true` for Thai (`th`) and `false` for all other languages.

Exceptions

`RangeError`

Thrown if `locales` or `options` contain invalid values.

Examples

Using Collator

The following example demonstrates the different potential results for a string occurring before, after, or at the same level as another:

```
console.log(new Intl.Collator().compare("a", "c")); // -1, or some other negative value
console.log(new Intl.Collator().compare("c", "a")); // 1, or some other positive value
console.log(new Intl.Collator().compare("a", "a")); // 0
```

Note that the results shown in the code above can vary between browsers and browser versions. This is because the values are implementation-specific. That is, the specification requires only that the before and after values are negative and positive.

- `Intl`

Intl.Collator.prototype.compare()

The **`compare()`** method of `Intl.Collator` instances compares two strings according to the sort order of this collator object.

Try it

```
const enCollator = new Intl.Collator("en");
const deCollator = new Intl.Collator("de");
const svCollator = new Intl.Collator("sv");

console.log(enCollator.compare("z", "a") > 0);
// Expected output: true

console.log(deCollator.compare("z", "ä") > 0);
// Expected output: true

console.log(svCollator.compare("z", "ä") > 0);
// Expected output: false
```

Syntax

```
compare(string1, string2)
```

Parameters

`string1`, `string2`

The strings to compare against each other.

Return value

A number indicating how `string1` and `string2` compare to each other according to the sort order of this `Intl.Collator` object:

- A negative value if `string1` comes before `string2`;
- A positive value if `string1` comes after `string2`;
- 0 if they are considered equal.

Examples

Using compare for array sort

Use the `compare` function for sorting arrays. Note that the function is bound to the collator from which it was obtained, so it can be passed directly to `Array.prototype.sort()`.

```
const a = ["Offenbach", "Österreich", "Odenwald"];
const collator = new Intl.Collator("de-u-co-phonebk");
a.sort(collator.compare);
console.log(a.join(", ")); // "Odenwald, Österreich, Offenbach"
```

Using compare for array search

Use the `compare` function for finding matching strings in arrays:

```
const a = ["Congrès", "congres", "Assemblée", "poisson"];
const collator = new Intl.Collator("fr", {
```

```
  usage: "search",
  sensitivity: "base",
});
const s = "congres";
const matches = a.filter((v) => collator.compare(v, s) === 0);
console.log(matches.join(", ")); // "Congrès, congres"
```

See also

- `Intl.Collator`
- `String.prototype.localeCompare()`

Intl.Collator.prototype.resolvedOptions()

The **`resolvedOptions()`** method of `Intl.Collator` instances returns a new object with properties reflecting the options computed during initialization of this `Collator` object.

Try it

```
const numberDe = new Intl.NumberFormat("de-DE");
const numberAr = new Intl.NumberFormat("ar");

console.log(numberDe.resolvedOptions().numberingSystem);
// Expected output: "latn"

console.log(numberAr.resolvedOptions().numberingSystem);
// Expected output: "arab"
```

Syntax

```
resolvedOptions()
```

Parameters

None.

Return value

A new object with properties reflecting the options computed during the initialization of this `Collator` object. The object has the following properties, in the order they are listed:

`locale`

> The BCP 47 language tag for the locale actually used, determined by the locale negotiation process. Only the `co`, `kn`, and `kf` Unicode extension keys, if requested and supported, may be included in the output.

`usage`

> The value provided for this property in the `options` argument, with default filled in as needed. It is either `"sort"` or `"search"`. The default is `"sort"`.

`sensitivity`

> The value provided for this property in the `options` argument, with default filled in as needed. It is either `"base"`, `"accent"`, `"case"`, or `"variant"`. The default is `"variant"` for usage `"sort"`; it's locale dependent for usage `"search"`.

`ignorePunctuation`

> The value provided for this property in the `options` argument, with default filled in as needed. It is a boolean. The default is `true` for Thai (`th`) and `false` for all other languages.

`collation`

> The value provided for this property in the `options` argument, or using the Unicode extension key `"co"`, with default filled in as needed. It is a supported collation type for this locale. The default is `"default"`.

`numeric`

> The value provided for this property in the `options` argument, or using the Unicode extension key `"kn"`, with default filled in as needed. It is a boolean. The default is `false`. If the implementation does not support this Unicode extension key, this property is omitted.

`caseFirst`

> The value provided for this property in the `options` argument, or using the Unicode extension key `"kf"`, with default filled in as needed. It is either `"upper"`, `"lower"`, or `"false"`. The default is `"false"`. If the implementation does not support this Unicode extension key, this property is omitted.

Examples

Using the resolvedOptions method

```
const de = new Intl.Collator("de", { sensitivity: "base" });
const usedOptions = de.resolvedOptions();

usedOptions.locale; // "de"
```

```
usedOptions.usage; // "sort"
usedOptions.sensitivity; // "base"
usedOptions.ignorePunctuation; // false
usedOptions.collation; // "default"
usedOptions.numeric; // false
```

- `Intl.Collator`

Intl.Collator.supportedLocalesOf()

The **`Intl.Collator.supportedLocalesOf()`** static method returns an array containing those of the provided locales that are supported in collation without having to fall back to the runtime's default locale.

Try it

```
const locales = ["ban", "id-u-co-pinyin", "de-ID"];
const options = { localeMatcher: "lookup" };

console.log(Intl.Collator.supportedLocalesOf(locales, options));
// Expected output: Array ["id-u-co-pinyin", "de-ID"]
// (Note: the exact output may be browser-dependent)
```

Syntax

```
Intl.Collator.supportedLocalesOf(locales)
Intl.Collator.supportedLocalesOf(locales, options)
```

Parameters

`locales`

A string with a BCP 47 language tag, or an array of such strings. For the general form and interpretation of the `locales` argument, see the parameter description on the `Intl` main page.

`options` Optional

An object that may have the following property:

`localeMatcher`

The locale matching algorithm to use. Possible values are `"lookup"` and `"best fit"`; the default is `"best fit"`. For information about this option, see the Intl page.

Return value

An array of strings representing a subset of the given locale tags that are supported in collation without having to fall back to the runtime's default locale.

Examples

Using supportedLocalesOf()

Assuming a runtime that supports Indonesian and German but not Balinese in collation, `supportedLocalesOf` returns the Indonesian and German language tags unchanged, even though `pinyin` collation is not used with Indonesian, and a specialized German for Indonesia is unlikely to be supported. Note the specification of the `"lookup"` algorithm here — a `"best fit"` matcher might decide that Indonesian is an adequate match for Balinese since most Balinese speakers also understand Indonesian, and therefore return the Balinese language tag as well.

```
const locales = ["ban", "id-u-co-pinyin", "de-ID"];
const options = { localeMatcher: "lookup" };
console.log(Intl.Collator.supportedLocalesOf(locales, options));
// ["id-u-co-pinyin", "de-ID"]
```

- `Intl.Collator`

Intl.DateTimeFormat

The **`Intl.DateTimeFormat`** object enables language-sensitive date and time formatting.

Try it

```
const date = new Date(Date.UTC(2020, 11, 20, 3, 23, 16, 738));
// Results below assume UTC timezone - your results may vary

// Specify default date formatting for language (locale)
console.log(new Intl.DateTimeFormat("en-US").format(date));
// Expected output: "12/20/2020"

// Specify default date formatting for language with a fallback language (in this case Indonesian)
console.log(new Intl.DateTimeFormat(["ban", "id"]).format(date));
// Expected output: "20/12/2020"
```

```
// Specify date and time format using "style" options (i.e. full, long, medium, short)
console.log(
  new Intl.DateTimeFormat("en-GB", {
    dateStyle: "full",
    timeStyle: "long",
    timeZone: "Australia/Sydney",
  }).format(date),
);
// Expected output: "Sunday, 20 December 2020 at 14:23:16 GMT+11"
```

Constructor

`Intl.DateTimeFormat()`

Creates a new `Intl.DateTimeFormat` object.

Static methods

`Intl.DateTimeFormat.supportedLocalesOf()`

Returns an array containing those of the provided locales that are supported without having to fall back to the runtime's default locale.

Instance properties

These properties are defined on `Intl.DateTimeFormat.prototype` and shared by all `Intl.DateTimeFormat` instances.

`Intl.DateTimeFormat.prototype.constructor`

The constructor function that created the instance object. For `Intl.DateTimeFormat` instances, the initial value is the `Intl.DateTimeFormat` constructor.

`Intl.DateTimeFormat.prototype[Symbol.toStringTag]`

The initial value of the `[Symbol.toStringTag]` property is the string `"Intl.DateTimeFormat"`. This property is used in `Object.prototype.toString()`.

Instance methods

`Intl.DateTimeFormat.prototype.format()`

Getter function that formats a date according to the locale and formatting options of this `DateTimeFormat` object.

`Intl.DateTimeFormat.prototype.formatRange()`

This method receives two Dates and formats the date range in the most concise way based on the locale and options provided when instantiating `DateTimeFormat`.

`Intl.DateTimeFormat.prototype.formatRangeToParts()`

This method receives two Dates and returns an Array of objects containing the locale-specific tokens representing each part of the formatted date range.

`Intl.DateTimeFormat.prototype.formatToParts()`

Returns an `Array` of objects representing the date string in parts that can be used for custom locale-aware formatting.

`Intl.DateTimeFormat.prototype.resolvedOptions()`

Returns a new object with properties reflecting the locale and formatting options computed during initialization of the object.

Examples

Using DateTimeFormat

In basic use without specifying a locale, `DateTimeFormat` uses the default locale and default options.

```
const date = new Date(Date.UTC(2012, 11, 20, 3, 0, 0));

// toLocaleString without arguments depends on the implementation,
// the default locale, and the default time zone
console.log(new Intl.DateTimeFormat().format(date));
// "12/19/2012" if run with en-US locale (language) and time zone America/Los_Angeles (UTC-0800)
```

Using locales

This example shows some of the variations in localized date and time formats. In order to get the format of the language used in the user interface of your application, make sure to specify that language (and possibly some fallback languages) using the `locales` argument:

```
const date = new Date(Date.UTC(2012, 11, 20, 3, 0, 0));

// Results below use the time zone of America/Los_Angeles (UTC-0800, Pacific Standard Time)

// US English uses month-day-year order
console.log(new Intl.DateTimeFormat("en-US").format(date));
// "12/19/2012"

// British English uses day-month-year order
```

```
console.log(new Intl.DateTimeFormat("en-GB").format(date));
// "19/12/2012"

// Korean uses year-month-day order
console.log(new Intl.DateTimeFormat("ko-KR").format(date));
// "2012. 12. 19."

// Arabic in most Arabic speaking countries uses real Arabic digits
console.log(new Intl.DateTimeFormat("ar-EG").format(date));
// "٢٠١٢/١٢/١٩"

// for Japanese, applications may want to use the Japanese calendar,
// where 2012 was the year 24 of the Heisei era
console.log(new Intl.DateTimeFormat("ja-JP-u-ca-japanese").format(date));
// "24/12/19"

// when requesting a language that may not be supported, such as
// Balinese, include a fallback language, in this case Indonesian
console.log(new Intl.DateTimeFormat(["ban", "id"]).format(date));
// "19/12/2012"
```

Using options

The date and time formats can be customized using the `options` argument:

```
const date = new Date(Date.UTC(2012, 11, 20, 3, 0, 0, 200));

// request a weekday along with a long date
let options = {
  weekday: "long",
  year: "numeric",
  month: "long",
  day: "numeric",
};
console.log(new Intl.DateTimeFormat("de-DE", options).format(date));
// "Donnerstag, 20. Dezember 2012"

// an application may want to use UTC and make that visible
options.timeZone = "UTC";
options.timeZoneName = "short";
console.log(new Intl.DateTimeFormat("en-US", options).format(date));
// "Thursday, December 20, 2012, GMT"

// sometimes you want to be more precise
options = {
  hour: "numeric",
  minute: "numeric",
  second: "numeric",
  timeZone: "Australia/Sydney",
  timeZoneName: "short",
};
console.log(new Intl.DateTimeFormat("en-AU", options).format(date));
// "2:00:00 pm AEDT"

// sometimes you want to be very precise
options.fractionalSecondDigits = 3; // number digits for fraction-of-seconds
console.log(new Intl.DateTimeFormat("en-AU", options).format(date));
// "2:00:00.200 pm AEDT"

// sometimes even the US needs 24-hour time
options = {
  year: "numeric",
  month: "numeric",
  day: "numeric",
  hour: "numeric",
  minute: "numeric",
  second: "numeric",
  hour12: false,
  timeZone: "America/Los_Angeles",
};
console.log(new Intl.DateTimeFormat("en-US", options).format(date));
// "12/19/2012, 19:00:00"

// to specify options but use the browser's default locale, use undefined
console.log(new Intl.DateTimeFormat(undefined, options).format(date));
// "12/19/2012, 19:00:00"

// sometimes it's helpful to include the period of the day
options = { hour: "numeric", dayPeriod: "short" };
console.log(new Intl.DateTimeFormat("en-US", options).format(date));
// 10 at night
```

The used calendar and numbering formats can also be set independently via `options` arguments:

```
const options = { calendar: "chinese", numberingSystem: "arab" };
const dateFormat = new Intl.DateTimeFormat(undefined, options);
const usedOptions = dateFormat.resolvedOptions();

console.log(usedOptions.calendar);
// "chinese"

console.log(usedOptions.numberingSystem);
// "arab"

console.log(usedOptions.timeZone);
// "America/New_York" (the users default timezone)
```

Intl.DateTimeFormat() constructor

The **`Intl.DateTimeFormat()`** constructor creates `Intl.DateTimeFormat` objects.

Try it

```
const date = new Date(Date.UTC(2020, 11, 20, 3, 23, 16, 738));
// Results below assume UTC timezone - your results may vary

// Specify default date formatting for language (locale)
console.log(new Intl.DateTimeFormat("en-US").format(date));
// Expected output: "12/20/2020"

// Specify default date formatting for language with a fallback language (in this case Indonesian)
console.log(new Intl.DateTimeFormat(["ban", "id"]).format(date));
// Expected output: "20/12/2020"

// Specify date and time format using "style" options (i.e. full, long, medium, short)
console.log(
  new Intl.DateTimeFormat("en-GB", {
    dateStyle: "full",
    timeStyle: "long",
    timeZone: "Australia/Sydney",
  }).format(date),
);
// Expected output: "Sunday, 20 December 2020 at 14:23:16 GMT+11"
```

Syntax

```
new Intl.DateTimeFormat()
new Intl.DateTimeFormat(locales)
new Intl.DateTimeFormat(locales, options)

Intl.DateTimeFormat()
Intl.DateTimeFormat(locales)
Intl.DateTimeFormat(locales, options)
```

> **Note:** `Intl.DateTimeFormat()` can be called with or without `new`. Both create a new `Intl.DateTimeFormat` instance. However, there's a special behavior when it's called without `new` and the `this` value is another `Intl.DateTimeFormat` instance; see Return value.

Parameters

`locales` Optional

A string with a BCP 47 language tag or an `Intl.Locale` instance, or an array of such locale identifiers. The runtime's default locale is used when `undefined` is passed or when none of the specified locale identifiers is supported. For the general form and interpretation of the `locales` argument, see the parameter description on the `Intl` main page.

The following Unicode extension keys are allowed:

`nu`

See `numberingSystem`.

`ca`

See `calendar`.

`hc`

See `hourCycle`.

These keys can also be set with `options` (as listed below). When both are set, the `options` property takes precedence.

`options` Optional

An object. For ease of reading, the property list is broken into sections based on their purposes, including locale options, date-time component options, and style shortcuts.

Locale options

`localeMatcher`

The locale matching algorithm to use. Possible values are `"lookup"` and `"best fit"`; the default is `"best fit"`. For information about this option, see Locale identification and negotiation.

`calendar`

The calendar to use, such as `"chinese"`, `"gregory"`, `"persian"`, and so on. For a list of supported calendar types, see `Intl.supportedValuesOf()`; the default is locale dependent. This option can also be set through the `ca` Unicode extension key; if both are provided, this `options` property takes precedence.

`numberingSystem`

The numbering system to use for number formatting, such as `"arab"`, `"hans"`, `"mathsans"`, and so on. For a list of supported numbering system types, see `Intl.supportedValuesOf()`; the default is locale dependent. This option can also be set through the `nu` Unicode extension key; if both are provided, this `options` property takes precedence.

`hour12`

Whether to use 12-hour time (as opposed to 24-hour time). Possible values are `true` and `false`; the default is locale dependent. When `true`, this option sets `hourCycle` to either `"h11"` or `"h12"`, depending on the locale. When `false`, it sets `hourCycle` to `"h23"`. `hour12` overrides both the `hc` locale extension tag and the `hourCycle` option, should either or both of those be present.

`hourCycle`

The hour cycle to use. Possible values are `"h11"`, `"h12"`, `"h23"`, and `"h24"`; the default is inferred from `hour12` and locale. This option can also be set through the `hc` Unicode extension key; if both are provided, this `options` property takes precedence.

`timeZone`

The time zone to use. Can be any IANA time zone name, including named identifiers such as `"UTC"`, `"America/New_York"`, and `"Etc/GMT+8"`, and offset identifiers such as `"+01:00"`, `"-2359"`, and `"+23"`. The default is the runtime's time zone, the same time zone used by `Date.prototype.toString()`.

Date-time component options

`weekday`

The representation of the weekday. Possible values are:

`"long"`

E.g., `Thursday`

`"short"`

E.g., `Thu`

`"narrow"`

E.g., `T`. Two weekdays may have the same narrow style for some locales (e.g., both `Tuesday`'s and `Thursday`'s narrow styles are `T` in the `en-US` locale).

`era`

The representation of the era. Possible values are:

`"long"`

E.g., `Anno Domini`

`"short"`

E.g., `AD`

`"narrow"`

E.g., `A`

`year`

The representation of the year. Possible values are `"numeric"` and `"2-digit"`.

`month`

The representation of the month. Possible values are:

`"numeric"`

E.g., `3`

`"2-digit"`

E.g., `03`

`"long"`

E.g., `March`

`"short"`

E.g., `Mar`

`"narrow"`

E.g., `M`. Two months may have the same narrow style for some locales (e.g., both `March`'s and `May`'s narrow styles are `M` in the `en-US` locale).

`day`

The representation of the day. Possible values are `"numeric"` and `"2-digit"`.

`dayPeriod`

The formatting style used for day periods like "in the morning", "am", "noon", "n" etc. Possible values are `"narrow"`, `"short"`, and `"long"`.

> **Note:** This option only has an effect if a 12-hour clock (`hourCycle: "h12"` or `hourCycle: "h11"`) is used. Many locales use the same string irrespective of the width specified.

`hour`

The representation of the hour. Possible values are `"numeric"` and `"2-digit"`.

`minute`

The representation of the minute. Possible values are `"numeric"` and `"2-digit"`.

`second`

The representation of the second. Possible values are `"numeric"` and `"2-digit"`.

`fractionalSecondDigits`

The number of digits used to represent fractions of a second (any additional digits are truncated). Possible values are from `1` to `3`.

`timeZoneName`

The localized representation of the time zone name. Possible values are:

`"long"`

Long localized form (e.g., `Pacific Standard Time`, `Nordamerikanische Westküsten-Normalzeit`)

`"short"`

Short localized form (e.g.: `PST`, `GMT-8`)

`"shortOffset"`

Short localized GMT format (e.g., `GMT-8`)

`"longOffset"`

Long localized GMT format (e.g., `GMT-08:00`)

`"shortGeneric"`

Short generic non-location format (e.g.: `PT`, `Los Angeles Zeit`).

`"longGeneric"`

Long generic non-location format (e.g.: `Pacific Time`, `Nordamerikanische Westküstenzeit`)

> **Note:** Timezone display may fall back to another format if a required string is unavailable. For example, the non-location formats should display the timezone without a specific country/city location like "Pacific Time", but may fall back to a timezone like "Los Angeles Time".

Date-time component default values

If any of the date-time component options are specified, then `dateStyle` and `timeStyle` must be `undefined`. If all date-time component options and `dateStyle`/`timeStyle` are `undefined`, some default options for date-time components are set, which depend on the object that the formatting method was called with:

- When formatting `Temporal.PlainDate` and `Date`, `year`, `month`, and `day` default to `"numeric"`.
- When formatting `Temporal.PlainTime`, `hour`, `minute`, and `second` default to `"numeric"`.
- When formatting `Temporal.PlainYearMonth`, `year` and `month` default to `"numeric"`.
- When formatting `Temporal.PlainMonthDay`, `month` and `day` default to `"numeric"`.
- When formatting `Temporal.PlainDateTime` and `Temporal.Instant`, `year`, `month`, `day`, `hour`, `minute`, and `second` default to `"numeric"`.

Format matching

Implementations are required to support displaying at least the following subsets of date-time components:

- `weekday`, `year`, `month`, `day`, `hour`, `minute`, `second`
- `weekday`, `year`, `month`, `day`
- `year`, `month`, `day`
- `year`, `month`
- `month`, `day`
- `hour`, `minute`, `second`
- `hour`, `minute`

The date-time component styles requested might not directly correspond to a valid format supported by the locale, so the format matcher allows you to specify how to match the requested styles to the closest supported format.

`formatMatcher`

> The format matching algorithm to use. Possible values are `"basic"` and `"best fit"`; the default is `"best fit"`. The algorithm for `"best fit"` is implementation-defined, and `"basic"` is defined by the spec. This option is only used when both `dateStyle` and `timeStyle` are `undefined` (so that each date-time component's format is individually customizable).

Style shortcuts

`dateStyle`

> The date formatting style to use. Possible values are `"full"`, `"long"`, `"medium"`, and `"short"`. It expands to styles for `weekday`, `day`, `month`, `year`, and `era`, with the exact combination of values depending on the locale. When formatting objects such as `Temporal.PlainDate`, `Temporal.PlainYearMonth`, and `Temporal.PlainMonthDay`, `dateStyle` will resolve to only those fields relevant to the object.

`timeStyle`

> The time formatting style to use. Possible values are `"full"`, `"long"`, `"medium"`, and `"short"`. It expands to styles for `hour`, `minute`, `second`, and `timeZoneName`, with the exact combination of values depending on the locale.

> **Note:** `dateStyle` and `timeStyle` can be used with each other, but not with other date-time component options (e.g., `weekday`, `hour`, `month`, etc.).

You can format different object types depending on which of the style shortcut options you include:

- If the `dateStyle` is specified, then you can format `Temporal.PlainDate`, `Temporal.PlainYearMonth`, and `Temporal.PlainMonthDay` objects.
- If the `timeStyle` is specified, then you can format `Temporal.PlainTime` objects.
- If either `dateStyle` or `timeStyle` is specified, then you can format `Temporal.PlainDateTime` and `Date` objects.

Return value

A new `Intl.DateTimeFormat` object.

> **Note:** The text below describes behavior that is marked by the specification as "optional". It may not work in all environments. Check the browser compatibility table.

Normally, `Intl.DateTimeFormat()` can be called with or without `new`, and a new `Intl.DateTimeFormat` instance is returned in both cases. However, if the `this` value is an object that is `instanceof` `Intl.DateTimeFormat` (doesn't necessarily mean it's created via `new Intl.DateTimeFormat`; just that it has `Intl.DateTimeFormat.prototype` in its prototype chain), then the value of `this` is returned instead, with the newly created `Intl.DateTimeFormat` object hidden in a `[Symbol(IntlLegacyConstructedSymbol)]` property (a unique symbol that's reused between instances).

```
const formatter = Intl.DateTimeFormat.call(
  { __proto__: Intl.DateTimeFormat.prototype },
  "en-US",
  { dateStyle: "full" },
);
console.log(Object.getOwnPropertyDescriptors(formatter));
// {
//   [Symbol(IntlLegacyConstructedSymbol)]: {
//     value: DateTimeFormat [Intl.DateTimeFormat] {},
//     writable: false,
//     enumerable: false,
//     configurable: false
```

```
//   }
// }
```

Note that there's only one actual `Intl.DateTimeFormat` instance here: the one hidden in `[Symbol(IntlLegacyConstructedSymbol)]`. Calling the `format()` and `resolvedOptions()` methods on `formatter` would correctly use the options stored in that instance, but calling all other methods (e.g., `formatRange()`) would fail: "TypeError: formatRange method called on incompatible Object", because those methods don't consult the hidden instance's options.

This behavior, called `ChainDateTimeFormat`, does not happen when `Intl.DateTimeFormat()` is called without `new` but with `this` set to anything else that's not an `instanceof Intl.DateTimeFormat`. If you call it directly as `Intl.DateTimeFormat()`, the `this` value is `Intl`, and a new `Intl.DateTimeFormat` instance is created normally.

Exceptions

`RangeError`

Thrown if `locales` or `options` contain invalid values.

Examples

Using DateTimeFormat

In basic use without specifying a locale, `DateTimeFormat` uses the default locale and default options.

```
const date = new Date(Date.UTC(2012, 11, 20, 3, 0, 0));

// toLocaleString without arguments depends on the implementation,
// the default locale, and the default time zone
console.log(new Intl.DateTimeFormat().format(date));
// "12/19/2012" if run with en-US locale (language) and time zone America/Los_Angeles (UTC-0800)
```

Using timeStyle and dateStyle

`dateStyle` and `timeStyle` provide a shortcut for setting multiple date-time component options at once. For example, for `en-US`, `dateStyle: "short"` is equivalent to setting `year: "2-digit", month: "numeric", day: "numeric"`, and `timeStyle: "short"` is equivalent to setting `hour: "numeric", minute: "numeric"`.

```
const shortTime = new Intl.DateTimeFormat("en-US", {
  timeStyle: "short",
});
console.log(shortTime.format(Date.now())); // "1:31 PM"

const shortDate = new Intl.DateTimeFormat("en-US", {
  dateStyle: "short",
});
console.log(shortDate.format(Date.now())); // "7/7/20"

const mediumTime = new Intl.DateTimeFormat("en-US", {
  timeStyle: "medium",
  dateStyle: "short",
});
console.log(mediumTime.format(Date.now())); // "7/7/20, 1:31:55 PM"
```

However, the exact (locale dependent) component styles they resolve to are not included in the resolved options. This ensures the result of `resolvedOptions()` can be passed directly to the `Intl.DateTimeFormat()` constructor (because an `options` object with both `dateStyle` or `timeStyle` and individual date or time component styles is not valid).

```
console.log(shortDate.resolvedOptions().year); // undefined
```

Using dayPeriod

Use the `dayPeriod` option to output a string for the times of day ("in the morning", "at night", "noon", etc.). Note, that this only works when formatting for a 12 hour clock (`hourCycle: 'h12'` or `hourCycle: 'h11'`) and that for many locales the strings are the same irrespective of the value passed for the `dayPeriod`.

```
const date = Date.UTC(2012, 11, 17, 4, 0, 42);

console.log(
  new Intl.DateTimeFormat("en-GB", {
    hour: "numeric",
    hourCycle: "h12",
    dayPeriod: "short",
    timeZone: "UTC",
  }).format(date),
);
// 4 at night"  (same formatting in en-GB for all dayPeriod values)

console.log(
  new Intl.DateTimeFormat("fr", {
    hour: "numeric",
    hourCycle: "h12",
    dayPeriod: "narrow",
    timeZone: "UTC",
  }).format(date),
);
// "4 mat."  (same output in French for both narrow/short dayPeriod)
```

```
console.log(
  new Intl.DateTimeFormat("fr", {
    hour: "numeric",
    hourCycle: "h12",
    dayPeriod: "long",
    timeZone: "UTC",
  }).format(date),
);
// "4 du matin"
```

Using timeZoneName

Use the `timeZoneName` option to output a string for the timezone ("GMT", "Pacific Time", etc.).

```
const date = Date.UTC(2021, 11, 17, 3, 0, 42);
const timezoneNames = [
  "short",
  "long",
  "shortOffset",
  "longOffset",
  "shortGeneric",
  "longGeneric",
];

for (const zoneName of timezoneNames) {
  // Do something with currentValue
  const formatter = new Intl.DateTimeFormat("en-US", {
    timeZone: "America/Los_Angeles",
    timeZoneName: zoneName,
  });
  console.log(`${zoneName}: ${formatter.format(date)}`);
}

// Logs:
// short: 12/16/2021, PST
// long: 12/16/2021, Pacific Standard Time
// shortOffset: 12/16/2021, GMT-8
// longOffset: 12/16/2021, GMT-08:00
// shortGeneric: 12/16/2021, PT
// longGeneric: 12/16/2021, Pacific Time
```

Intl.DateTimeFormat.prototype.format()

The **`format()`** method of `Intl.DateTimeFormat` instances formats a date according to the locale and formatting options of this `Intl.DateTimeFormat` object.

Try it

```
const options = {
  weekday: "long",
  year: "numeric",
  month: "long",
  day: "numeric",
};
const date = new Date(2012, 5);

const dateTimeFormat1 = new Intl.DateTimeFormat("sr-RS", options);
console.log(dateTimeFormat1.format(date));
// Expected output: "петак, 1. јун 2012."

const dateTimeFormat2 = new Intl.DateTimeFormat("en-GB", options);
console.log(dateTimeFormat2.format(date));
// Expected output: "Friday, 1 June 2012"

const dateTimeFormat3 = new Intl.DateTimeFormat("en-US", options);
console.log(dateTimeFormat3.format(date));
// Expected output: "Friday, June 1, 2012"
```

Syntax

```
format(date)
```

Parameters

`date`

> The date to format. Can be a `Date` or `Temporal.PlainDateTime` object. Additionally can be a `Temporal.PlainTime`, `Temporal.PlainDate`, `Temporal.PlainYearMonth`, or `Temporal.PlainMonthDay` object if the `DateTimeFormat` object was configured to print at least one relevant part of the date.

> **Note:** A `Temporal.ZonedDateTime` object will always throw a `TypeError`; use `Temporal.ZonedDateTime.prototype.toLocaleString()` or convert it to a `Temporal.PlainDateTime` object instead.

Omitting it results in formatting the current date (as returned by `Date.now()`), which could be slightly confusing, so it is advisable to always explicitly pass a date.

Return value

A string representing the given `date` formatted according to the locale and formatting options of this `Intl.DateTimeFormat` object.

> **Note:** Most of the time, the formatting returned by `format()` is consistent. However, the output may vary between implementations, even within the same locale — output variations are by design and allowed by the specification. It may also not be what you expect. For example, the string may use non-breaking spaces or be surrounded by bidirectional control characters. You should not compare the results of `format()` to hardcoded constants.

Examples

Using format

Use the `format` getter function for formatting a single date, here for Serbia:

```
const options = {
  weekday: "long",
  year: "numeric",
  month: "long",
  day: "numeric",
};
const dateTimeFormat = new Intl.DateTimeFormat("sr-RS", options);
console.log(dateTimeFormat.format(new Date()));
// "недеља, 7. април 2013."
```

Using format with map

Use the `format` getter function for formatting all dates in an array. Note that the function is bound to the `Intl.DateTimeFormat` from which it was obtained, so it can be passed directly to `Array.prototype.map()`.

```
const a = [new Date(2012, 8), new Date(2012, 11), new Date(2012, 3)];
const options = { year: "numeric", month: "long" };
const dateTimeFormat = new Intl.DateTimeFormat("pt-BR", options);
const formatted = a.map(dateTimeFormat.format);
console.log(formatted.join("; "));
// "setembro de 2012; dezembro de 2012; abril de 2012"
```

Intl.DateTimeFormat.prototype.formatRange()

The **`formatRange()`** method of `Intl.DateTimeFormat` instances formats a date range in the most concise way based on the locales and options provided when instantiating this `Intl.DateTimeFormat` object.

Try it

```
const options1 = {
  weekday: "long",
  year: "numeric",
  month: "long",
  day: "numeric",
};
const options2 = { year: "2-digit", month: "numeric", day: "numeric" };

const startDate = new Date(Date.UTC(2007, 0, 10, 10, 0, 0));
const endDate = new Date(Date.UTC(2008, 0, 10, 11, 0, 0));

const dateTimeFormat = new Intl.DateTimeFormat("en", options1);
console.log(dateTimeFormat.formatRange(startDate, endDate));
// Expected output: "Wednesday, January 10, 2007 – Thursday, January 10, 2008"

const dateTimeFormat2 = new Intl.DateTimeFormat("en", options2);
console.log(dateTimeFormat2.formatRange(startDate, endDate));
// Expected output: "1/10/07 – 1/10/08"
```

Syntax

```
formatRange(startDate, endDate)
```

Parameters

`startDate`

The start of the date range. Can be a `Date` or `Temporal.PlainDateTime` object. Additionally can be a `Temporal.PlainTime`, `Temporal.PlainDate`, `Temporal.PlainYearMonth`, or `Temporal.PlainMonthDay` object if the `DateTimeFormat` object was configured to print at least one relevant part of the date.

> **Note:** A `Temporal.ZonedDateTime` object will always throw a `TypeError`; use `Temporal.ZonedDateTime.prototype.toLocaleString()` or convert it to a `Temporal.PlainDateTime` object instead.

`endDate`

The end of the date range. Must have the same type as `startDate`.

Return value

A string representing the given date range formatted according to the locale and formatting options of this `Intl.DateTimeFormat` object. If the start and end dates are equivalent at the precision of the output, the output will only contain a single date.

Examples

Basic formatRange usage

This method receives two `Date`s and formats the date range in the most concise way based on the `locale` and `options` provided when instantiating `Intl.DateTimeFormat`.

```
const date1 = new Date(Date.UTC(1906, 0, 10, 10, 0, 0)); // Wed, 10 Jan 1906 10:00:00 GMT
const date2 = new Date(Date.UTC(1906, 0, 10, 11, 0, 0)); // Wed, 10 Jan 1906 11:00:00 GMT
const date3 = new Date(Date.UTC(1906, 0, 20, 10, 0, 0)); // Sat, 20 Jan 1906 10:00:00 GMT

const fmt1 = new Intl.DateTimeFormat("en", {
  year: "2-digit",
  month: "numeric",
  day: "numeric",
  hour: "numeric",
  minute: "numeric",
});
console.log(fmt1.format(date1)); // '1/10/06, 10:00 AM'
console.log(fmt1.formatRange(date1, date2)); // '1/10/06, 10:00 – 11:00 AM'
console.log(fmt1.formatRange(date1, date3)); // '1/10/06, 10:00 AM – 1/20/07, 10:00 AM'

const fmt2 = new Intl.DateTimeFormat("en", {
  year: "numeric",
  month: "short",
  day: "numeric",
});
console.log(fmt2.format(date1)); // 'Jan 10, 1906'
console.log(fmt2.formatRange(date1, date2)); // 'Jan 10, 1906'
console.log(fmt2.formatRange(date1, date3)); // 'Jan 10 – 20, 1906'
```

Intl.DateTimeFormat.prototype.formatRangeToParts()

The **`formatRangeToParts()`** method of `Intl.DateTimeFormat` instances returns an array of objects representing each part of the formatted string that would be returned by `formatRange()`. It is useful for building custom strings from the locale-specific tokens.

Try it

```
const startDate = new Date(Date.UTC(2007, 0, 10, 10, 0, 0)); // > 'Wed, 10 Jan 2007 10:00:00 GMT'
const endDate = new Date(Date.UTC(2007, 0, 10, 11, 0, 0)); // > 'Wed, 10 Jan 2007 11:00:00 GMT'

const dateTimeFormat = new Intl.DateTimeFormat("en", {
  hour: "numeric",
  minute: "numeric",
});

const parts = dateTimeFormat.formatRangeToParts(startDate, endDate);
for (const part of parts) {
  console.log(part);
}
// Expected output (in GMT timezone):
// Object { type: "hour", value: "2", source: "startRange" }
// Object { type: "literal", value: ":", source: "startRange" }
// Object { type: "minute", value: "00", source: "startRange" }
// Object { type: "literal", value: " – ", source: "shared" }
// Object { type: "hour", value: "3", source: "endRange" }
// Object { type: "literal", value: ":", source: "endRange" }
// Object { type: "minute", value: "00", source: "endRange" }
// Object { type: "literal", value: " ", source: "shared" }
// Object { type: "dayPeriod", value: "AM", source: "shared" }
```

Syntax

```
formatRangeToParts(startDate, endDate)
```

Parameters

`startDate`

> The start of the date range. Can be a `Date` or `Temporal.PlainDateTime` object. Additionally can be a `Temporal.PlainTime`, `Temporal.PlainDate`, `Temporal.PlainYearMonth`, or `Temporal.PlainMonthDay` object if the `DateTimeFormat` object was configured to print at least one relevant part of the date.
>
> > **Note:** A `Temporal.ZonedDateTime` object will always throw a `TypeError`; use `Temporal.ZonedDateTime.prototype.toLocaleString()` or convert it to a `Temporal.PlainDateTime` object instead.

`endDate`

> The end of the date range. Must have the same type as `startDate`.

Return value

An `Array` of objects containing the formatted date range in parts. Each object has three properties, `type`, `value`, and `source`, each containing a string. The string concatenation of `value`, in the order provided, will result in the same string as `formatRange()`. The `type` may have the same values as `formatToParts()`. The `source` can be one of the following:

`startRange`

> The token is a part of the start date.

`endRange`

> The token is a part of the end date.

`shared`

> The token is shared between the start and end; for example, if the start and end dates share the same day period, that token may get reused. All literals that are part of the range pattern itself, such as the `" – "` separator, are also marked as `shared`.

If the start and end dates are equivalent at the precision of the output, then the output has the same list of tokens as calling `formatToParts()` on the start date, with all tokens marked as `source: "shared"`.

Examples

Using formatRangeToParts()

The `formatRange()` method outputs localized, opaque strings that cannot be manipulated directly:

```
const date1 = new Date(Date.UTC(1906, 0, 10, 10, 0, 0)); // Wed, 10 Jan 1906 10:00:00 GMT
const date2 = new Date(Date.UTC(1906, 0, 10, 11, 0, 0)); // Wed, 10 Jan 1906 11:00:00 GMT

const fmt = new Intl.DateTimeFormat("en", {
  hour: "numeric",
  minute: "numeric",
});

console.log(fmt.formatRange(date1, date2)); // '10:00 – 11:00 AM'
```

However, in many user interfaces you may want to customize the formatting of this string, or interleave it with other texts. The `formatRangeToParts()` method produces the same information in parts:

```
console.log(fmt.formatRangeToParts(date1, date2));

// return value:
[
  { type: "hour", value: "10", source: "startRange" },
  { type: "literal", value: ":", source: "startRange" },
  { type: "minute", value: "00", source: "startRange" },
  { type: "literal", value: " – ", source: "shared" },
  { type: "hour", value: "11", source: "endRange" },
  { type: "literal", value: ":", source: "endRange" },
  { type: "minute", value: "00", source: "endRange" },
  { type: "literal", value: " ", source: "shared" },
  { type: "dayPeriod", value: "AM", source: "shared" },
];
```

Intl.DateTimeFormat.prototype.formatToParts()

The **`formatToParts()`** method of `Intl.DateTimeFormat` instances returns an array of objects representing each part of the formatted string that would be returned by `format()`. It is useful for building custom strings from the locale-specific tokens.

Try it

```
const date = new Date(2012, 5);
const options = {
  weekday: "long",
  year: "numeric",
  month: "long",
  day: "numeric",
};
const dateTimeFormat = new Intl.DateTimeFormat("en-US", options);

const parts = dateTimeFormat.formatToParts(date);
const partValues = parts.map((p) => p.value);

console.log(partValues);
// Expected output: "["Friday", ", ", "June", " ", "1", ", ", "2012"]"
```

Syntax

```
formatToParts(date)
```

Parameters

`date` Optional

The date to format. Can be a `Date` or `Temporal.PlainDateTime` object. Additionally can be a `Temporal.PlainTime`, `Temporal.PlainDate`, `Temporal.PlainYearMonth`, or `Temporal.PlainMonthDay` object if the `DateTimeFormat` object was configured to print at least one relevant part of the date.

> **Note:** A `Temporal.ZonedDateTime` object will always throw a `TypeError`; use `Temporal.ZonedDateTime.prototype.toLocaleString()` or convert it to a `Temporal.PlainDateTime` object instead.

Omitting it results in formatting the current date (as returned by `Date.now()`), which could be slightly confusing, so it is advisable to always explicitly pass a date.

Return value

An `Array` of objects containing the formatted date in parts. Each object has two properties, `type` and `value`, each containing a string. The string concatenation of `value`, in the order provided, will result in the same string as `format()`. The `type` may be one of the date-time components:

`weekday`

For example `"M"`, `"Monday"`, or `"Montag"`.

`era`

For example `"BC"` or `"AD"`.

`year`

For example `"2012"` or `"96"`.

`month`

For example `"12"` or `"January"`.

`day`

For example `"17"`.

`dayPeriod`

For example `"AM"`, `"PM"`, `"in the morning"`, or `"noon"`.

`hour`

For example `"3"` or `"03"`.

`minute`

For example `"00"`.

`second`

For example `"07"` or `"42"`.

`fractionalSecond`

For example `"0"`, `"00"`, or `"000"`.

`timeZoneName`

For example `"UTC"`, `"CET"`, or `"Central European Time"`.

The `type` may also be one of the following:

`literal`

Any string that's a part of the format pattern and not influenced by the `date`; for example `"/"`, `", "`, `"o'clock"`, `"de"`, `" "`, etc.

`relatedYear`

A 4-digit Gregorian year, in the event that the calendar's representation would be a `yearName` instead of a year; for example `"2019"`. See named years for more details.

`yearName`

The name given to the year, usually in calendars without the concept of continuous years; for example `"geng-zi"`.

`unknown`

Reserved for any token that's not recognized as any of the above; should be rarely encountered.

Examples

Using formatToParts()

The `format()` method outputs localized, opaque strings that cannot be manipulated directly:

```
const date = Date.UTC(2012, 11, 17, 3, 0, 42);

const formatter = new Intl.DateTimeFormat("en-us", {
  weekday: "long",
  year: "numeric",
  month: "numeric",
  day: "numeric",
  hour: "numeric",
  minute: "numeric",
  second: "numeric",
  fractionalSecondDigits: 3,
  hour12: true,
  timeZone: "UTC",
});

formatter.format(date);
// "Monday, 12/17/2012, 3:00:42.000 AM"
```

However, in many user interfaces you may want to customize the formatting of this string, or interleave it with other texts. The `formatToParts()` method produces the same information in parts:

```
formatter.formatToParts(date);

// return value:
[
  { type: "weekday", value: "Monday" },
  { type: "literal", value: ", " },
  { type: "month", value: "12" },
  { type: "literal", value: "/" },
  { type: "day", value: "17" },
  { type: "literal", value: "/" },
  { type: "year", value: "2012" },
  { type: "literal", value: ", " },
  { type: "hour", value: "3" },
  { type: "literal", value: ":" },
  { type: "minute", value: "00" },
  { type: "literal", value: ":" },
  { type: "second", value: "42" },
  { type: "fractionalSecond", value: "000" },
  { type: "literal", value: " " },
  { type: "dayPeriod", value: "AM" },
];
```

Now the information is available separately and it can be formatted and concatenated again in a customized way. For example by using `Array.prototype.map()`, arrow functions, a switch statement, template literals, and `Array.prototype.join()`, to insert additional markup for certain components.

```
const dateString = formatter
  .formatToParts(date)
  .map(({ type, value }) => {
    switch (type) {
      case "dayPeriod":
        return `<em>${value}</em>`;
      default:
        return value;
    }
  })
  .join("");

console.log(dateString);
// "Monday, 12/17/2012, 3:00:42.000 <em>AM</em>"
```

Named years

Some calendars use named years; for example, the Chinese and Tibetan calendars use a 60-year sexagenary cycle of named years. These calendars do not have a universal way to unambiguously number each year, so years are disambiguated by relationship to corresponding years on the Gregorian calendar. In this case, when the `DateTimeFormat` is configured to output the year component, a token for `relatedYear` is output instead of `year`.

```
const df = new Intl.DateTimeFormat("zh-u-ca-chinese");
df.formatToParts(Date.UTC(2012, 11, 17, 3, 0, 42));

// return value:
[
  { type: "relatedYear", value: "2012" },
  { type: "literal", value: "年" },
  { type: "month", value: "十一月" },
  { type: "day", value: "4" },
];
```

Sometimes, the combination of date-time component options maps to a format that also includes a `yearName`. There isn't a separate option that controls whether `yearName` is displayed or not. For example, the options below sets `month` to `"long"` and results in a `yearName` token, despite `year` still being `"numeric"`:

```
const opts = { year: "numeric", month: "long", day: "numeric" };
const df = new Intl.DateTimeFormat("zh-u-ca-chinese", opts);
df.formatToParts(Date.UTC(2012, 11, 17, 3, 0, 42));

// return value:
[
  { type: "relatedYear", value: "2012" },
  { type: "yearName", value: "壬辰" },
  { type: "literal", value: "年" },
  { type: "month", value: "十一月" },
  { type: "day", value: "4" },
];
```

Because `format()` just concatenates all the `value` strings together, you will see the Gregorian year and the year name together in the output in this case.

See also

- `Intl.DateTimeFormat`
- `Intl.DateTimeFormat.prototype.format()`

Intl.DateTimeFormat.prototype.resolvedOptions()

The **`resolvedOptions()`** method of `Intl.DateTimeFormat` instances returns a new object with properties reflecting the options computed during initialization of this `DateTimeFormat` object.

Try it

```
const region = new Intl.DateTimeFormat("zh-CN", { timeZone: "UTC" });
const options = region.resolvedOptions();

console.log(options.locale);
// Expected output: "zh-CN"

console.log(options.calendar);
// Expected output: "gregory"

console.log(options.numberingSystem);
// Expected output: "latn"
```

Syntax

```
resolvedOptions()
```

Parameters

None.

Return value

A new object with properties reflecting the options computed during the initialization of this `DateTimeFormat` object. The object has the following properties, in the order they are listed:

`locale`

> The BCP 47 language tag for the locale actually used, determined by the locale negotiation process. Only the `ca`, `hc`, and `nu` Unicode extension keys, if requested, may be included in the output.

`calendar`

> The value provided for this property in the `options` argument, or using the Unicode extension key `"ca"`, with default filled in as needed. It is a supported calendar type for this locale. The default is locale dependent.

`numberingSystem`

The value provided for this property in the `options` argument, or using the Unicode extension key `"nu"`, with default filled in as needed. It is a supported numbering system for this locale. The default is locale dependent.

`timeZone`

The value provided for this property in the `options` argument, with default filled in as needed. It is an IANA time zone name. The default is the runtime's default time zone.

> **Note:** The standardization of `Temporal` requires browsers to use the same identifier as originally specified, without canonicalization to a different alias. See time zones and offsets for more information.

`hourCycle` Optional

The value provided for this property in the `options` argument, or using the Unicode extension key `"hc"`, with default filled in as needed. If `hour12` was provided in the `options`, then that overrides other `hourCycle` settings. It is only present if the resolved options also include `hour` or `timeStyle`. It is either `"h11"`, `"h12"`, `"h23"`, or `"h24"`. The default is locale dependent, although `"h24"` is never a default.

`hour12` Optional

Calculated from `hourCycle`. It is only present if the resolved options also include `hour` or `timeStyle`. It is `true` if `hourCycle` is `"h11"` or `"h12"`, and `false` if `hourCycle` is `"h23"` or `"h24"`.

`weekday`, `era`, `year`, `month`, `day`, `dayPeriod`, `hour`, `minute`, `second`, `fractionalSecondDigits`, `timeZoneName` Optional

The values resulting from format matching between the corresponding properties in the `options` argument and the available combinations and representations for date-time formatting in the selected locale. Some of these properties may not be present, indicating that the corresponding components will not be represented in formatted output. `weekday`, `era`, and `dayPeriod` are either `"narrow"`, `"short"`, or `"long"`; `year`, `day`, `hour`, `minute`, and `second` are either `"numeric"`, `"2-digit"`, or `"narrow"`; `month` is either `"numeric"`, `"2-digit"`, `"narrow"`, `"short"`, or `"long"`; `fractionalSecondDigits` is either `1`, `2`, or `3`; `timeZoneName` is either `"short"`, `"long"`, `"shortOffset"`, `"longOffset"`, `"shortGeneric"`, or `"longGeneric"`.

If these properties were requested in `options`, the constructor prevents `dateStyle` and `timeStyle` from being specified, so the below group will never be present.

`dateStyle`, `timeStyle` Optional

The values provided for these properties in the `options` argument. They are either `"full"`, `"long"`, `"medium"`, `"short"`, or `"none"`. Some of these properties may not be present, indicating that the corresponding components will not be represented in formatted output.

If these properties were requested in `options`, the constructor prevents individual date time component options from being specified, so the above group will never be present.

> **Note:** Although `dateStyle` and `timeStyle` are shortcuts for individual date and time component styles, the exact (locale dependent) component styles they resolve to are not included in the resolved options. This ensures the result of `resolvedOptions()` can be passed directly to the `Intl.DateTimeFormat()` constructor (because an `options` object with both `dateStyle` or `timeStyle` and individual date or time component styles is not valid).

Examples

Using the resolvedOptions method

```
const germanFakeRegion = new Intl.DateTimeFormat("de-XX", { timeZone: "UTC" });
const usedOptions = germanFakeRegion.resolvedOptions();

usedOptions.locale; // "de" (because "de-XX" does not exist)
usedOptions.calendar; // "gregory"
usedOptions.numberingSystem; // "latn"
usedOptions.timeZone; // "UTC"
usedOptions.month; // "numeric"
```

Getting the user's time zone and locale preferences

The `Intl.DateTimeFormat` constructor without any options uses the current system settings. You can use `resolvedOptions()` to get the user's current time zone and locale's preferred calendar and numbering system:

```
const systemOptions = new Intl.DateTimeFormat().resolvedOptions();
systemOptions.timeZone; // e.g., "Europe/Brussels" or "Asia/Riyadh"
systemOptions.calendar; // e.g., "gregory" or "islamic-umalqura"
systemOptions.numberingSystem; // e.g., "latn" or "arab"
systemOptions.locale; // e.g., "nl-BE" or "ar-SA"
```

See also

- `Intl.DateTimeFormat`

Intl.DateTimeFormat.supportedLocalesOf()

The **`Intl.DateTimeFormat.supportedLocalesOf()`** static method returns an array containing those of the provided locales that are supported in date and time formatting without having to fall back to the runtime's default locale.

Try it

```
const locales = ["ban", "id-u-co-pinyin", "de-ID"];
const options = { localeMatcher: "lookup" };

console.log(Intl.DateTimeFormat.supportedLocalesOf(locales, options));
// Expected output: Array ["id-u-co-pinyin", "de-ID"]
// (Note: the exact output may be browser-dependent)
```

Syntax

```
Intl.DateTimeFormat.supportedLocalesOf(locales)
Intl.DateTimeFormat.supportedLocalesOf(locales, options)
```

Parameters

`locales`

A string with a BCP 47 language tag, or an array of such strings. For the general form and interpretation of the `locales` argument, see the parameter description on the `Intl` main page.

`options` Optional

An object that may have the following property:

`localeMatcher`

The locale matching algorithm to use. Possible values are `"lookup"` and `"best fit"`; the default is `"best fit"`. For information about this option, see the Intl page.

Return value

An array of strings representing a subset of the given locale tags that are supported in date and time formatting without having to fall back to the runtime's default locale.

Examples

Using supportedLocalesOf()

Assuming a runtime that supports Indonesian and German but not Balinese in date and time formatting, `supportedLocalesOf` returns the Indonesian and German language tags unchanged, even though `pinyin` collation is neither relevant to date and time formatting nor used with Indonesian, and a specialized German for Indonesia is unlikely to be supported. Note the specification of the `"lookup"` algorithm here — a `"best fit"` matcher might decide that Indonesian is an adequate match for Balinese since most Balinese speakers also understand Indonesian, and therefore return the Balinese language tag as well.

```
const locales = ["ban", "id-u-co-pinyin", "de-ID"];
const options = { localeMatcher: "lookup" };
console.log(Intl.DateTimeFormat.supportedLocalesOf(locales, options));
// ["id-u-co-pinyin", "de-ID"]
```

See also

- `Intl.DateTimeFormat`

Intl.DisplayNames

The **`Intl.DisplayNames`** object enables the consistent translation of language, region and script display names.

Try it

```
const regionNamesInEnglish = new Intl.DisplayNames(["en"], { type: "region" });
const regionNamesInTraditionalChinese = new Intl.DisplayNames(["zh-Hant"], {
  type: "region",
});

console.log(regionNamesInEnglish.of("US"));
// Expected output: "United States"

console.log(regionNamesInTraditionalChinese.of("US"));
// Expected output: "美國"
```

Constructor

`Intl.DisplayNames()`

Creates a new `Intl.DisplayNames` object.

Static methods

`Intl.DisplayNames.supportedLocalesOf()`

Returns an array containing those of the provided locales that are supported without having to fall back to the runtime's default locale.

Instance properties

These properties are defined on `Intl.DisplayNames.prototype` and shared by all `Intl.DisplayNames` instances.

`Intl.DisplayNames.prototype.constructor`

The constructor function that created the instance object. For `Intl.DisplayNames` instances, the initial value is the `Intl.DisplayNames` constructor.

`Intl.DisplayNames.prototype[Symbol.toStringTag]`

The initial value of the `[Symbol.toStringTag]` property is the string `"Intl.DisplayNames"`. This property is used in `Object.prototype.toString()`.

Instance methods

`Intl.DisplayNames.prototype.of()`

This method receives a `code` and returns a string based on the locale and options provided when instantiating `Intl.DisplayNames`.

`Intl.DisplayNames.prototype.resolvedOptions()`

Returns a new object with properties reflecting the locale and formatting options computed during initialization of the object.

Examples

Region Code Display Names

To create an `Intl.DisplayNames` for a locale and get the display name for a region code.

```
// Get display names of region in English
let regionNames = new Intl.DisplayNames(["en"], { type: "region" });
regionNames.of("419"); // "Latin America"
regionNames.of("BZ"); // "Belize"
regionNames.of("US"); // "United States"
regionNames.of("BA"); // "Bosnia & Herzegovina"
regionNames.of("MM"); // "Myanmar (Burma)"

// Get display names of region in Traditional Chinese
regionNames = new Intl.DisplayNames(["zh-Hant"], { type: "region" });
regionNames.of("419"); // "拉丁美洲"
regionNames.of("BZ"); // "貝里斯"
regionNames.of("US"); // "美國"
regionNames.of("BA"); // "波士尼亞與赫塞哥維納"
regionNames.of("MM"); // "緬甸"
```

Language Display Names

To create an `Intl.DisplayNames` for a locale and get the display name for a language-script-region sequence.

```
// Get display names of language in English
let languageNames = new Intl.DisplayNames(["en"], { type: "language" });
languageNames.of("fr"); // "French"
languageNames.of("de"); // "German"
languageNames.of("fr-CA"); // "Canadian French"
languageNames.of("zh-Hant"); // "Traditional Chinese"
languageNames.of("en-US"); // "American English"
languageNames.of("zh-TW"); // "Chinese (Taiwan)"]

// Get display names of language in Traditional Chinese
languageNames = new Intl.DisplayNames(["zh-Hant"], { type: "language" });
languageNames.of("fr"); // "法文"
languageNames.of("zh"); // "中文"
languageNames.of("de"); // "德文"
```

Script Code Display Names

To create an `Intl.DisplayNames` for a locale and get the display name for a script code.

```
// Get display names of script in English
let scriptNames = new Intl.DisplayNames(["en"], { type: "script" });
// Get script names
scriptNames.of("Latn"); // "Latin"
scriptNames.of("Arab"); // "Arabic"
scriptNames.of("Kana"); // "Katakana"

// Get display names of script in Traditional Chinese
scriptNames = new Intl.DisplayNames(["zh-Hant"], { type: "script" });
scriptNames.of("Latn"); // "拉丁文"
scriptNames.of("Arab"); // "阿拉伯文"
scriptNames.of("Kana"); // "片假名"
```

Currency Code Display Names

To create an `Intl.DisplayNames` for a locale and get the display name for currency code.

```
// Get display names of currency code in English
let currencyNames = new Intl.DisplayNames(["en"], { type: "currency" });
// Get currency names
currencyNames.of("USD"); // "US Dollar"
```

```
currencyNames.of("EUR"); // "Euro"
currencyNames.of("TWD"); // "New Taiwan Dollar"
currencyNames.of("CNY"); // "Chinese Yuan"

// Get display names of currency code in Traditional Chinese
currencyNames = new Intl.DisplayNames(["zh-Hant"], { type: "currency" });
currencyNames.of("USD"); // "美元"
currencyNames.of("EUR"); // "歐元"
currencyNames.of("TWD"); // "新台幣"
currencyNames.of("CNY"); // "人民幣"
```

- `Intl`

Intl.DisplayNames() constructor

The **`Intl.DisplayNames()`** constructor creates `Intl.DisplayNames` objects.

Try it

```
const regionNamesInEnglish = new Intl.DisplayNames(["en"], { type: "region" });
const regionNamesInTraditionalChinese = new Intl.DisplayNames(["zh-Hant"], {
  type: "region",
});

console.log(regionNamesInEnglish.of("US"));
// Expected output: "United States"

console.log(regionNamesInTraditionalChinese.of("US"));
// Expected output: "美國"
```

Syntax

```
new Intl.DisplayNames(locales, options)
```

> **Note:** `Intl.DisplayNames()` can only be constructed with `new`. Attempting to call it without `new` throws a `TypeError`.

Parameters

`locales`

A string with a BCP 47 language tag or an `Intl.Locale` instance, or an array of such locale identifiers. The runtime's default locale is used when `undefined` is passed or when none of the specified locale identifiers is supported. For the general form and interpretation of the `locales` argument, see the parameter description on the `Intl` main page.

`options`

An object containing the following properties, in the order they are retrieved:

`localeMatcher` Optional

The locale matching algorithm to use. Possible values are `"lookup"` and `"best fit"`; the default is `"best fit"`. For information about this option, see Locale identification and negotiation.

`style` Optional

The formatting style to use. Possible values are `"narrow"`, `"short"`, and `"long"`; the default is `"long"`.

`type`

The type of display names to return from `of()`. Possible values are `"language"`, `"region"`, `"script"`, `"currency"`, `"calendar"`, and `"dateTimeField"`.

`fallback` Optional

What to return from `of()` if the input is structurally valid but there's no matching display name. Possible values are:

`"code"` (default)

Return the input code itself.

`"none"`

Return `undefined`.

`languageDisplay` Optional

How language names should be displayed. Only usable along with `type: "language"`. Possible values are:

`"dialect"` (default)

Display special regional dialects using their own name. E.g. `"nl-BE"` will be displayed as `"Flemish"`.

`"standard"`

Display all languages using standard format. E.g. `"nl-BE"` will be displayed as `"Dutch (Belgium)"`.

Exceptions

`TypeError`

Thrown if `options.type` is not provided.

`RangeError`

Thrown if `locales` or `options` contain invalid values.

Examples

Basic usage

In basic use without specifying a locale, a formatted string in the default locale and with default options is returned.

```
console.log(new Intl.DisplayNames([], { type: "language" }).of("US"));
// 'us'
```

Using type <code>dateTimeField</code>

Example using `dateTimeField` as a type option, will return the localized date time names strings.

```
const dn = new Intl.DisplayNames("pt", { type: "dateTimeField" });
console.log(dn.of("era")); // 'era'
console.log(dn.of("year")); // 'ano'
console.log(dn.of("month")); // 'mês'
console.log(dn.of("quarter")); // 'trimestre'
console.log(dn.of("weekOfYear")); // 'semana'
console.log(dn.of("weekday")); // 'dia da semana'
console.log(dn.of("dayPeriod")); // 'AM/PM'
console.log(dn.of("day")); // 'dia'
console.log(dn.of("hour")); // 'hora'
console.log(dn.of("minute")); // 'minuto'
console.log(dn.of("second")); // 'segundo'
```

Using type <code>calendar</code>

Example using `calendar` as a type option, will return the localized calendar names strings.

```
const dn = new Intl.DisplayNames("en", { type: "calendar" });
console.log(dn.of("roc")); // 'Minguo Calendar'
console.log(dn.of("gregory")); // 'Gregorian Calendar'
console.log(dn.of("chinese")); // 'Chinese Calendar'
```

Using type <code>language</code> with <code>languageDisplay</code>

Example using `language` as a type with `languageDisplay` options.

```
// Using `dialect` option
const dnDialect = new Intl.DisplayNames("en", {
  type: "language",
  languageDisplay: "dialect",
});
console.log(dnDialect.of("en-GB")); // 'British English'

// Using `standard` option
const dnStd = new Intl.DisplayNames("en", {
  type: "language",
  languageDisplay: "standard",
});
console.log(dnStd.of("en-GB")); // 'English (United Kingdom)'
```

Intl.DisplayNames.prototype.of()

The **`of()`** method of `Intl.DisplayNames` instances receives a code and returns a string based on the locale and options provided when instantiating this `Intl.DisplayNames` object.

Try it

```
const regionNamesInEnglish = new Intl.DisplayNames(["en"], { type: "region" });
const regionNamesInTraditionalChinese = new Intl.DisplayNames(["zh-Hant"], {
  type: "region",
```

```
});

console.log(regionNamesInEnglish.of("US"));
// Expected output: "United States"

console.log(regionNamesInTraditionalChinese.of("US"));
// Expected output: "美國"
```

Syntax

```
of(code)
```

Parameters

`code`

The `code` to provide depends on the `type`:

- If the type is "region", `code` should be either a two-letter ISO 3166 region code, or a three-digit UN M49 geographic region. It is required to follow the `unicode_region_subtag` grammar. Use uppercase codes (e.g., `"US"`), because lowercase ones (e.g., `"us"`) may not work reliably everywhere.
- If the type is "script", `code` should be a four-letter ISO 15924 script code. It is required to follow the `unicode_script_subtag` grammar.
- If the type is "language", `code` should be matched by the `unicode_language_id` nonterminal.
- If the type is "currency", `code` should be a three-letter ISO 4217 currency code. It is required to have exactly three alphabetic characters.
- If the type is "dateTimeField", `code` should be one of: `"era"`, `"year"`, `"quarter"`, `"month"`, `"weekOfYear"`, `"weekday"`, `"day"`, `"dayPeriod"`, `"hour"`, `"minute"`, `"second"`, `"timeZoneName"`.
- If the type is "calendar", `code` should be a calendar key. It is required to follow the `type` grammar of a Unicode locale identifier.

Return value

A language-specific formatted string, or `undefined` if there's no data for the input and `fallback` is `"none"`.

> **Note:** `fallback` is only used if `code` is structurally valid. See using fallback.

Exceptions

`RangeError`

Thrown if `code` is not structurally valid for the given `type`.

Examples

Using the of method

```
const regionNames = new Intl.DisplayNames("en", { type: "region" });
regionNames.of("419"); // "Latin America"

const languageNames = new Intl.DisplayNames("en", { type: "language" });
languageNames.of("fr"); // "French"

const currencyNames = new Intl.DisplayNames("en", { type: "currency" });
currencyNames.of("EUR"); // "Euro"

const languageNamesStandard = new Intl.DisplayNames("fr", {
  type: "language",
  languageDisplay: "standard",
});
languageNamesStandard.of("fr-CA"); // "français (Canada)"

const languageNamesDialect = new Intl.DisplayNames("fr", {
  type: "language",
  languageDisplay: "dialect",
});
languageNamesDialect.of("fr-CA"); // "français canadien"
```

Using fallback

When the `Intl.DisplayNames` is constructed with `fallback: "code"`, the `of()` method will return the `code` if the input looks structurally valid but there's no data for the input. If `fallback` is `"none"`, `undefined` is returned.

```
console.log(
  new Intl.DisplayNames("en", { type: "region", fallback: "code" }).of("ZL"),
); // "ZL"

console.log(
  new Intl.DisplayNames("en", { type: "region", fallback: "none" }).of("ZL"),
); // undefined
```

However, this only applies if the `code` is structurally valid. For example, if `type` is `"region"` but `code` does not follow the `unicode_region_subtag` grammar (2 alphabetic characters or 3 numeric characters), a `RangeError` is directly thrown instead of using the fallback.

```
console.log(
  new Intl.DisplayNames("en", { type: "region", fallback: "code" }).of("ZLC"),
); // throws RangeError: invalid value "ZLC" for option region
```

See also

- `Intl.DisplayNames`

Intl.DisplayNames.prototype.resolvedOptions()

The **`resolvedOptions()`** method of `Intl.DisplayNames` instances returns a new object with properties reflecting the options computed during initialization of this `DisplayNames` object.

Syntax

```
resolvedOptions()
```

Parameters

None.

Return value

A new object with properties reflecting the options computed during the initialization of this `DisplayNames` object. The object has the following properties, in the order they are listed:

`locale`

The BCP 47 language tag for the locale actually used, determined by the locale negotiation process. No Unicode extension key will be included in the output.

`style`

The value provided for this property in the `options` argument, with default filled in as needed. It is either `"narrow"`, `"short"`, or `"long"`. The default is `"long"`.

`type`

The value provided for this property in the `options` argument. It is either `"language"`, `"region"`, `"script"`, `"currency"`, `"calendar"`, or `"dateTimeField"`. It is required so there is no default.

`fallback`

The value provided for this property in the `options` argument. It is either `"code"` or `"none"`. The default is `"code"`.

`languageDisplay`

The value provided for this property in the `options` argument. It is either `"dialect"` or `"standard"`. The default is `"dialect"`.

Examples

Using resolvedOptions

```
const displayNames = new Intl.DisplayNames(["de-DE"], { type: "region" });

const usedOptions = displayNames.resolvedOptions();
console.log(usedOptions.locale); // "de-DE"
console.log(usedOptions.style); // "long"
console.log(usedOptions.type); // "region"
console.log(usedOptions.fallback); // "code"
```

```
const displayNames = new Intl.DisplayNames("en", {
  type: "language",
  languageDisplay: "standard",
});

const usedOptions = displayNames.resolvedOptions();
console.log(usedOptions.type); // "language"
console.log(usedOptions.languageDisplay); // "standard"
```

- `Intl.DisplayNames`

Intl.DisplayNames.supportedLocalesOf()

The **`Intl.DisplayNames.supportedLocalesOf()`** static method returns an array containing those of the provided locales that are supported in display names without having to fall back to the runtime's default locale.

Syntax

```
Intl.DisplayNames.supportedLocalesOf(locales)
Intl.DisplayNames.supportedLocalesOf(locales, options)
```

Parameters

`locales`

A string with a BCP 47 language tag, or an array of such strings. For the general form and interpretation of the `locales` argument, see the parameter description on the `Intl` main page.

`options` Optional

An object that may have the following property:

`localeMatcher`

The locale matching algorithm to use. Possible values are `"lookup"` and `"best fit"`; the default is `"best fit"`. For information about this option, see the Intl page.

Return value

An array of strings representing a subset of the given locale tags that are supported in display names without having to fall back to the runtime's default locale.

Examples

Using supportedLocalesOf()

Assuming a runtime that supports Indonesian and German but not Balinese in display names, `supportedLocalesOf` returns the Indonesian and German language tags unchanged, even though `pinyin` collation is neither relevant to display names nor used with Indonesian, and a specialized German for Indonesia is unlikely to be supported. Note the specification of the `"lookup"` algorithm here — a `"best fit"` matcher might decide that Indonesian is an adequate match for Balinese since most Balinese speakers also understand Indonesian, and therefore return the Balinese language tag as well.

```
const locales = ["ban", "id-u-co-pinyin", "de-ID"];
const options = { localeMatcher: "lookup" };
console.log(Intl.DisplayNames.supportedLocalesOf(locales, options));
// ["id-u-co-pinyin", "de-ID"]
```

- `Intl.DisplayNames`

Intl.DurationFormat

The **`Intl.DurationFormat`** object enables language-sensitive duration formatting.

Constructor

`Intl.DurationFormat()`

Creates a new `Intl.DurationFormat` object.

Static methods

`Intl.DurationFormat.supportedLocalesOf()`

Returns an array containing those of the provided locales that are supported without having to fall back to the runtime's default locale.

Instance properties

These properties are defined on `Intl.DurationFormat.prototype` and shared by all `Intl.DurationFormat` instances.

`Intl.DurationFormat.prototype.constructor`

The constructor function that created the instance object. For `Intl.DurationFormat` instances, the initial value is the `Intl.DurationFormat` constructor.

`Intl.DurationFormat.prototype[Symbol.toStringTag]`

The initial value of the `[Symbol.toStringTag]` property is the string `"Intl.DurationFormat"`. This property is used in `Object.prototype.toString()`.

Instance methods

`Intl.DurationFormat.prototype.format()`

Getter function that formats a duration according to the locale and formatting options of this `DurationFormat` object.

`Intl.DurationFormat.prototype.formatToParts()`

Returns an `Array` of objects representing the formatted duration in parts.

`Intl.DurationFormat.prototype.resolvedOptions()`

Returns a new object with properties reflecting the locale and formatting options computed during initialization of the object.

Examples

Using Intl.DurationFormat

The examples below show how to use the `Intl.DurationFormat` object to format a duration object with various locales and styles.

```
const duration = {
  hours: 1,
  minutes: 46,
  seconds: 40,
};

// With style set to "long" and locale "fr-FR"
new Intl.DurationFormat("fr-FR", { style: "long" }).format(duration);
// "1 heure, 46 minutes et 40 secondes"

// With style set to "short" and locale "en"
new Intl.DurationFormat("en", { style: "short" }).format(duration);
// "1 hr, 46 min and 40 sec"

// With style set to "narrow" and locale "pt"
new Intl.DurationFormat("pt", { style: "narrow" }).format(duration);
// "1 h 46 min 40 s"
```

See also

- Polyfill of `Intl.DurationFormat` in FormatJS
- `Intl`
- `Temporal.Duration.prototype.toLocaleString()`

Intl.DurationFormat() constructor

The **`Intl.DurationFormat()`** constructor creates `Intl.DurationFormat` objects.

Syntax

```
new Intl.DurationFormat()
new Intl.DurationFormat(locales)
new Intl.DurationFormat(locales, options)
```

> **Note:** `Intl.DurationFormat()` can only be constructed with `new`. Attempting to call it without `new` throws a `TypeError`.

Parameters

`locales` Optional

A string with a BCP 47 language tag or an `Intl.Locale` instance, or an array of such locale identifiers. The runtime's default locale is used when `undefined` is passed or when none of the specified locale identifiers is supported. For the general form and interpretation of the `locales` argument, see the parameter description on the `Intl` main page.

The following Unicode extension key is allowed:

`nu`

See `numberingSystem`.

This key can also be set with `options` (as listed below). When both are set, the `options` property takes precedence.

`options` Optional

An object containing the following properties, in the order they are retrieved (all of them are optional):

`localeMatcher`

The locale matching algorithm to use. Possible values are `"lookup"` and `"best fit"`; the default is `"best fit"`. For information about this option, see Locale identification and negotiation.

`numberingSystem`

The numbering system to use for number formatting, such as `"arab"`, `"hans"`, `"mathsans"`, and so on. For a list of supported numbering system types, see `Intl.supportedValuesOf()`; the default is locale dependent. This option can also be set through the `nu` Unicode extension key; if both are provided, this `options` property takes precedence.

`style`

The style of the formatted duration. This value is used as the default for all other unit options, and also corresponds to the `style` option of `Intl.ListFormat()` when concatenating the list of duration units. Possible values are:

`"long"`

E.g., 1 hour and 50 minutes

`"short"` (default)

E.g., 1 hr, 50 min

`"narrow"`

E.g., 1h 50m

`"digital"`

E.g., 1:50:00

`years`

The style of the formatted years. Possible values are `"long"`, `"short"`, and `"narrow"`; the default is `options.style` if it's not `"digital"`, and `"short"` otherwise.

`yearsDisplay`

Whether to always display years, or only if nonzero. Possible values are `"always"` and `"auto"`; the default is `"auto"` if `years` is unspecified, and `"always"` otherwise.

`months`

The style of the formatted months. Possible values are `"long"`, `"short"`, and `"narrow"`; the default is `options.style` if it's not `"digital"`, and `"short"` otherwise.

`monthsDisplay`

Whether to always display months, or only if nonzero. Possible values are `"always"` and `"auto"`; the default is `"auto"` if `months` is unspecified, and `"always"` otherwise.

`weeks`

The style of the formatted weeks. Possible values are `"long"`, `"short"`, and `"narrow"`; the default is `options.style` if it's not `"digital"`, and `"short"` otherwise.

`weeksDisplay`

Whether to always display weeks, or only if nonzero. Possible values are `"always"` and `"auto"`; the default is `"auto"` if `weeks` is unspecified, and `"always"` otherwise.

`days`

The style of the formatted days. Possible values are `"long"`, `"short"`, and `"narrow"`; the default is `options.style` if it's not `"digital"`, and `"short"` otherwise.

`daysDisplay`

Whether to always display days, or only if nonzero. Possible values are `"always"` and `"auto"`; the default is `"auto"` if `days` is unspecified, and `"always"` otherwise.

`hours`

The style of the formatted hours. Possible values are `"long"`, `"short"`, `"narrow"`, `"numeric"`, and `"2-digit"`; the default is `options.style` if it's not `"digital"`, and `"numeric"` otherwise.

`hoursDisplay`

Whether to always display hours, or only if nonzero. Possible values are `"always"` and `"auto"`; the default is `"auto"` if `hours` is unspecified and `options.style` is not `"digital"`, and `"always"` otherwise.

`minutes`

The style of the formatted minutes.

- If `hours` is `"numeric"` or `"2-digit"`, possible values are `"numeric"` and `"2-digit"`, and `"numeric"` is normalized to `"2-digit"`; the default is `"numeric"`.
- Otherwise, possible values are `"long"`, `"short"`, `"narrow"`, `"numeric"`, and `"2-digit"`; the default is `options.style` if it's not `"digital"`, and `"numeric"` otherwise.

`minutesDisplay`

Whether to always display minutes, or only if nonzero. Possible values are `"always"` and `"auto"`; the default is `"auto"` if `minutes` is unspecified and `options.style` is not `"digital"`, and `"always"` otherwise.

`seconds`

The style of the formatted seconds.

- If `minutes` is `"numeric"` or `"2-digit"`, possible values are `"numeric"` and `"2-digit"`, and `"numeric"` is normalized to `"2-digit"`; the default is `"numeric"`.
- Otherwise, possible values are `"long"`, `"short"`, `"narrow"`, `"numeric"`, and `"2-digit"`; the default is `options.style` if it's not `"digital"`, and `"numeric"` otherwise.

`secondsDisplay`

Whether to always display seconds, or only if nonzero. Possible values are `"always"` and `"auto"`; the default is `"auto"` if `seconds` is unspecified and `options.style` is not `"digital"`, and `"always"` otherwise.

`milliseconds`

The style of the formatted milliseconds.

- If `seconds` is `"numeric"` or `"2-digit"`, the only possible value is `"numeric"`; the default is `"numeric"`.
- Otherwise, possible values are `"long"`, `"short"`, `"narrow"`, and `"numeric"`; the default is `options.style` if it's not `"digital"`, and `"numeric"` otherwise.

`millisecondsDisplay`

Whether to always display milliseconds, or only if nonzero.

- If `seconds` is `"numeric"` or `"2-digit"`, the only possible value is `"auto"`; the default is only `"auto"` when `milliseconds` is unspecified.
- Otherwise, possible values are `"always"` and `"auto"`; the default is `"auto"` if `milliseconds` is unspecified, and `"always"` otherwise.

`microseconds`

The style of the formatted microseconds.

- If `milliseconds` is `"numeric"`, the only possible value is `"numeric"`; the default is `"numeric"`.
- Otherwise, possible values are `"long"`, `"short"`, `"narrow"`, and `"numeric"`; the default is `options.style` if it's not `"digital"`, and `"numeric"` otherwise.

`microsecondsDisplay`

Whether to always display microseconds, or only if nonzero.

- If `milliseconds` is `"numeric"`, the only possible value is `"auto"`; the default is only `"auto"` when `microseconds` is unspecified.
- Otherwise, possible values are `"always"` and `"auto"`; the default is `"auto"` if `microseconds` is unspecified, and `"always"` otherwise.

`nanoseconds`

The style of the formatted nanoseconds.

- If `microseconds` is `"numeric"`, the only possible value is `"numeric"`; the default is `"numeric"`.
- Otherwise, possible values are `"long"`, `"short"`, `"narrow"`, and `"numeric"`; the default is `options.style` if it's not `"digital"`, and `"numeric"` otherwise.

`nanosecondsDisplay`

Whether to always display nanoseconds, or only if nonzero.

- If `microseconds` is `"numeric"`, the only possible value is `"auto"`; the default is only `"auto"` when `nanoseconds` is unspecified.
- Otherwise, possible values are `"always"` and `"auto"`; the default is `"auto"` if `nanoseconds` is unspecified, and `"always"` otherwise.

`fractionalDigits`

Number of how many fractional second digits to display in the output. Possible values are from `0` to `9`; the default is `undefined` (include as many fractional digits as necessary).

Exceptions

`RangeError`

Thrown if `locales` or `options` contain invalid values.

Description

For each time segment, an `Intl.NumberFormat` object is constructed under the hood. It uses the following options (see `Intl.NumberFormat()` for details):

- `numberingSystem`: the value of `options.numberingSystem`

When `milliseconds`, `microseconds`, or `nanoseconds` uses the `"numeric"` style, the following options are also used:

- `minimumFractionDigits`: `0` when `options.fractionalDigits` is `undefined`, `options.fractionalDigits` otherwise
- `maximumFractionDigits`: `9` when `options.fractionalDigits` is `undefined`, `options.fractionalDigits` otherwise
- `roundingMode`: `"trunc"`

When the time segment uses the `"2-digit"` style, the following options are also used:

- `minimumIntegerDigits`: `2`

When the time segment uses the `"long"`, `"short"`, or `"narrow"` style, the following options are also used:

- `style`: `"unit"` when `"long"`, `"short"`, or `"narrow"` is specified, `undefined` otherwise
- `unit`: the currently formatted unit (`"years"`, `"days"`, `"nanoseconds"`, etc.)
- `unitDisplay`: the value of the time segment style (`"long"`, `"short"`, or `"narrow"`)

Examples

Using the Intl.DurationFormat() constructor

```
const duration = {
  hours: 2,
  minutes: 20,
  seconds: 35,
};

console.log(new Intl.DurationFormat("pt", { style: "long" }).format(duration));
// "2 horas, 20 minutos e 35 segundos"
```

Intl.DurationFormat.prototype.format()

The **`format()`** method of `Intl.DurationFormat` instances formats a duration according to the locale and formatting options of this `Intl.DurationFormat` object.

Syntax

```
format(duration)
```

Parameters

`duration`

> The duration object to be formatted. It should include some or all of the following properties: `years`, `months`, `weeks`, `days`, `hours`, `minutes`, `seconds`, `milliseconds`, `microseconds`, `nanoseconds`. Each property's value should be an integer, and their signs should be consistent. This can be a `Temporal.Duration` object; see the `Temporal.Duration` documentation for more information about these properties.

Return value

A string representing the given `duration` formatted according to the locale and formatting options of this `Intl.DurationFormat` object.

> **Note:** Most of the time, the formatting returned by `format()` is consistent. However, the output may vary between implementations, even within the same locale — output variations are by design and allowed by the specification. It may also not be what you expect. For example, the string may use non-breaking spaces or be surrounded by bidirectional control characters. You should not compare the results of `format()` to hardcoded constants.

Examples

Using format()

The following example shows how to create a Duration formatter using the English language.

```
const duration = {
  years: 1,
  months: 2,
  weeks: 3,
  days: 3,
  hours: 4,
  minutes: 5,
  seconds: 6,
  milliseconds: 7,
  microseconds: 8,
  nanoseconds: 9,
};

// Without options, style defaults to "short"
new Intl.DurationFormat("en").format(duration);
// "1 yr, 2 mths, 3 wks, 3 days, 4 hr, 5 min, 6 sec, 7 ms, 8 µs, 9 ns"

// With style set to "long"
new Intl.DurationFormat("en", { style: "long" }).format(duration);
// "1 year, 2 months, 3 weeks, 3 days, 4 hours, 5 minutes, 6 seconds, 7 milliseconds, 8 microseconds, 9 nanoseconds"

// With style set to "narrow"
new Intl.DurationFormat("en", { style: "narrow" }).format(duration);
// "1y 2mo 3w 3d 4h 5m 6s 7ms 8µs 9ns"
```

Using format() with different locales and styles

```
const duration = {
  hours: 1,
  minutes: 46,
  seconds: 40,
};

// With style set to "long" and locale "fr-FR"
new Intl.DurationFormat("fr-FR", { style: "long" }).format(duration);
// "1 heure, 46 minutes et 40 secondes"

// With style set to "short" and locale set to "en"
new Intl.DurationFormat("en", { style: "short" }).format(duration);
// "1 hr, 46 min and 40 sec"

// With style set to "short" and locale set to "pt"
new Intl.DurationFormat("pt", { style: "narrow" }).format(duration);
// "1 h 46 min 40 s"

// With style set to "digital" and locale set to "en"
new Intl.DurationFormat("en", { style: "digital" }).format(duration);
// "1:46:40"

// With style set to "digital", locale set to "en", and hours set to "long"
new Intl.DurationFormat("en", { style: "digital", hours: "long" }).format(
  duration,
);
// "1 hour, 46:40"
```

Using format() with the fractionalDigits option

```
const duration = {
  hours: 11,
  minutes: 30,
  seconds: 12,
  milliseconds: 345,
  microseconds: 600,
};

new Intl.DurationFormat("en", { style: "digital" }).format(duration);
// "11:30:12.3456"

new Intl.DurationFormat("en", { style: "digital", fractionalDigits: 5 }).format(
  duration,
);
// "11:30:12.34560"

new Intl.DurationFormat("en", { style: "digital", fractionalDigits: 3 }).format(
  duration,
);
// "11:30:12.346"
```

Intl.DurationFormat.prototype.formatToParts()

The **`formatToParts()`** method of `Intl.DurationFormat` instances returns an array of objects representing each part of the formatted string that would be returned by `format()`. It is useful for building custom strings from the locale-specific tokens.

Syntax

```
formatToParts(duration)
```

Parameters

`duration` Optional

> The duration object to be formatted. It should include some or all of the following properties: `years`, `months`, `weeks`, `days`, `hours`, `minutes`, `seconds`, `milliseconds`, `microseconds`, `nanoseconds`. Each property's value should be an integer, and their signs should be consistent. This can be a `Temporal.Duration` object; see the `Temporal.Duration` documentation for more information about these properties.

Return value

An `Array` of objects containing the formatted duration in parts. Each object has two or three properties, `type`, `value`, and optionally `unit`, each containing a string. The string concatenation of `value`, in the order provided, will result in the same string as `format()`. The parts can be thought of as directly obtained from calling `Intl.NumberFormat.prototype.formatToParts()` with the numeric value and their respective units. All tokens that are produced by the `NumberFormat` have an additional `unit` property, which is the singular form of the input `unit`; this is for programmatic usage and is not localized. The localized unit is output as a separate `unit` token as part of the `NumberFormat` result. The parts from each duration unit are concatenated together in the same fashion as calling `Intl.ListFormat.prototype.formatToParts()` with `{ type: "unit" }`, so additional literal tokens are inserted.

Examples

The `formatToParts` method enables locale-aware formatting of strings produced by `DurationFormat` formatters by providing you the string in parts:

```
const duration = {
  hours: 7,
  minutes: 8,
  seconds: 9,
  milliseconds: 123,
  microseconds: 456,
  nanoseconds: 789,
};

new Intl.DurationFormat("en", { style: "long" }).formatToParts(duration);

// Returned value:
[
  { type: "integer", value: "7", unit: "hour" },
  { type: "literal", value: " ", unit: "hour" },
  { type: "unit", value: "hours", unit: "hour" },
  { type: "literal", value: ", " },
  { type: "integer", value: "8", unit: "minute" },
  { type: "literal", value: " ", unit: "minute" },
  { type: "unit", value: "minutes", unit: "minute" },
  { type: "literal", value: ", " },
  { type: "integer", value: "9", unit: "second" },
  { type: "literal", value: " ", unit: "second" },
  { type: "unit", value: "seconds", unit: "second" },
  { type: "literal", value: ", " },
```

```
  { type: "integer", value: "123", unit: "millisecond" },
  { type: "literal", value: " ", unit: "millisecond" },
  { type: "unit", value: "milliseconds", unit: "millisecond" },
  { type: "literal", value: ", " },
  { type: "integer", value: "456", unit: "microsecond" },
  { type: "literal", value: " ", unit: "microsecond" },
  { type: "unit", value: "microseconds", unit: "microsecond" },
  { type: "literal", value: ", " },
  { type: "integer", value: "789", unit: "nanosecond" },
  { type: "literal", value: " ", unit: "nanosecond" },
  { type: "unit", value: "nanoseconds", unit: "nanosecond" },
];
```

Intl.DurationFormat.prototype.resolvedOptions()

The **`resolvedOptions()`** method of `Intl.DurationFormat` instances returns a new object with properties reflecting the options computed during initialization of this `DurationFormat` object.

Syntax

```
resolvedOptions()
```

Parameters

None.

Return value

A new object with properties reflecting the options computed during the initialization of this `DurationFormat` object. The object has the following properties, in the order they are listed:

`locale`

> The BCP 47 language tag for the locale actually used, determined by the locale negotiation process. Only the `nu` Unicode extension key, if requested, may be included in the output.

`numberingSystem`

> The value provided for this property in the `options` argument, or using the Unicode extension key `"nu"`, with default filled in as needed. It is a supported numbering system for this locale. The default is locale dependent.

`style`

> The value provided for this property in the `options` argument, with default filled in as needed. It is either `"long"`, `"short"`, `"narrow"`, or `"digital"`. The default is `"short"`.

`years`, `yearsDisplay`, `months`, `monthsDisplay`, `weeks`, `weeksDisplay`, `days`, `daysDisplay`, `hours`, `hoursDisplay`, `minutes`, `minutesDisplay`, `seconds`, `secondsDisplay`, `milliseconds`, `millisecondsDisplay`, `nanoseconds`, `nanosecondsDisplay`

> The values provided for these properties in the `options` argument, with defaults filled in as needed. For the valid values and defaults for each, see the `options` argument of the constructor.

`fractionalDigits` Optional

> The value provided for this property in the `options` argument. It is only present if specified in `options`. It is an integer from 0 to 9, inclusive.

Examples

Using the resolvedOptions method

```
const duration = new Intl.DurationFormat("en");
const usedOptions = duration.resolvedOptions();

usedOptions.locale; // "en"
usedOptions.numberingSystem; // "latn"
usedOptions.years; // "long"
usedOptions.yearsDisplay; // "auto"
usedOptions.style; // "long"
```

- `Intl`

Intl.DurationFormat.supportedLocalesOf()

The **`Intl.DurationFormat.supportedLocalesOf()`** static method returns an array containing those of the provided locales that are supported in duration formatting without having to fall back to the runtime's default locale.

Syntax

```
Intl.DurationFormat.supportedLocalesOf(locales)
Intl.DurationFormat.supportedLocalesOf(locales, options)
```

Parameters

`locales`

> A string with a BCP 47 language tag, or an array of such strings. For the general form and interpretation of the `locales` argument, see the parameter description on the `Intl` main page.

`options` Optional

> An object that may have the following property:
>
> `localeMatcher`
>
> > The locale matching algorithm to use. Possible values are `"lookup"` and `"best fit"`; the default is `"best fit"`. For information about this option, see the Intl page.

Return value

An array of strings representing a subset of the given locale tags that are supported in duration formatting without having to fall back to the runtime's default locale.

Examples

Using supportedLocalesOf()

Assuming a runtime that supports Indonesian and German but not Balinese in duration formatting, `supportedLocalesOf` returns the Indonesian and German language tags unchanged, even though `pinyin` collation is neither relevant to duration formatting nor used with Indonesian, and a specialized German for Indonesia is unlikely to be supported. Note the specification of the `"lookup"` algorithm here — a `"best fit"` matcher might decide that Indonesian is an adequate match for Balinese since most Balinese speakers also understand Indonesian, and therefore return the Balinese language tag as well.

```
const locales = ["ban", "id-u-co-pinyin", "de-ID"];
const options = { localeMatcher: "lookup" };
console.log(Intl.DurationFormat.supportedLocalesOf(locales, options));
// ["id-u-co-pinyin", "de-ID"]
```

See also

- `Intl.DurationFormat`

Intl.getCanonicalLocales()

The **`Intl.getCanonicalLocales()`** static method returns an array containing the canonical locale names. Duplicates will be omitted and elements will be validated as structurally valid language tags.

Try it

```
console.log(Intl.getCanonicalLocales("EN-US"));
// Expected output: Array ["en-US"]

console.log(Intl.getCanonicalLocales(["EN-US", "Fr"]));
// Expected output: Array ["en-US", "fr"]

try {
  Intl.getCanonicalLocales("EN_US");
} catch (err) {
  console.log(err.toString());
  // Expected output: RangeError: invalid language tag: "EN_US"
}
```

Syntax

```
Intl.getCanonicalLocales(locales)
```

Parameters

`locales`

> A list of `String` values for which to get the canonical locale names.

Return value

An array containing the canonical locale names.

Examples

Using getCanonicalLocales

```
Intl.getCanonicalLocales("EN-US"); // ["en-US"]
Intl.getCanonicalLocales(["EN-US", "Fr"]); // ["en-US", "fr"]

Intl.getCanonicalLocales("EN_US");
// RangeError: invalid language tag: "EN_US"
```

Intl.ListFormat

The **`Intl.ListFormat`** object enables language-sensitive list formatting.

Try it

```
const vehicles = ["Motorcycle", "Bus", "Car"];

const formatter = new Intl.ListFormat("en", {
  style: "long",
  type: "conjunction",
});
console.log(formatter.format(vehicles));
// Expected output: "Motorcycle, Bus, and Car"

const formatter2 = new Intl.ListFormat("de", {
  style: "short",
  type: "disjunction",
});
console.log(formatter2.format(vehicles));
// Expected output: "Motorcycle, Bus oder Car"

const formatter3 = new Intl.ListFormat("en", { style: "narrow", type: "unit" });
console.log(formatter3.format(vehicles));
// Expected output: "Motorcycle Bus Car"
```

Constructor

`Intl.ListFormat()`

Creates a new `Intl.ListFormat` object.

Static methods

`Intl.ListFormat.supportedLocalesOf()`

Returns an array containing those of the provided locales that are supported without having to fall back to the runtime's default locale.

Instance properties

These properties are defined on `Intl.ListFormat.prototype` and shared by all `Intl.ListFormat` instances.

`Intl.ListFormat.prototype.constructor`

The constructor function that created the instance object. For `Intl.ListFormat` instances, the initial value is the `Intl.ListFormat` constructor.

`Intl.ListFormat.prototype[Symbol.toStringTag]`

The initial value of the `[Symbol.toStringTag]` property is the string `"Intl.ListFormat"`. This property is used in `Object.prototype.toString()`.

Instance methods

`Intl.ListFormat.prototype.format()`

Returns a language-specific formatted string representing the elements of the list.

`Intl.ListFormat.prototype.formatToParts()`

Returns an array of objects representing the different components that can be used to format a list of values in a locale-aware fashion.

`Intl.ListFormat.prototype.resolvedOptions()`

Returns a new object with properties reflecting the locale and style formatting options computed during the construction of the current `Intl.ListFormat` object.

Examples

Using format

The following example shows how to create a List formatter using the English language.

```
const list = ["Motorcycle", "Bus", "Car"];

console.log(
  new Intl.ListFormat("en-GB", { style: "long", type: "conjunction" }).format(
    list,
  ),
);
// Motorcycle, Bus and Car

console.log(
  new Intl.ListFormat("en-GB", { style: "short", type: "disjunction" }).format(
    list,
  ),
);
// Motorcycle, Bus or Car

console.log(
  new Intl.ListFormat("en-GB", { style: "narrow", type: "unit" }).format(list),
);
// Motorcycle Bus Car
```

Using formatToParts

The following example shows how to create a List formatter returning formatted parts

```
const list = ["Motorcycle", "Bus", "Car"];
console.log(
  new Intl.ListFormat("en-GB", {
    style: "long",
    type: "conjunction",
  }).formatToParts(list),
);

// [ { "type": "element", "value": "Motorcycle" },
//   { "type": "literal", "value": ", " },
//   { "type": "element", "value": "Bus" },
//   { "type": "literal", "value": ", and " },
//   { "type": "element", "value": "Car" } ];
```

- Polyfill of `Intl.ListFormat` in FormatJS
- `Intl`

Intl.ListFormat.prototype.format()

The **`format()`** method of `Intl.ListFormat` instances returns a string with a language-specific representation of the list.

Try it

```
const vehicles = ["Motorcycle", "Bus", "Car"];

const formatter = new Intl.ListFormat("en", {
  style: "long",
  type: "conjunction",
});
console.log(formatter.format(vehicles));
// Expected output: "Motorcycle, Bus, and Car"

const formatter2 = new Intl.ListFormat("de", {
  style: "short",
  type: "disjunction",
});
console.log(formatter2.format(vehicles));
// Expected output: "Motorcycle, Bus oder Car"

const formatter3 = new Intl.ListFormat("en", { style: "narrow", type: "unit" });
console.log(formatter3.format(vehicles));
// Expected output: "Motorcycle Bus Car"
```

Syntax

```
format(list)
```

Parameters

`list`

An iterable object, such as an Array, containing strings. Omitting it results in formatting the empty array, which could be slightly confusing, so it is advisable to always explicitly pass a list.

Return value

A language-specific formatted string representing the elements of the list.

> **Note:** Most of the time, the formatting returned by `format()` is consistent. However, the output may vary between implementations, even within the same locale — output variations are by design and allowed by the specification. It may also not be what you expect. For example, the string may use non-breaking spaces or be surrounded by bidirectional control characters. You should not compare the results of `format()` to hardcoded constants.

Examples

Using format

The following example shows how to create a List formatter using the English language.

```
const list = ["Motorcycle", "Bus", "Car"];

console.log(
  new Intl.ListFormat("en-GB", { style: "long", type: "conjunction" }).format(
    list,
  ),
);
// Motorcycle, Bus and Car

console.log(
  new Intl.ListFormat("en-GB", { style: "short", type: "disjunction" }).format(
    list,
  ),
);
// Motorcycle, Bus or Car

console.log(
  new Intl.ListFormat("en-GB", { style: "narrow", type: "unit" }).format(list),
);
// Motorcycle Bus Car
```

See also

- `Intl.ListFormat`

Intl.ListFormat.prototype.formatToParts()

The **`formatToParts()`** method of `Intl.ListFormat` instances returns an array of objects representing each part of the formatted string that would be returned by `format()`. It is useful for building custom strings from the locale-specific tokens.

Try it

```
const vehicles = ["Motorcycle", "Bus", "Car"];

const formatterEn = new Intl.ListFormat("en", {
  style: "long",
  type: "conjunction",
});

const formatterFr = new Intl.ListFormat("fr", {
  style: "long",
  type: "conjunction",
});

const partValuesEn = formatterEn.formatToParts(vehicles).map((p) => p.value);
const partValuesFr = formatterFr.formatToParts(vehicles).map((p) => p.value);

console.log(partValuesEn);
// Expected output: "["Motorcycle", ", ", "Bus", ", and ", "Car"]"
console.log(partValuesFr);
// Expected output: "["Motorcycle", ", ", "Bus", " et ", "Car"]"
```

Syntax

```
formatToParts(list)
```

Parameters

`list`

> An iterable object, such as an Array, containing strings. Omitting it results in formatting the empty array, which could be slightly confusing, so it is advisable to always explicitly pass a list.

Return value

An `Array` of objects containing the formatted list in parts. Each object has two properties, `type` and `value`, each containing a string. The string concatenation of `value`, in the order provided, will result in the same string as `format()`. The `type` may be one of the following:

`literal`

> Any string that's a part of the format pattern; for example `", "`, `", and"`, etc.

`element`

An element of the list, exactly as provided.

Examples

Using formatToParts()

```
const fruits = ["Apple", "Orange", "Pineapple"];
const myListFormat = new Intl.ListFormat("en-GB", {
  style: "long",
  type: "conjunction",
});

console.table(myListFormat.formatToParts(fruits));
// [
//  { "type": "element", "value": "Apple" },
//  { "type": "literal", "value": ", " },
//  { "type": "element", "value": "Orange" },
//  { "type": "literal", "value": " and " },
//  { "type": "element", "value": "Pineapple" }
// ]
```

See also

- `Intl.ListFormat`
- `Intl.ListFormat.prototype.format()`

Intl.ListFormat() constructor

The **`Intl.ListFormat()`** constructor creates `Intl.ListFormat` objects.

Try it

```
const vehicles = ["Motorcycle", "Bus", "Car"];

const formatter = new Intl.ListFormat("en", {
  style: "long",
  type: "conjunction",
});
console.log(formatter.format(vehicles));
// Expected output: "Motorcycle, Bus, and Car"

const formatter2 = new Intl.ListFormat("de", {
  style: "short",
  type: "disjunction",
});
console.log(formatter2.format(vehicles));
// Expected output: "Motorcycle, Bus oder Car"

const formatter3 = new Intl.ListFormat("en", { style: "narrow", type: "unit" });
console.log(formatter3.format(vehicles));
// Expected output: "Motorcycle Bus Car"
```

Syntax

```
new Intl.ListFormat()
new Intl.ListFormat(locales)
new Intl.ListFormat(locales, options)
```

> **Note:** `Intl.ListFormat()` can only be constructed with `new`. Attempting to call it without `new` throws a `TypeError`.

Parameters

`locales` Optional

A string with a BCP 47 language tag or an `Intl.Locale` instance, or an array of such locale identifiers. The runtime's default locale is used when `undefined` is passed or when none of the specified locale identifiers is supported. For the general form and interpretation of the `locales` argument, see the parameter description on the `Intl` main page.

`options` Optional

An object containing the following properties, in the order they are retrieved (all of them are optional):

`localeMatcher`

The locale matching algorithm to use. Possible values are `"lookup"` and `"best fit"`; the default is `"best fit"`. For information about this option, see Locale identification and negotiation.

`type`

Indicates the type of grouping. Possible values are:

`"conjunction"` (default)

For "and"-based grouping of the list items: "A, B, and C"

`"disjunction"`

For "or"-based grouping of the list items: "A, B, or C"

`"unit"`

For grouping the list items as a compound unit (neither "and"-based nor "or"-based): "A, B, C"

`style`

The grouping style (for example, whether list separators and conjunctions are included). Possible values are:

`"long"` (default)

The typical list format. For example, "A, B, and C"

`"short"`

The spacing, the length or presence of a conjunction, and the separators may change. Usually, you would want the input elements to be abbreviated too. For example, "A, B, & C"

`"narrow"`

Where possible, the list format is further abbreviated, so that the output is as short as possible. For example, "A, B, C"

Exceptions

`RangeError`

Thrown if `locales` or `options` contain invalid values.

Examples

Using format

The following example shows how to create a List formatter using the English language.

```
const list = ["Motorcycle", "Bus", "Car"];

console.log(new Intl.ListFormat("en-GB", { type: "conjunction" }).format(list));
// Motorcycle, Bus and Car

console.log(new Intl.ListFormat("en-GB", { type: "disjunction" }).format(list));
// Motorcycle, Bus or Car
```

Oxford comma

Oxford comma is a comma placed immediately before the coordinating conjunction (usually "and" or "or") in a list of three or more terms. Somewhat controversially, the `en-US` locale uses the Oxford comma, while the `en-GB` locale does not.

```
const list = ["Motorcycle", "Bus", "Car"];

console.log(new Intl.ListFormat("en-GB", { type: "conjunction" }).format(list));
// Motorcycle, Bus and Car

console.log(new Intl.ListFormat("en-US", { type: "conjunction" }).format(list));
// Motorcycle, Bus, and Car
```

Unit formatting

Use `style: "unit"` to format the list items as a compound unit. In fact, `Intl.DurationFormat` uses unit-style list formatting under the hood to format durations.

```
const marathon = [
  [42, "kilometer"],
  [195, "meter"],
];

console.log(
  new Intl.ListFormat("en-US", { type: "unit" }).format(
    marathon.map((component) =>
      component[0].toLocaleString("en-US", {
        style: "unit",
        unit: component[1],
        unitDisplay: "long",
      }),
    ),
  ),
);
// 42 kilometers, 195 meters
```

Short and narrow style

The `"short"` and `"narrow"` styles are useful for compact representations of lists.

```
const list = ["Motorcycle", "Bus", "Car"];
console.log(new Intl.ListFormat("en-US", { style: "short" }).format(list));
// Motorcycle, Bus, & Car

console.log(new Intl.ListFormat("en-US", { style: "narrow" }).format(list));
// Motorcycle, Bus, Car

console.log(new Intl.ListFormat("en-GB", { style: "short" }).format(list));
// Motorcycle, Bus and Car

console.log(new Intl.ListFormat("en-GB", { style: "narrow" }).format(list));
// Motorcycle, Bus, Car
```

The input elements are not transformed, but you will often want to abbreviate them too.

```
const marathon = [
  [42, "kilometer"],
  [195, "meter"],
];

function formatDistance(locale, distance, style) {
  return new Intl.ListFormat(locale, { type: "unit", style }).format(
    marathon.map((component) =>
      component[0].toLocaleString(locale, {
        style: "unit",
        unit: component[1],
        unitDisplay: style,
      }),
    ),
  );
}

console.log(formatDistance("en-US", marathon, "long"));
// 42 kilometers, 195 meters
console.log(formatDistance("en-US", marathon, "short"));
// 42 km, 195 m
console.log(formatDistance("en-US", marathon, "narrow"));
// 42km 195m
```

Selection of conjunction

The conjunction word used may depend on the list items' string values. For example, in Spanish, the conjunction is `"y"` for most words, but `"e"` for words starting with the vowel `"i"`.

```
const words = ["fuerte", "indomable"];
const formatter = new Intl.ListFormat("es-ES", { type: "conjunction" });

console.log(formatter.format(words));
// fuerte e indomable
console.log(formatter.format(words.toReversed()));
// indomable y fuerte
```

The algorithm used to determine the conjunction is not perfect (for example, it can't always tell a word's pronunciation from its spelling), but it should work in the general case.

Intl.ListFormat.prototype.resolvedOptions()

The **`resolvedOptions()`** method of `Intl.ListFormat` instances returns a new object with properties reflecting the options computed during initialization of this `ListFormat` object.

Try it

```
const deListFormatter = new Intl.ListFormat("de-DE", { type: "disjunction" });
const options = deListFormatter.resolvedOptions();

console.log(options.locale);
// Expected output: "de-DE"

console.log(options.style);
// Expected output: "long"

console.log(options.type);
// Expected output: "disjunction"
```

Syntax

```
resolvedOptions()
```

Parameters

None.

Return value

A new object with properties reflecting the options computed during the initialization of this `ListFormat` object. The object has the following properties, in the order they are listed:

`locale`

> The BCP 47 language tag for the locale actually used, determined by the locale negotiation process. No Unicode extension key will be included in the output.

`type`

> The value provided for this property in the `options` argument, with default filled in as needed. It is either `"conjunction"`, `"disjunction"`, or `"unit"`. The default is `"conjunction"`.

`style`

> The value provided for this property in the `options` argument, with default filled in as needed. It is either `"long"`, `"short"`, or `"narrow"`. The default is `"long"`.

Examples

Using resolvedOptions

```
const deListFormatter = new Intl.ListFormat("de-DE", { style: "short" });

const usedOptions = de.resolvedOptions();
console.log(usedOptions.locale); // "de-DE"
console.log(usedOptions.style); // "short"
console.log(usedOptions.type); // "conjunction" (the default value)
```

Intl.ListFormat.supportedLocalesOf()

The **`Intl.ListFormat.supportedLocalesOf()`** static method returns an array containing those of the provided locales that are supported in list formatting without having to fall back to the runtime's default locale.

Syntax

```
Intl.ListFormat.supportedLocalesOf(locales)
Intl.ListFormat.supportedLocalesOf(locales, options)
```

Parameters

`locales`

> A string with a BCP 47 language tag, or an array of such strings. For the general form and interpretation of the `locales` argument, see the parameter description on the `Intl` main page.

`options` Optional

> An object that may have the following property:
>
> `localeMatcher`
>
> > The locale matching algorithm to use. Possible values are `"lookup"` and `"best fit"`; the default is `"best fit"`. For information about this option, see the Intl page.

Return value

An array of strings representing a subset of the given locale tags that are supported in list formatting without having to fall back to the runtime's default locale.
