CSS: Cascading Style Sheets

Cascading Style Sheets (**CSS**) is a stylesheet language used to describe the presentation of a document written in HTML or XML (including XML dialects such as SVG, MathML or XHTML). CSS describes how elements should be rendered on screen, on paper, in speech, or on other media.

CSS is among the core languages of the **open web** and is standardized across web browsers according to W3C specifications. Previously, the development of various parts of CSS specification was done synchronously, which allowed the versioning of the latest recommendations. You might have heard about CSS1, CSS2.1, or even CSS3. There will never be a CSS3 or a CSS4; rather, everything is now just "CSS" with individual CSS modules having version numbers.

After CSS 2.1, the scope of the specification increased significantly and the progress on different CSS modules started to differ so much, that it became more effective to develop and release recommendations separately per module. Instead of versioning the CSS specification, W3C now periodically takes a snapshot of the latest stable state of the CSS specification and individual modules progress. CSS modules now have version numbers, or levels, such as CSS Color Module Level 5.

Beginner's tutorials

Our learn web development core modules contain modern, up-to-date tutorials covering CSS fundamentals.

Your first website: Styling the content

> This article provides a brief tour of what CSS is and how to use it, aimed at people who are completely new to web development.

CSS styling basics

> This module provides all the CSS fundamentals you'll need to start learning the technology effectively, including syntax, features, and techniques.

CSS text styling

> Here we look at CSS text fundamentals including setting font, boldness, italics, line and letter spacing, and drop shadows. We round off the module by looking at applying custom fonts to your page, and styling lists and links.

CSS layout

> This module looks at floats, positioning, other modern layout tools, and building responsive designs that will adapt to different devices, screen sizes, and resolutions.

Guides

CSS guides are organized by modules and are there to help you learn what you can achieve using CSS. Browse the complete list at CSS guides, which includes topics such as:

- CSS syntax including declarations and rulesets.
- Specificity, inheritance, and cascade
- Nesting, scoping and shadow parts
- Media and container queries
- Numeric and textual data types
- Box model and margin collapse
- Containing block
- Stacking and block-formatting contexts
- Property value processing
- Shorthand properties
- Flexible box, multi-column and grid layouts
- Animations, transitions, and transforms

How to

CSS layout cookbook

> Recipes for common layout patterns you might need to implement in your sites. These recipes provide code you can use as a starting point in your projects. These recipes also highlight the different ways layout specifications can be used and the choices you can make as a developer.

Tools

Border-image generator

> Generate CSS `border-image` values.

Border-radius generator

> Generate CSS `border-radius` effects.

Box-shadow generator

> Add `box-shadow` effects to your CSS objects.

Color format converter

> Enter or pick a color and copy its corresponding value in any CSS color format.

Color mixer

> Mix two colors in any color space using the `color-mix()` function and copy the resulting color in any CSS color format.

Shape generator

> Define coordinates and syntax for `<basic-shape>` features.

You can also use the following resources:

- W3C CSS Validation Service: To check if your CSS is valid. This is an invaluable debugging tool.
- Firefox Developer Tools: To view and edit a page's live CSS via the Inspector and the Style Editor tools.
- Web Developer extension: To track and edit live CSS on websites in Firefox.

Reference

Browse the complete CSS reference documentation.

CSS properties

> Reference for all CSS properties.

CSS selectors

Reference for CSS selectors, combinators, pseudo-classes, and pseudo-elements.

CSS at-rules

Reference for CSS at-rules including media queries.

CSS values

Reference for CSS keywords, data types, and functions.

CSS guides

This page lists CSS modules, which reflect how CSS specifications are structured. Each module provides an overview of the specification, lists the features it provides (such as properties, at-rules, and data types), and shows how they relate to other parts of CSS and the web platform. You can use the module pages as a starting point to navigate through the related guides and dive deeper into reference documentation for specific features.

To access the individual guides within each module, click on a module name from the following list to visit its landing page, or use the sidebar to navigate directly to a topic and discover all related guides.

CSS anchor positioning

The **CSS anchor positioning** module defines features that allow you to tether elements together. Certain elements are defined as **anchor elements**; **anchor-positioned elements** can then have their size and position set based on the size and location of the anchor elements to which they are bound.

CSS animation triggers

The **CSS animation triggers** module provides functionality to trigger standard time-based CSS animations when a specific timeline trigger occurs.

CSS animations

The **CSS animations** module lets you animate the values of CSS properties, such as background-position and transform, over time by using keyframes. Each keyframe describes how the animated element should render at a given time during the animation sequence. You can use the properties in the animations module to control the duration, number of repetitions, delayed start, and other aspects of an animation.

CSS backgrounds and borders

The **CSS backgrounds and borders** module provides properties for adding backgrounds, borders, rounded corners, and box shadows to elements.

CSS basic user interface

The **CSS basic user interface** module allows you to define the rendering and functionality of features related to the user interface, including outline properties, visual feedback for pointing devices and keyboards, and modifying the default appearance of UI widgets.

CSS borders and box decorations

The **CSS borders and box decorations** module provides properties for adding borders, shaped corners, and box shadows to elements. This module extends borders and box decorations introduced in the CSS backgrounds and borders module, adding `corner-shape` and `border-shape` properties, logical `border-radius` properties, longhand properties for the `box-shadow` property, and properties to create partial borders.

CSS box alignment

The **CSS box alignment** module specifies CSS features relating to the alignment of boxes within their containers. It defines the alignment of the various CSS box layout models including block layout, table layout, flexible box layout (flexbox), and grid layout, creating a consistent alignment method across all of CSS.

CSS box model

The **CSS box model** module defines the `margin` and `padding` properties, which along with the height, width and border properties, make up the CSS box model.

CSS box sizing

The **CSS box sizing** module enables you to specify how elements fit their content or fit into a particular layout context. It defines sizing, minimum sizing, and maximum sizing properties, and also extends the CSS sizing properties with keywords that represent content-based intrinsic size and context-based extrinsic size.

CSS cascading and inheritance

The **CSS cascading and inheritance** module defines the rules for assigning values to properties by way of cascading and inheritance. This module specifies the rules for finding the specified value for all properties on all elements.

CSS color adjustment

The **CSS color adjustment** module provides a model and controls automatic color adjustment by the user agent to handle user preferences, such as "Dark Mode", contrast adjustment, and other color scheme preferences.

CSS colors

The **CSS colors** module defines colors, color types, color blending, opacity, and how you can apply these colors and effects to HTML content.

CSS compositing and blending

The **CSS compositing and blending** module defines how an element's background layers can be blended together, how an element can be blended with its container, and whether the element must create a new stacking context.

CSS conditional rules

The **CSS conditional rules** module defines CSS media and support queries, enabling you to define styles that are only applied if specific conditions are met. The conditional rules defined in this module are based on device, user-agent, and viewport capabilities. With conditional rules, you can target CSS styles based on query values or browser and device features, independent of the document being rendered.

CSS containment

The **CSS containment** module defines containment and container queries.

CSS counter styles

The **CSS counter styles** module lets you define your own counter styles to manage the appearance of markers in lists and counters in generated content. It also enables you to extend native browser list styles with your own customizations.

CSS custom functions and mixins

The **CSS custom functions and mixins** module allows developers to create reusable blocks of CSS code that can accept arguments, contain complex logic (defined using features such as CSS `if()` functions and `@media` at-rules), and return values based on that logic.

CSS custom highlight API

The **CSS custom highlight API** module provides a programmatic way to target specific ranges of text defined by range objects, without affecting the underlying DOM structure. The range objects can then be selected via `::highlight()` pseudo-elements, and have highlight styles added and removed. The features of this module can create highlight effects similar to how text editors highlight spelling or grammar errors, and code editors highlight syntax errors.

CSS custom properties for cascading variables

The **CSS custom properties for cascading variables** module adds support for cascading variables in CSS properties and lets you create custom properties to define these variables along with the mechanisms to use custom properties as the values for other CSS properties.

CSS display

The **CSS display** module defines how the CSS formatting box tree is generated from the document element tree and defines properties controlling it.

CSS easing functions

The **CSS easing functions** module defines easing functions, which provide a means to control the transformation of values. The functions defined include linear, cubic bezier, and step easing functions. These easing functions can be applied to animations and transitions.

CSS environment variables

The **CSS environment variables** module defines the concept of environment variables and the `env` function. Environment variables work similarly to custom properties and the `var` function, except that they are globally defined; they are global variables scoped to the entire document. They are user agent values, provided by the browser or operating system, you can access using the `env` function enabling you to adapt your styles to the user's device or context.

CSS filter effects

The properties in the **CSS filter effects** module let you define a way of processing an element's rendering before the element is displayed in the document. Examples of such effects include blurring and changing the intensity of the color of an element.

CSS flexible box layout

The **CSS flexible box layout** module defines a CSS box model optimized for user interface design, and the layout of items in one dimension. In the flex layout model, the children of a flex container can be laid out in any direction, and can "flex" their sizes, either growing to fill unused space or shrinking to avoid overflowing the parent. Both horizontal and vertical alignment of the children can be easily manipulated.

CSS font loading

The **CSS font loading** module describes events and interfaces used for dynamically loading font resources.

CSS fonts

The **CSS fonts** module defines font-related properties and how font resources are loaded. It lets you define the style of a font, such as its family, size and weight, and the glyph variants to use when multiple are available for a single character.

CSS fragmentation

The **CSS fragmentation** module defines how content is displayed when it is broken (fragmented) and flows across multiple pages, regions, or columns. This module defines features for pagination, breaking variable fragment size and orientation, widows and orphans.

CSS gaps

The **CSS gaps** module lets you specify spacing, or "gaps", between items in multi-column, flexbox, and grid layouts. The CSS multi-column layout module originally defined gaps and rules that control the spacing between columns in multi-column containers. This module expands on these visible separators, called *gap decorations*, extending it to grid and flexbox.

CSS generated content

The **CSS generated content** module defines how an element's content can be replaced and content can be added to a document with CSS.

CSS grid layout

The **CSS grid layout** module excels at dividing a page into major regions or defining the relationship in terms of size, position, and layering between parts of a control built from HTML primitives.

CSS images

The **CSS images** module defines the types of images that can be used (the `image` type, containing URLs, gradients and other types of images), how to resize them and how they, and other replaced content, interact with the different layout models.

CSS inline layout

The **CSS inline layout** module defines the block-axis alignment and sizing of inline-level content and adds a special layout mode for drop-caps. It describes the CSS formatting model for a flow of elements and text inside a container to be wrapped across multiple lines.

CSS lists and counters

The **CSS lists and counters** module enables styling and positioning of list item bullets and manipulating their values with a combination of strings, counters, and other features.

CSS logical properties and values

The **CSS logical properties and values** module defines logical properties and values that can control layout through logical rather than physical direction and dimension mappings. Logical properties define direction-relative equivalents to their corresponding physical properties.

CSS masking

The **CSS masking** module defines masking and clipping, two different graphical operations that are used to partially or fully hide portions of visual elements.

CSS media queries

The **CSS media queries** module enables testing and querying of viewport values and browser or device features, to conditionally apply CSS styles based on the current user environment. Media queries are used in the CSS `@media` rule and other contexts and languages such as HTML and JavaScript.

CSS motion path

The **CSS motion path** module allows authors to animate any graphical object along a custom path.

CSS multi-column layout

The **CSS multi-column layout** module lets you divide content across multiple columns. By using the properties in this module, you can define the preferred number and width of columns, the gap size between columns, and the visual appearance of the optional column dividing lines (known as column rules). You can also define how content should flow from column to column and how to break content

between columns.

CSS namespaces

The **CSS namespaces** module defines the syntax for using namespaces in CSS.

CSS nesting

The **CSS nesting** module defines a syntax for nesting selectors, providing the ability to nest one style rule inside another, with the selector of the child rule relative to the selector of the parent rule.

CSS overflow

The **CSS overflow** module properties enable you to handle scrollable overflow in visual media.

CSS overscroll behavior

The **CSS overscroll behavior** module provides properties to control the behavior of a scroll container when its scroll position reaches the scroll boundary. Controlling this aspect is particularly useful in scenarios where embedded scrollable areas should not trigger scrolling of the parent container.

CSS paged media

The **CSS paged media** module defines the properties that control the presentation of content for print or any other media that splits content into discrete pages. It allows you to set page breaks, control printable areas, and style left and right pages differently.

CSS positioned layout

The **CSS positioned layout** module defines the coordinate-based positioning and offsetting schemes available in CSS and the properties used to position and stack elements on a web page. The module is best known for defining the basic positioning methods, including relative positioning, sticky positioning, absolute positioning, and fixed positioning. It also defines how positioned elements are painted and layered, clarifying stacking behavior and visual order.

CSS properties and values API

The **CSS properties and values API** module defines a method for registering new CSS properties, defining the property's data type, inheritance behavior, and, optionally, an initial value. This API expands on CSS custom properties for cascading variables module, which allows authors to define custom properties in CSS using two dash syntax (`--`). The CSS properties and values API is part of the CSS Houdini umbrella of APIs.

CSS pseudo-elements

The **CSS pseudo-element** module defines abstract elements that are not directly present in the document tree. These abstract elements, called pseudo-elements, represent portions of the render tree that can be selected and styled. Pseudo-elements are used to create abstractions about the document tree beyond those provided by the document tree.

CSS round display

The **CSS round display** module defines CSS extensions to support a round display, such as wrist-watches, to help developers build web pages suitable for those devices.

CSS ruby layout

The **CSS ruby layout** module provides the rendering model and formatting controls related to the display of ruby annotations. Ruby annotations are a form of interlinear annotation, consisting of short runs of text alongside the base text. They are typically used in East Asian documents to indicate pronunciation or define meaning.

CSS scoping

The **CSS scoping** module defines the CSS scoping and encapsulation mechanisms, focusing on the Shadow DOM scoping mechanism.

CSS scroll anchoring

The **CSS scroll anchoring** module defines a mechanism to prevent page movement due to DOM changes above the visible region of a scrolling box while the user is consuming the visible content.

CSS scroll snap

The **CSS scroll snap** module provides properties that let you control the panning and scrolling behavior by defining snap positions. Content can be snapped into position as the user scrolls overflowing content within a scroll container, providing paging and scroll positioning.

CSS scroll-driven animations

The **CSS scroll-driven animations** module provides functionality that builds on the CSS animations module and Web Animations API. It allows you to animate property values along a scroll-based timeline rather than the default time-based document timeline. This means that you can animate an element by scrolling the element, its scroll container, or its root element, rather than just by the passing of time.

CSS scrollbars styling

The **CSS scrollbars styling** module defines properties that you can use for visual styling of scrollbars. You can customize the scrollbar width as needed. You can also customize the scrollbar *track* color (the background) and the scrollbar *thumb* color (the draggable handle).

CSS selectors

The **CSS selectors** module defines the patterns to select elements to which a set of CSS rules are then applied along with their specificity. The CSS selectors module provides us with more than 60 selectors and five combinators. Other modules provide additional pseudo-class selectors and pseudo-elements.

CSS shadow parts

The **CSS shadow parts** module defines the `::part()` pseudo-element that can be set on a shadow host. Using this pseudo-element, you can enable shadow hosts to expose the selected element in the shadow tree to the outside page for styling purposes.

CSS shapes

The **CSS shapes** module describes geometric shapes. It also defines CSS properties that can use the shapes to control the geometry of an element's float area; this area can then be applied to exclusions, or specify an element's content area.

CSS syntax

The **CSS syntax** module describes, in general terms, the structure and syntax of cascading stylesheets, or CSS. It defines CSS as the language for describing the rendering of structured documents (such as HTML and XML), on the web and elsewhere.

CSS table

The **CSS table** module helps you define how to lay out table data.

CSS text

The **CSS text** module defines how to perform text manipulation, like line breaking, justification and alignment, white space handling, and text transformation.

CSS text decoration

The **CSS text decoration** module defines features relating to text decoration, such as underlines, text shadows, and emphasis marks. Text decoration features can provide visual cues for spelling errors, grammar issues, and links. These features can help improve the usability, accessibility, functionality, and aesthetics of your text.

CSS transforms

The **CSS transforms** module defines how elements styled with CSS can be transformed in two-dimensional or three-dimensional space.

CSS transitions

The **CSS transitions** module specifies functionality for creating gradual transitions between different CSS property values. The behavior of these transitions can be controlled by specifying their easing function, duration, and other values.

CSS values and units

Every CSS declaration consists of a property/value pair. The value can take various forms depending on the property, such as a single integer, keyword, function, or a combination of different items; some values have units, while others do not. Every property also accepts the CSS-wide values. The CSS values and units module defines the data types — values and units — that CSS properties accept. This module also defines the CSS value definition syntax, or formal grammar, used to define the set of valid values for every CSS property and function.

CSS view transitions

The **CSS view transitions** module defines the behavior of the View Transition API, which allows developers to create animated transitions between different states within a document and across documents. This module also defines the CSS properties and pseudo-elements for styling these transitions.

CSS viewport

The **CSS viewport** module enables specifying the size, zoom factor, and orientation of the user-agent's initial containing block, or *viewport*.

CSS will-change

The **CSS will change** module provides a hint to the browser to enable optimizations that can improve rendering performance by doing potentially expensive work before it is required via the `will-change` property.

CSS writing modes

The **CSS writing modes** module defines support for various international writing modes and their combinations, including left-to-right and right-to-left text ordering as well as horizontal and vertical orientations.

CSSOM view

The **CSSOM view** module lets you manipulate the visual view of a document, including getting the position of element layout boxes, obtaining the width or height of the viewport through script, and also scrolling an element.

WebXR DOM overlays

The **WebXR DOM overlays** module, an immersive web specification, expands the WebXR Device API to allow HTML content — such as text and controls — to be displayed during an immersive virtual reality (VR) or augmented reality (AR) session.

CSS anchor positioning

The **CSS anchor positioning** module defines features that allow you to tether elements together. Certain elements are defined as **anchor elements**; **anchor-positioned elements** can then have their size and position set based on the size and location of the anchor elements to which they are bound.

In addition, the specification provides CSS-only mechanisms to:

- Specify a set of alternative positions for an anchored element; when the default rendering position causes it to overflow its containing block and/or be rendered offscreen, the browser will try rendering the anchored element in the alternative positions instead.
- Declare conditions under which anchor-positioned elements should be hidden, in situations where it is not appropriate to tether them to anchor elements.

Using anchored container queries

CSS anchor positioning includes mechanisms for providing fallback options. These are alternative positions that the browser can try placing an anchor-positioned element in, relative to its anchor, to put it back on-screen if the positioned element starts to overflow the viewport.

Anchored container queries further increase the usefulness of anchor positioning fallback options by enabling different styling of the anchor-positioned element depending on which fallback position it is placed in. This guide shows how to use anchored container queries and provides a couple of examples.

> **Note:** For information on the basic fundamentals of CSS anchor positioning, see Using CSS anchor positioning.

Feature summary

When positioning a tooltip relative to a UI element using anchor positioning, it is useful to provide `position-try` fallback options, via the `position-try-fallbacks` property. These can be used to ensure that the tooltip is displayed on-screen for as long as possible.

For example, if the tooltip is placed above the UI element it is anchored to by default, if the user scrolls upward you can use fallbacks to move the tooltip below the element just before the tooltip goes off-screen.

One problem this doesn't solve on its own is updating the styling of the anchor-positioned element to suit the different fallback options. For example, it is common to include a small arrow on the tooltip that points to the anchor element it is associated with, improving UX by making the visual association clearer. When the tooltip moves to a different position, the position and orientation of the arrow must also change, otherwise it will look wrong.

To solve this problem, you can use anchored container queries. These extend the functionality of CSS container queries to enable you to detect when a specific fallback option is applied to an anchor-positioned element, and apply CSS to its descendants as a result. Specifically, anchored container queries rely on two features:

- The `container-type` property `anchored` value: Apply this to the anchor-positioned element to start detecting when different fallback options are applied to it.
- The `@container` at-rule `anchored()` function: This is given a `fallback` descriptor as an argument. The descriptor's value is a `position-try-fallbacks` value.

For example, let's say we have a tooltip element that is positioned above its anchor by default via a `position-area` value of `top`, but has a `position-try-fallbacks` value of `flip-block` specified. This will cause the tooltip to flip in the block direction to the bottom of its anchor when it starts to overflow the top of the viewport. If we want to detect when the fallback is applied to the tooltip, we first need to set `container-type: anchored` on it to turn it into an anchored query container.

```
.tooltip {
  position: absolute;
  position-anchor: --my-anchor;
  position-area: top;
  position-try-fallbacks: flip-block;
  container-type: anchored;
}
```

With this in place, we can now write a container query like so:

```
@container anchored(fallback: flip-block) {
  /* Descendant styles here */
}
```

The query test — `anchored(fallback: flip-block)` — will return true when the `flip-block` fallback option is applied to the tooltip, in which case the styles specified within the `@container` block will be applied. You might for example want to change the position and orientation of an arrow so that it points upwards rather than downwards, or change the direction of a gradient.

> **Note:** Bear in mind that, as with all container queries, the applied styles can only affect descendants of the container, not the container itself. This might require you to apply some of your positioned element styles to a wrapper element inside it, rather than to the element itself, as demonstrated in Multiple fallbacks example.

Basic usage example

This example includes an anchor element that has an infobox positioned relative to it. Initially, the infobox is positioned above the anchor and includes an arrow pointing down towards the anchor. We include a position try fallback so that the infobox moves below the anchor when the content scrolls up enough that the infobox starts to scroll off the top of the viewport. In addition, we use an anchored container query to change styles once the fallback kicks in, moving the arrow and pointing it upwards instead.

The anchor and infobox are represented by two `<div>` elements, as shown below. They are surrounded by text content in the final rendering to cause the page to scroll, but we've hidden it for brevity:

```
<div class="anchor">⚓</div>

<div class="infobox">Infobox</div>
```

```
<p>Lorem ipsum dolor sit amet, consectetur adipiscing elit.</p>

<p>

</p>
```

In our CSS, we start by specifying the `anchor` `<div>` as an anchor element by giving it an `anchor-name` of `--my-anchor`.

```
* {
  box-sizing: border-box;
}

html {
  font-family: sans-serif;
}

body {
  width: 80%;
  max-width: 600px;
  margin: 0 auto;
}

p {
  font-size: 1.4em;
  line-height: 1.5;
}

.anchor {
  font-size: 2em;
  color: white;
  text-shadow: 1px 1px 1px black;
  background-color: blue;
  width: fit-content;
  padding: 5px 10px;
}

.infobox {
  color: white;
  background-color: black;
  font-size: 1.4em;
  padding: 10px;
  margin: 1rem;
  border-radius: 10px;
}

.infobox::before {
  color: black;
  font-size: 1rem;
  margin: 0;
  line-height: 0.5;
  left: 0;
  width: 100%;
  text-align: center;
}

@supports not (container-type: anchored) {
  body::before {
    content: "Your browser does not support anchored container queries.";
    background-color: wheat;
    display: block;
    text-align: center;
    padding: 1rem 0;
  }
}
```

```
.anchor {
  anchor-name: --my-anchor;
}
```

Next, we give the `infobox` `<div>` a `position` value of `fixed` and a `position-anchor` value of `--my-anchor` to associate it with the anchor element. We then give the infobox a `position-area` value of `top` to position it above the anchor element and a `position-try-fallbacks` value of `bottom` so that the infobox will be moved below the anchor when it starts to overflow the top of the viewport as the content is scrolled upwards.

Finally, we set a `container-type` value of `anchored` on the infobox to designate it as an anchored query container, meaning that we can now detect when different `position-try-fallbacks` are active on the infobox via `@container` at-rules, and update styles on its descendants as a result.

```
.infobox {
  position: fixed;
  position-anchor: --my-anchor;
  position-area: top;
  position-try-fallbacks: bottom;
  container-type: anchored;
}
```

Now we'll add the arrow to the infobox using generated content on its `::before` pseudo-element. We set the pseudo-element's `content` property to a suitable down arrow icon, position it absolutely, and set its `top` property to `105%` to position it at the bottom of the infobox (we set it to more than `100%` so that it visually matches up with the position of the corresponding up arrow).

```
.infobox::before {
  content: "▼";
  position: absolute;
  top: 105%;
}
```

Next we add the anchored container query. We include a `@container` at-rule with its test defined as `anchored(fallback: bottom)`. This means that when the `bottom` position-try fallback is applied to the infobox, the CSS inside the at-rule is applied to the document. Inside, we define alternative styling for the infobox `::before` pseudo-element that swaps out the down arrow icon for an up arrow and positions it at the top of the infobox.

```
@container anchored(fallback: bottom) {
  .infobox::before {
    content: "▲";
    bottom: 100%;
    top: auto;
  }
}
```

> **Note:** There is more CSS included in this example to handle the basic styling of all the elements, but we've only shown you the parts relevant to anchored container queries. To see the full code, open the example in the MDN Playground by pressing the "Play" button on one of the code blocks or the live rendering.

This example renders like so:

Try scrolling the demo so that the anchor moves near to the top of the viewport and note how, not only does the infobox move below the anchor to remain on the screen, but the styling also updates so that the arrow icon still works for the new infobox position.

If you scroll the anchor back down towards the bottom of the viewport, the infobox will move back up above it again. We don't need to specify an additional `position-try-fallbacks` value of `top` to achieve this because `position-area: top` is the infobox's default provided position. If the provided fallbacks don't stop the anchor-positioned element from overflowing, the browser will revert to its default position.

Multiple fallbacks example

This example shows multiple position-try fallbacks and anchored container queries in action, and also addresses the problem of what to do if you want to use anchored container queries to set styles on the anchor-positioned element itself, rather than its descendants, using an extra wrapper element. The example also includes some JavaScript that allows you to move the anchor element around the screen using the mouse or the keyboard to check out the different fallbacks.

The HTML for this example includes two `<div>` elements to represent the anchor and infobox. The `anchor` `<div>` includes a `tabindex` attribute to make it keyboard-focusable, while the `infobox` `<div>` includes an extra wrapper `<div>` to apply the infobox styles to, so we can style it via `@container` at-rules.

```
<div class="anchor" tabindex="0">⚓</div>

<div class="infobox">
  <div>Infobox</div>
</div>
```

We start off our styles by specifying the `anchor` `<div>` as an anchor element, again by giving it an `anchor-name` of `--my-anchor`. We also absolutely position it so that we can move it around by setting different inset property values on it via JavaScript.

```
* {
  box-sizing: border-box;
}

html {
  font-family: sans-serif;
  height: 100%;
}

body {
  height: inherit;
}

p {
  font-size: 1.4em;
  line-height: 1.5;
}

.anchor {
  font-size: 2em;
  color: white;
  text-shadow: 1px 1px 1px black;
  background-color: blue;
  width: fit-content;
  padding: 5px 10px;
}

@supports not (container-type: anchored) {
  body::before {
    content: "Your browser does not support anchored container queries.";
    background-color: wheat;
    display: block;
    text-align: center;
    padding: 1rem 0;
  }
}
```

```
.anchor {
  anchor-name: --my-anchor;
  position: absolute;
}
```

Next, we position our infobox relative to our anchor by absolutely positioning it and giving it a `position-anchor` value of `--my-anchor`. This time we position it at the top-left of the anchor with a `position-area` value of `top left`. We then set three `position-try-fallbacks` — `flip-block`, `flip-inline`, and `flip-block flip-inline` — this causes the infobox to flip its position along its block axis, inline axis, or both, to stay on-screen when the anchor gets near to the different edges of the viewport.

Finally, we turn the infobox into an anchored query container by setting `container-type: anchored`.

```
.infobox {
  position: absolute;
  position-anchor: --my-anchor;
  position-area: top left;
  position-try-fallbacks:
    flip-block,
    flip-inline,
    flip-block flip-inline;
  container-type: anchored;
}
```

At this point, we will show you the basic visual styles set on the infobox, to illustrate the fact that, in this case, we are setting these styles on the wrapper `<div>` inside the infobox rather than the infobox itself. As mentioned earlier, we are doing this so we can manipulate these styles via anchored container queries. This wouldn't be possible if they were set directly on the infobox, as it is the anchored query container.

Most notably, here we are setting a `border-radius` value that creates a rounded corner on every corner of the infobox except for the bottom-right corner. Since the infobox is positioned to the top-left of the anchor, this corner acts as an arrow, pointing at the anchor.

```
.infobox div {
  color: white;
```

```
  background-color: black;
  font-size: 1.4em;
  padding: 10px;
  margin: 1px;

  border-radius: 10px 10px 0 10px;
}
```

Finally, we define an anchored container query for each position-try fallback that may be applied to the infobox using `@container` at-rules. In each case, we alter the rounded corners applied to the infobox wrapper `<div>` so that the nearest corner to the anchor is always not rounded.

```
@container anchored(fallback: flip-block) {
  .infobox div {
    border-radius: 10px 0 10px 10px;
  }
}

@container anchored(fallback: flip-inline) {
  .infobox div {
    border-radius: 10px 10px 10px 0;
  }
}

@container anchored(fallback: flip-block flip-inline) {
  .infobox div {
    border-radius: 0 10px 10px 10px;
  }
}
```

> **Note:** Again, we've hidden most of the basic styling for brevity, as well as the JavaScript that provides the movement controls (this isn't relevant to what we are trying to demonstrate here). To see the full code, open the example in the MDN Playground by pressing the "Play" button on one of the code blocks or the live rendering.

```
const anchorDiv = document.querySelector(".anchor");

let xPos = 250;
let yPos = 120;

function setPos() {
  const maxX = document.body.clientWidth - anchorDiv.clientWidth - 25;
  const maxY = document.body.clientHeight - anchorDiv.clientHeight - 25;

  if (xPos < 25) {
    xPos = 25;
  }

  if (xPos > maxX) {
    xPos = maxX;
  }

  if (yPos < 25) {
    yPos = 25;
  }

  if (yPos > maxY) {
    yPos = maxY;
  }

  anchorDiv.style.left = `${xPos}px`;
  anchorDiv.style.top = `${yPos}px`;
}

setPos();

document.body.addEventListener("keydown", (e) => {
  if (e.key === "w") {
    yPos -= 25;
  } else if (e.key === "d") {
    xPos += 25;
  } else if (e.key === "s") {
    yPos += 25;
  } else if (e.key === "a") {
    xPos -= 25;
  }

  setPos();
});

document.body.addEventListener("click", (e) => {
  xPos = e.clientX;
  yPos = e.clientY;

  setPos();
});
```

This example renders like so:

Try moving the anchor element around the viewport by:

- Clicking the mouse (or tapping the screen if you're on a touchscreen device) in the position you want to move the anchor to.
- Using the `W`, `A`, `S`, and `D` keys to move the anchor up, left, down, and right, respectively.

When you move the anchor element near the edges of the screen, note how the infobox moves to different positions around it to stay on-screen, and also how the `border-radius` set on the infobox changes so that the non-rounded corner is always pointing at the anchor. Moving the anchor into the different corners is guaranteed to show you the different effects.

Fallback options and conditional hiding for overflow

When using CSS anchor positioning, an important consideration is ensuring that anchor-positioned elements always appear in a convenient place for the user to interact with them, if at all possible, regardless of where the anchor is positioned. For example, when you scroll the page, anchors and their associated positioned elements will move toward the edge of the viewport. When a positioned element starts to overflow the viewport, you will want to change its position to put it back on the screen again, for example on the opposite side of the anchor.

Alternatively, in some situations it may be preferable to just hide overflowing positioned elements — for example, if their anchors are off-screen their content might not make sense.

This guide explains how to use CSS anchor positioning mechanisms to manage these issues — **position-try fallback options** and **conditional hiding**. Position-try fallback options provide alternative positions for the browser to try placing positioned elements in as they start to overflow, to keep them on-screen. Conditional hiding allows conditions to be specified under which the anchor or a positioned element will be hidden.

> **Note:** For information on the basic fundamentals of CSS anchor positioning, see Using CSS anchor positioning.

Feature summary

If a tooltip is fixed to the top-right of a UI element, when the user scrolls the content so that the UI feature is in the top-right corner of the viewport, that UI feature's tooltip will have scrolled off the screen. CSS anchor positioning solves such problems. The module's `position-try-fallbacks` property specifies one or more alternative position-try fallback options for the browser to try to prevent the positioned element from overflowing.

Position-try fallback options can be specified using:

- Predefined fallback options.
- `position-area` values.
- Custom options defined using the `@position-try` at-rule.

In addition, the `position-try-order` property allows you to specify various options that result in an available position try option being set in preference to the element's initial positioning when it first renders. For example, you might want to initially display the element in a space that has more available height or width.

The shorthand property `position-try` can be used to specify `position-try-order` and `position-try-fallbacks` values in a single declaration.

In some situations, anchor-positioned content does not make sense if the anchor is off-screen, or vice-versa. For example, you might have an anchor containing a quiz question, and answers contained in associated positioned elements, and wish to show them both together or not at all. This can be achieved with conditional hiding, which is managed via the `position-visibility` property. This property takes various values that define conditions under which overflowing elements will be hidden.

Predefined fallback options

The predefined fallback option values of the `position-try-fallbacks` property (defined as `<try-tactic>`s in the spec) will "flip" the position of the anchor-positioned element across one or both axes if the element would otherwise overflow.

The element can be set to flip across the block axis (`flip-block`), the inline axis (`flip-inline`), or diagonally across an imaginary line drawn from a corner of the anchor through its center to its opposite corner (`flip-start`). These three values flip the element, mirroring its position on an opposite side for the first two values, and an adjacent side for `flip-start`. For example, if an element positioned `10px` above its anchor starts to overflow at the top of the anchor, the `flip-block` value would flip the positioned element to be 10px below its anchor.

In this example, we include two `<div>` elements. The first one will be our anchor element, and the second one will be positioned relative to the anchor:

```
<div class="anchor">⚓</div>

<div class="infobox">
  <p>This is an information box.</p>
</div>
```

We style the `<body>` element to be larger than the viewport so that we can scroll the anchor and the positioned element around in the viewport, both horizontally and vertically:

```
body {
  width: 1500px;
  height: 500px;
}
```

For illustrative purposes, we absolutely position the anchor so that it appears near the center of the initial `<body>` rendering:

```
.anchor {
  font-size: 1.8rem;
  color: white;
  text-shadow: 1px 1px 1px black;
  background-color: hsl(240 100% 75%);
  width: fit-content;
  border-radius: 10px;
  border: 1px solid black;
  padding: 3px;
}

.anchor {
  anchor-name: --my-anchor;
  position: absolute;
  top: 100px;
  left: 45%;
}
```

The anchor-positioned element is given fixed positioning and tethered to the anchor's top-left corner using a `position-area`. It is given `position-try-fallbacks: flip-block, flip-inline;` to provide it with some fallback options for moving the positioned element to stop it from overflowing when the anchor gets near the edge of the viewport.

```
.infobox {
  color: darkblue;
  background-color: azure;
  border: 1px solid #dddddd;
  padding: 10px;
  border-radius: 10px;
  font-size: 1rem;
}
```

```
.infobox {
  position: fixed;
  position-anchor: --my-anchor;
  position-area: top left;
  position-try-fallbacks: flip-block, flip-inline;
}
```

> **Note:** When multiple position try fallback options are specified, they are separated by commas, and tried in the order they are specified.

Try scrolling the demo so that the anchor starts to get near the edges:

- Move the anchor to the top of the viewport. The positioned element flips to the bottom-left of the anchor to avoid overflowing.
- Move the anchor to the left of the viewport. The positioned element flips to the top-right of the anchor to avoid overflowing.

If you move the anchor towards the top-left corner of the viewport, you'll notice a problem — as the positioned element starts to overflow in the block and inline direction, it flips back to its default top-left position and overflows in both directions, which is not what we want.

This happens because we only gave the browser position options of `flip-block` *or* `flip-inline`. We didn't give it the option of trying both at the same time. The browser tries the fallback options, looking for one that causes the positioned element to be rendered completely inside the viewport or containing block. If it doesn't find one, it renders the positioned element in its originally-defined rendering position, with no position fallback options applied.

The next section demonstrates how to fix this issue.

Combining multiple values into one option

It is possible to put multiple predefined try fallback options or custom try option names into a single space-separated try fallback option value within the comma-separated `position-try-fallbacks` list. When trying to apply these fallback options, the browser will combine the individual effects into a single combined fallback option.

Let's use a combined try fallback option to fix the problem we found with the previous demo. The HTML and CSS in this demo are the same, except for the infobox positioning styles. In this case, it is given a third position try fallback option: `flip-block flip-inline`:

```
<div class="anchor">⚓</div>

<div class="infobox">
  <p>This is an information box.</p>
</div>
```

```
body {
  width: 1500px;
  height: 500px;
}

.anchor {
  font-size: 1.8rem;
  color: white;
  text-shadow: 1px 1px 1px black;
  background-color: hsl(240 100% 75%);
  width: fit-content;
  border-radius: 10px;
  border: 1px solid black;
  padding: 3px;
}

.anchor {
  anchor-name: --my-anchor;
  position: absolute;
  top: 100px;
  left: 45%;
}

.infobox {
  color: darkblue;
  background-color: azure;
  border: 1px solid #dddddd;
  padding: 10px;
  border-radius: 10px;
  font-size: 1rem;
}
```

```
.infobox {
  position: fixed;
  position-anchor: --my-anchor;
  position-area: top left;
  position-try-fallbacks:
    flip-block,
    flip-inline,
    flip-block flip-inline;
}
```

This means that the browser will first try `flip-block` and then try `flip-inline` to avoid overflow. If those fallback options both fail, it will then try combining the two, flipping the element's position in the block *and* inline directions at the same time. Now when you scroll the anchor towards the top *and* left edges of the viewport, the positioned element will flip over to the bottom-right.

Using <code>position-area</code> try fallback options

The predefined `<try-tactic>` try fallback options are useful but limited, as they only allow positioned element placement to be flipped across axes. What if you had an anchor-positioned element positioned to the top left of its anchor, and wanted to change its position to directly below the anchor if it started to overflow?

To achieve this, you can use a `position-area` value as a position-try fallback option, including it in the `position-try-fallbacks` list. This automatically creates a try fallback option based on that position area. In effect, it is a shortcut for creating a custom position option that contains only that `position-area` property value.

The following example shows `position-area` position try fallback options in use. We use the same HTML and CSS, except for the infobox positioning. In this case, our position-try fallback options are `position-area` values — `top`, `top-right`, `right`, `bottom-right`, `bottom`, `bottom-left`, and `left`. The positioned element will be reasonably positioned no matter which viewport edge the anchor approaches. This verbose approach is more granular and flexible than the predefined values approach.

```
<div class="anchor">⚓</div>

<div class="infobox">
```

```
  <p>This is an information box.</p>
</div>
```

```
body {
  width: 1500px;
  height: 500px;
}

.anchor {
  font-size: 1.8rem;
  color: white;
  text-shadow: 1px 1px 1px black;
  background-color: hsl(240 100% 75%);
  width: fit-content;
  border-radius: 10px;
  border: 1px solid black;
  padding: 3px;
}

.anchor {
  anchor-name: --my-anchor;
  position: absolute;
  top: 100px;
  left: 45%;
}

.infobox {
  color: darkblue;
  background-color: azure;
  border: 1px solid #dddddd;
  padding: 10px;
  border-radius: 10px;
  font-size: 1rem;
}
```

```
.infobox {
  position: fixed;
  position-anchor: --my-anchor;
  position-area: top left;
  position-try-fallbacks:
    top, top right, right,
    bottom right, bottom,
    bottom left, left;
}
```

> **Note:** You can't add `position-area` try fallback options into a space-separated combined position option within a position-try fallback list.

Scroll the page and check out the effect of these position-try fallback options as the anchor nears the edge of the viewport:

Custom fallback options

To use custom position fallback options that aren't available via the above mechanisms, you can create your own with the `@position-try` at-rule. The syntax is:

```
@position-try --try-fallback-name {
  descriptor-list
}
```

The `--try-fallback-name` is a developer-defined name for the position try fallback option. This name can then be specified within the comma-separated list of try fallback options within the `position-try-fallbacks` property value. If multiple `@position-try` rules have the same name, the last one in the document order overrides the others. Avoid using the same name for your try fallback options *and* your anchor or custom property names; it doesn't invalidate the at-rule, but it will make your CSS very difficult to follow.

The `descriptor-list` defines the property values for that individual custom try fallback option, including how the positioned element should be placed and sized, and any margins. The limited list of property descriptors allowed includes:

- `position-area`
- Inset properties
- Margin properties (e.g., `margin-left`, `margin-block-start`)
- self-alignment properties
- Sizing properties (`width`, `block-size`, etc.)
- `position-anchor`

The values you include in the at-rule get applied to the positioned element if the named custom-try fallback option gets applied. If any of the properties were previously set on the positioned element, those property values get overridden by the descriptor values. If the user scrolls, causing a different try fallback option or no try fallback option to be applied, the values from the previously-applied try fallback option are unset.

In this example, we set up and use several custom try fallback options. We use the same base HTML and CSS code as in the previous examples.

We start by defining four custom try fallback options using `@position-try`:

```
<div class="anchor">⚓</div>

<div class="infobox">
  <p>This is an information box.</p>
</div>
```

```
body {
  width: 1500px;
  height: 500px;
}

.anchor {
  font-size: 1.8rem;
  color: white;
  text-shadow: 1px 1px 1px black;
  background-color: hsl(240 100% 75%);
  width: fit-content;
  border-radius: 10px;
```

```
  border: 1px solid black;
  padding: 3px;
}

.anchor {
  anchor-name: --my-anchor;
  position: absolute;
  top: 100px;
  left: 45%;
}

.infobox {
  color: darkblue;
  background-color: azure;
  border: 1px solid #dddddd;
  padding: 10px;
  border-radius: 10px;
  font-size: 1rem;
}
```

```
@position-try --custom-left {
  position-area: left;
  width: 100px;
  margin-right: 10px;
}

@position-try --custom-bottom {
  position-area: bottom;
  margin-top: 10px;
}

@position-try --custom-right {
  position-area: right;
  width: 100px;
  margin-left: 10px;
}

@position-try --custom-bottom-right {
  position-area: bottom right;
  margin: 10px 0 0 10px;
}
```

Once our custom try fallback options are created, we can include them in the position list by referencing their names:

```
.infobox {
  position: fixed;
  position-anchor: --my-anchor;
  position-area: top;
  width: 200px;
  margin-bottom: 10px;
  position-try-fallbacks:
    --custom-left, --custom-bottom, --custom-right, --custom-bottom-right;
}
```

Note that our default position is defined by `position-area: top`. When the infobox isn't overflowing the page in any direction, the infobox sits above the anchor, and the position-try fallback options set in the `position-try-fallbacks` property are ignored. Also, note that the infobox has a fixed width and bottom margin set. These values will change as different position-try fallback options are applied.

If the infobox starts to overflow, the browser tries the position options listed in the `position-try-fallbacks` property:

- The browser first tries the `--custom-left` fallback position. This moves the infobox to the left of the anchor, adjusts the margin to suit, and also gives the infobox a different width.
- Next, the browser tries the `--custom-bottom` position. This moves the infobox to the bottom of the anchor, and sets an appropriate margin. It doesn't include a `width` descriptor, so the infobox returns to its default width of `200px` set by the `width` property.
- The browser next tries the `--custom-right` position. This works much the same as the `--custom-left` position, with the same `width` descriptor value applied, but the `position-area` and `margin` values are mirrored to place the infobox appropriately to the right.
- If none of the other fallbacks succeed in stopping the positioned element from overflowing, the browser tries the `--custom-bottom-right` position as a last resort. This works in much the same way as the other fallback options, but it places the positioned element to the bottom-right of the anchor.

If none of the fallbacks succeed in stopping the positioned element from overflowing, the position will revert to the initial `position-area: top;` value.

> **Note:** When a position try fallback option is applied, its values will override the default values set on the positioned element. For example, the default `width` set on the positioned element is `200px`, but when the `--custom-right` position try fallback option is applied, its width is set to `100px`.

Scroll the page and check out the effect of these position-try fallback options as the anchor nears the edge of the viewport:

Styling anchor-positioned elements based on active fallback

One problem the above functionality doesn't solve is updating the styling of an anchor-positioned element to suit its different fallback options. For example, it is common to include a small arrow on a tooltip that points to the anchor element it is associated with, improving UX by making the visual association clearer. When the tooltip moves to a different position, you'll need to change the position and orientation of the arrow, otherwise it will look wrong.

To solve this problem, you can use anchored container queries. These extend the functionality of CSS container queries to enable you to detect when a specific fallback option is applied to an anchor-positioned element, and apply CSS to its descendants as a result. Specifically, anchored container queries rely on two features:

- The `container-type` property `anchored` value: Apply this to the anchor-positioned element to start detecting when different fallback options are applied to it.
- The `@container` at-rule `anchored` keyword: This is followed by a set of parentheses inside which the `fallback` descriptor is included. The descriptor's value is a `position-try-fallbacks` value.

For example, let's say we have an anchor-positioned tooltip element that is positioned above its anchor by default via a `position-area` value of `top`, but has a `position-try-fallbacks` value of `flip-block` specified. This will cause the tooltip to flip in the block direction to the bottom of its anchor when it starts to overflow the top of the viewport. If we want to detect when the fallback is applied to the tooltip, we first need to set `container-type: anchored` on it to turn it into an anchored query container.

```
.tooltip {
  position: absolute;
  position-anchor: --my-anchor;
  position-area: top;
  position-try-fallbacks: flip-block;
```

```
  container-type: anchored;
}
```

With this in place, we can now write a container query like so:

```
@container anchored(fallback: flip-block) {
  /* Descendant styles here */
}
```

The query test — `anchored(fallback: flip-block)` — will return true when the `flip-block` fallback option is applied to the tooltip, in which case the styles specified within the `@container` block will be applied. You might for example want to change the position and orientation of the arrow icon so that it continues to point towards the anchor, change the direction of a gradient, etc.

For more information on anchored container queries and some examples, see Using anchored container queries.

Using <code>position-try-order</code>

The `position-try-order` property has a slightly different focus from the rest of the position-try features, in that it influences which position-try fallback option is applied when the positioned element is first displayed, rather than when it is being scrolled. For example, you might want to initially display the element in a space that has more available height or width than the default initial position.

The browser tests the available `position-try-fallbacks` to find which one gives the anchor-positioned element the most space in the specified direction. It will then apply that option, overriding the element's initial styling when the page first renders.

Check out the `position-try-order` reference page for more information and a live example that demonstrates the property's effect.

Conditionally hiding anchor-positioned elements

In some situations, you might want to hide an anchor-positioned element. For example, if the anchor element is clipped because it's too close to the edge of the viewport, you might want to just hide its associated element altogether. The `position-visibility` property allows you to specify conditions under which positioned elements are hidden.

By default, the positioned element is `always` displayed. The `no-overflow` value will **strongly hide** the positioned element if it starts to overflow its containing element or the viewport.

The `anchors-visible` value, on the other hand, strongly hides the positioned element if its associated anchor(s) are *completely* hidden, either by overflowing its containing element (or the viewport) or being covered by other elements. The positioned element will be visible if any part of the anchor(s) is still visible.

A strongly hidden element acts as though it and its descendant elements have a `visibility` value of `hidden` set, regardless of what their actual `visibility` value is.

Let's see this property in action.

This example uses the same HTML and CSS as in the previous examples, with the infobox tethered to the anchor's bottom edge. The infobox is given `position-visibility: no-overflow;` to hide it completely when it is scrolled upwards to the point where it starts to overflow the viewport.

```
<p>
  Malesuada nunc vel risus commodo viverra maecenas accumsan lacus. Vel elit
  scelerisque mauris pellentesque pulvinar pellentesque habitant morbi
  tristique.
</p>

<p>
  Lorem ipsum dolor sit amet, consectetur adipiscing elit, sed do eiusmod tempor
  incididunt ut labore et dolore magna aliqua. Dui nunc mattis enim ut tellus
  elementum sagittis vitae et.
</p>

<div class="anchor">⚓</div>

<div class="infobox">
  <p>This is an information box.</p>
</div>

<p>
  Nisi quis eleifend quam adipiscing vitae proin sagittis nisl rhoncus. In arcu
  cursus euismod quis viverra nibh cras pulvinar. Vulputate ut pharetra sit amet
  aliquam.
</p>

<p>
  Malesuada nunc vel risus commodo viverra maecenas accumsan lacus. Vel elit
  scelerisque mauris pellentesque pulvinar pellentesque habitant morbi
  tristique. Porta lorem mollis aliquam ut porttitor. Turpis cursus in hac
  habitasse platea dictumst quisque. Dolor sit amet consectetur adipiscing elit.
  Ornare lectus sit amet est placerat. Nulla aliquet porttitor lacus luctus
  accumsan.
</p>
```

```
.anchor {
  font-size: 1.8rem;
  color: white;
  text-shadow: 1px 1px 1px black;
  background-color: hsl(240 100% 75%);
  width: fit-content;
  border-radius: 10px;
  border: 1px solid black;
  padding: 3px;
}

.anchor {
  anchor-name: --my-anchor;
}

body {
  width: 50%;
  margin: 0 auto;
}
```

```
.infobox {
  color: darkblue;
  background-color: azure;
  border: 1px solid #dddddd;
  padding: 10px;
  border-radius: 10px;
```

```
  font-size: 1rem;
}
```

```
.infobox {
  position: fixed;
  position-anchor: --my-anchor;
  margin-bottom: 5px;
  position-area: top span-all;
  position-visibility: no-overflow;
}
```

Scroll down the page and note how the positioned element is hidden once it reaches the top of the viewport:

Using CSS anchor positioning

The **CSS anchor positioning** module defines features that allow you to tether elements together. Elements can be defined as **anchor elements** and **anchor-positioned elements**. Anchor-positioned elements can be bound to anchor elements. The anchor-positioned elements can then have their size and position set relative to the size and location of the anchor elements to which they are bound.

CSS anchor positioning also provides CSS-only mechanisms for specifying multiple alternative positions for an anchor-positioned element. For example, if a tooltip is anchored to a form field but the tooltip would otherwise be rendered offscreen in its default position settings, the browser can try rendering it in a different suggested position so it is placed onscreen, or, alternatively, hide it altogether if desired.

This article explains the fundamental anchor positioning concepts, and how to use the module's association, positioning, and sizing features at a basic level. We've included links to reference pages with additional examples and syntax details for each concept discussed below. For information on specifying alternative positions and hiding anchor-positioned elements, see the Fallback options and conditional hiding for overflow guide.

Fundamental concepts

It's very common to want to tether, or bind, one element to another. For example:

- Error messages that appear alongside form controls.
- Tooltips or infoboxes that pop up next to a UI element to provide more information about it.
- Settings or options dialogs that can be accessed to quickly configure UI elements.
- Drop-down or popover menus that appear next to an associated navigation bar or button.

Modern interfaces frequently call for some content — often reusable and dynamically-generated — to be situated relative to an anchor element. Creating such use cases would be fairly straightforward if the element to tether to (aka the **anchor element**) was always in the same place in the UI and the tethered element (aka the **anchor-positioned element**, or just **positioned element**) could always be placed immediately before or after it in the source order. However, things are rarely that simple.

The location of positioned elements relative to their anchor element needs to be maintained and adjusted as the anchor element moves or otherwise changes configuration (e.g., by scrolling, changing the viewport size, drag and drop, etc.). For example, if an element such as a form field gets close to the edge of the viewport, its tooltip may end up offscreen. Generally, you want to bind the tooltip to its form control and ensure the tooltip is kept fully visible on-screen as long as the form field is visible, automatically moving the tooltip if needed. You may have noticed this as the default behavior in your operating system when you right-click (`Ctrl` + click) context menus on your desktop or laptop.

Historically, associating an element with another element and dynamically changing a positioned element's location and size based on an anchor's position required JavaScript, which added complexity and performance issues. It also wasn't guaranteed to work in all situations. The features defined in the CSS anchor positioning module enable implementing such use cases performantly and declaratively with CSS (and HTML) instead of JavaScript.

Associating anchor and positioned elements

To associate an element with an anchor, you need to first declare which element is the anchor, and then specify which positioned element(s) to associate with that anchor. This creates an anchor reference between the two. This association can be created explicitly via CSS or implicitly.

Explicit CSS anchor association

To declare an element as an anchor with CSS, you need to set an anchor name on it via the `anchor-name` property. The anchor name needs to be a `<dashed-ident>`. In this example, we also set the anchor's `width` to `fit-content` to get a small square anchor, which better demonstrates the anchoring effect.

```
.anchor {
  font-size: 1.8rem;
  color: white;
  text-shadow: 1px 1px 1px black;
  background-color: hsl(240 100% 75%);
  border-radius: 10px;
  border: 1px solid black;
  padding: 3px;
}
```

```
.anchor {
  anchor-name: --my-anchor;
  width: fit-content;
}
```

Converting an element to an anchor-positioned element requires two steps: It needs to be absolutely or fixed positioned using the `position` property. The positioned element then has its `position-anchor` property set to the value of the anchor element's `anchor-name` property to associate the two together:

```
.infobox {
  color: darkblue;
  background-color: azure;
  border: 1px solid #dddddd;
  padding: 10px;
  border-radius: 10px;
  font-size: 1rem;
}
```

```
.infobox {
  position: fixed;
  position-anchor: --my-anchor;
}
```

We'll apply the above CSS to the following HTML:

```
<div class="anchor">⚓</div>

<div class="infobox">
  <p>This is an information box.</p>
</div>
```

This will render as follows:

The anchor and infobox are now associated, but for the moment you'll have to trust us on this. They are not tethered to each other yet — if you were to position the anchor and move it somewhere else on the page, it would move on its own, leaving the infobox in the same place. You'll see the actual tethering in action when we look at positioning elements based on anchor position.

Implicit anchor association

In some cases, an implicit anchor reference will be made between two elements, due to the semantic nature of their relationship:

- When using the Popover API to associate a popover with a control, an implicit anchor reference is made between the two. This can occur when:
  - Declaratively associating a popover with a control using the `popovertarget` and `id` attributes or the `commandfor` and `id` attributes.
  - Programmatically associating a popover action such as `showPopover()` with a control using the `source` option.
- A `<select>` element and its dropdown picker are opted into customizable select element functionality via the `appearance` property `base-select` value. In this case, an implicit popover-invoker relationship is created between the two, which also means they'll have an implicit anchor reference.

> **Note:** The methods above associate an anchor with an element, but they are not yet tethered. To tether them together, the positioned element needs to be positioned relative to its anchor, which is done with CSS.

Removing an anchor association

If you wish to remove an explicit anchor association previously made between an anchor element and a positioned element, you can do one of the following:

1. Set the anchor's `anchor-name` property value to `none`, or to a different `<dashed-ident>`, if you want a different element to be anchored to it.
2. Set the `position-anchor` property of the positioned element to `none`, or to an anchor name that doesn't exist in the current document, such as `--not-an-anchor-name`.

In the case of implicit anchor associations, you'll need to use the second method — the first method doesn't work. This is because the association is controlled internally, and you can't remove the `anchor-name` via CSS.

For example, to stop a customizable `<select>` element's picker from being anchored to the `<select>` element itself, you could use the following rule:

```
::picker(select) {
  position-anchor: none;
}
```

Anchor scoping

When multiple anchor elements are given the same `anchor-name` value and a positioned element has that name as its `position-anchor` property value, the positioned element will be associated with the *last* anchor element in the source order with that `anchor-name` value.

For example, if a document contains multiple repeated components, each with a positioned element tethered to an anchor, all the positioned elements will be anchored to the last anchor on the page unless each component uses a different anchor name. This is likely not the desired behavior.

The `anchor-scope` property can fix this problem by limiting the visibility, or "scope", of an `anchor-name` value to a specific subtree. The result is that each positioned element can only be anchored to an element within the same subtree of the element that has the scope set on it.

- `anchor-scope: all` sets the scope so that *any* `anchor-name` values set in the subtree can only be bound to by positioned elements in the same subtree.
- `anchor-scope: --my-anchor, --my-anchor2` sets the scope so that the specified `anchor-name` values, when set in the subtree, can only be bound to by positioned elements in the same subtree.
- `anchor-scope: none` is the default value; it specifies that no anchor scoping is set.

For example, let's say you have multiple anchors and anchor-positioned `<div>` elements inside `<section>` containers:

```
<section class="scoped">
  <div class="anchor">⚓</div>
  <div class="positioned">Positioned 1</div>
</section>

<section class="scoped">
  <div class="anchor">⚓</div>
  <div class="positioned">Positioned 2</div>
</section>

<section class="scoped">
  <div class="anchor">⚓</div>
  <div class="positioned">Positioned 3</div>
</section>
```

We turn each `anchor` `<div>` into an anchor element by giving them an `anchor-name` of `--my-anchor`. We then position each `positioned` `<div>` relative to an element with the `--my-anchor` anchor name by giving them absolute positioning, a `position-anchor` value of `--my-anchor`, and a `position-area` value of `right`. Finally, we set the anchor scope of each `<section>` container using `anchor-scope: --my-anchor`:

```
html {
  height: 100%;
}

body {
  height: inherit;
  display: flex;
  justify-content: space-evenly;
  align-items: center;
}

.scoped {
  padding: 20px;
  background: #eeeeee;
}

.anchor {
  font-size: 1.8rem;
  color: white;
```

```
  text-shadow: 1px 1px 1px black;
  background-color: blue;
  width: fit-content;
  padding: 3px;
}

.positioned {
  background: orange;
  width: fit-content;
  padding: 3px;
}
```

```
.anchor {
  anchor-name: --my-anchor;
}

.positioned {
  position: absolute;
  position-anchor: --my-anchor;
  position-area: right;
}

.scoped {
  anchor-scope: --my-anchor;
}
```

This results in the following positioning behavior:

Each positioned element is positioned relative to the anchor inside the same `<section>` element. This is because each `<section>` element has an `anchor-scope` of `--my-anchor` set on it; positioned elements inside each scoped container can therefore only be positioned relative to `my-anchor` anchors inside the same container.

If we didn't set `anchor-scope: --my-anchor` on the containers, all of the positioned elements would be positioned relative to the last anchor on the page.

Positioning elements relative to their anchor

As we saw earlier, associating a positioned element with an anchor is not really much use on its own. Our goal is to place the positioned element relative to its associated anchor element. This is done either by setting a CSS `anchor()` function value on an inset property, specifying a `position-area`, or centering the positioned element with the `anchor-center` placement value.

> **Note:** CSS anchor positioning also provides mechanisms for specifying fallback positions if the positioned element's default position causes it to overflow the viewport. See the Fallback options and conditional hiding guide for details.

> **Note:** The anchor element must be a visible DOM node for the association and positioning to work. If it is hidden (for example via `display: none`), the positioned element will be positioned relative to its nearest positioned ancestor. We discuss how to hide an anchor-positioned element when its anchor disappears in Conditional hiding using `position-visibility`.

Using inset properties with <code>anchor()</code> function values

Conventional absolutely and fixed positioned elements are explicitly positioned by setting `<length>` or `<percentage>` values on inset properties. With `position: absolute`, this inset position value is an absolute distance relative to the edges of the nearest positioned ancestor. With `position: fixed`, the inset position value is an absolute distance relative to the viewport.

CSS anchor positioning changes this paradigm, enabling anchor-positioned elements to be placed relative to the edges of their associated anchor(s). The module defines the `anchor()` function, which is a valid value for each of the inset properties. When used, the function sets the inset position value as an absolute distance relative to the anchor element by defining the anchor element, the side of the anchor element the positioned element is being positioned relative to, and the distance from that side.

The function components look like this:

```
anchor(<anchor-name> <anchor-side>, <fallback>)
```

`<anchor-name>`

The `anchor-name` property value of the anchor element you want to position the element's side relative to. This is a `<dashed-ident>` value. If omitted, the element's **default anchor** is used. This is the anchor referenced in its `position-anchor` property, or associated with the element via the non-standard `anchor` HTML attribute.

> **Note:** Specifying an `<anchor-name>` positions the element relative to that anchor, but does not provide element association. While you can position an element's sides relative to multiple anchors by specifying different `<anchor-name>` values inside different `anchor()` functions on the same element, the positioned element is only associated with a single anchor.

`<anchor-side>`

Specifies the position relative to a side, or sides, of the anchor. Valid values include the `center` of the anchor, physical (`top`, `left`, etc.) or logical (`start`, `self-end`, etc.) sides of the anchor, or a `<percentage>` between the start (`0%`) and end (`100%`) of the axis of the inset property `anchor()` is set on. If a value is used that is not compatible with the inset property on which the `anchor()` function is set, the fallback value is used.

`<fallback>`

A `<length-percentage>` defining the distance to use as a fallback value if the element is not absolutely or fixed positioned, if the `<anchor-side>` value used is not compatible with the inset property on which the `anchor()` function is set, or if the anchor element doesn't exist.

The return value of the `anchor()` function is a length value calculated based on the position of the anchor. If you set a length or percentage directly on an anchor-positioned element's inset property, it is positioned as if it were not bound to the anchor element. This is the same behavior seen if the `<anchor-side>` value is incompatible with the inset property on which it is set and the fallback is used. These two declarations are equivalent:

```
bottom: anchor(right, 50px);
bottom: 50px;
```

Both will place the positioned element `50px` above the bottom of the element's closest positioned ancestor (if any) or of the initial containing block.

The most common `anchor()` parameters you'll use will refer to a side of the default anchor. You will also often either add a `margin` to create spacing between the edge of the anchor and positioned element or use `anchor()` within a `calc()` function to add that spacing.

For example, this rule positions the left edge of the positioned element flush to the anchor element's right edge, then adds some `margin-left` to make some space between the edges:

```
.positionedElement {
  left: anchor(right);
```

```
  margin-left: 10px;
}
```

The return value of an `anchor()` function is a length. This means you can use it within a `calc()` function. This rule positions the positioned element's logical block end edge `10px` from the anchor element's logical block start edge, adding the spacing using the `calc()` function so we don't need to add a margin:

```
.positionedElement {
  inset-block-end: calc(anchor(start) + 10px);
}
```

`anchor()` example

Let's look at an example of `anchor()` in action. We've used the same HTML as in the previous examples, but with some filler text placed below and above it to cause the content to overflow its container and scroll. We'll also give the anchor element the same `anchor-name` as in the previous examples:

```
<p>
  Lorem ipsum dolor sit amet, consectetur adipiscing elit, sed do eiusmod tempor
  incididunt ut labore et dolore magna aliqua. Dui nunc mattis enim ut tellus
  elementum sagittis vitae et.
</p>

<div class="anchor">⚓</div>

<div class="infobox">
  <p>This is an information box.</p>
</div>

<p>
  Nisi quis eleifend quam adipiscing vitae proin sagittis nisl rhoncus. In arcu
  cursus euismod quis viverra nibh cras pulvinar. Vulputate ut pharetra sit amet
  aliquam.
</p>

<p>
  Malesuada nunc vel risus commodo viverra maecenas accumsan lacus. Vel elit
  scelerisque mauris pellentesque pulvinar pellentesque habitant morbi
  tristique. Porta lorem mollis aliquam ut porttitor. Turpis cursus in hac
  habitasse platea dictumst quisque. Dolor sit amet consectetur adipiscing elit.
  Ornare lectus sit amet est placerat. Nulla aliquet porttitor lacus luctus
  accumsan.
</p>
```

```
.anchor {
  font-size: 1.8rem;
  color: white;
  text-shadow: 1px 1px 1px black;
  background-color: hsl(240 100% 75%);
  width: fit-content;
  border-radius: 10px;
  border: 1px solid black;
  padding: 3px;
}

body {
  width: 50%;
  margin: 0 auto;
}
```

```
.anchor {
  anchor-name: --my-anchor;
}
```

The infobox is associated with the anchor via the anchor name and given fixed positioning. By including the `inset-block-start` and `inset-inline-start` properties (which are equivalent to `top` and `left` in horizontal left-to-right writing modes) we have tethered it to the anchor. We add a `margin` to the infobox to add space between the positioned element and its anchor:

```
.infobox {
  color: darkblue;
  background-color: azure;
  border: 1px solid #dddddd;
  padding: 10px;
  border-radius: 10px;
  font-size: 1rem;
}
```

```
.infobox {
  position-anchor: --my-anchor;
  position: fixed;
  inset-block-start: anchor(end);
  inset-inline-start: anchor(self-end);
  margin: 5px 0 0 5px;
}
```

Let's look at the inset property positioning declarations in more detail:

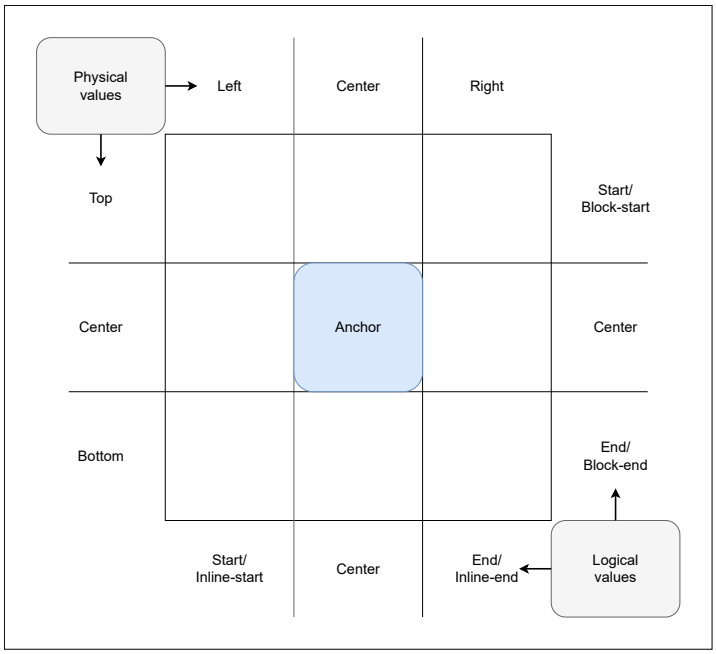
- `inset-block-start: anchor(end)`: This sets the positioned element's block start edge to the anchor's block end edge, calculated using the `anchor(end)` function.
- `inset-inline-start: anchor(self-end)`: This sets the positioned element's inline start edge to the anchor's inline end edge, calculated using the `anchor(self-end)` function.

This gives us the following result:

The positioned element is `5px` below and `5px` to the right of the anchor element. If you scroll the document up and down, the positioned element maintains its position relative to the anchor element — it is fixed to the anchor element, not the viewport.

Setting a <code>position-area</code>

The `position-area` property provides an alternative to the `anchor()` function for positioning elements relative to anchors. The `position-area` property works on the concept of a 3x3 grid of tiles, with the anchor element being the center tile. The `position-area` property can be used to position the anchor positioned element in any of the nine tiles, or have it span across two or three tiles.



The grid tiles are broken up into rows and columns:

- The three rows are represented by the physical values `top`, `center`, and `bottom`. They also have logical equivalents such as `start`, `center`, and `end`, and coordinate equivalents such as `y-start`, `center`, and `y-end`.
- The three columns are represented by the physical values `left`, `center`, and `right`. They also have logical equivalents such as `start`, `center`, and `end`, and coordinate equivalents such as `x-start`, `center`, and `x-end`.

The dimensions of the center tile are defined by the containing block of the anchor element, while the distance between the center tile and the grid's outer edge is defined by the positioned element's containing block.

`position-area` property values are composed of one or two values based on the row and column values described above, with spanning options available to define the region of the grid where the element should be positioned.

For example:

You can specify two values to place the positioned element in a specific grid square. For example:

- `top left` (logical equivalent `start start`) will place the positioned element in the top-left square.
- `bottom center` (logical equivalent `end center`) will place the positioned element in the bottom center square.

You can specify a row or column value plus a `span-*` value. The first value specifies the row or column to place the positioned element in, placing it initially in the center, and the other one specifies the amount of that column to span. For example:

- `top span-left` causes the positioned element to be placed in the top row, and span across the center and left tiles of that row.
- `y-end span-x-end` causes the positioned element to be placed in the end of the y column, and span across the center and x-end tiles of that column.
- `block-end span-all` causes the positioned element to be placed in the block end row, and span across the inline-start, center, and inline-end tiles of that row.

If you only specify one value, the effect is different depending on which value is set:

- A physical side value (`top`, `bottom`, `left`, or `right`) or coordinate value (`y-start`, `y-end`, `x-start`, `x-end`) acts as if the other value is `span-all`. For example, `top` gives the same effect as `top span-all`.
- A logical side value (`start` or `end`) acts as if the other value is set to the same value; for example `start` gives the same effect as `start start`.
- A value of `center` acts as if both values are set to `center` (so, `center center`).

> **Note:** See the `<position-area>` value reference page for a detailed description of all the available values. Mixing a logical value with a physical value will invalidate the declaration.

Let's demonstrate some of these values; this example uses the same HTML and base CSS styles as the previous example, except that we've included a `<select>` element to enable changing the positioned element's `position-area` value.

```
<p>
  Lorem ipsum dolor sit amet, consectetur adipiscing elit, sed do eiusmod tempor
  incididunt ut labore et dolore magna aliqua. Dui nunc mattis enim ut tellus
  elementum sagittis vitae et.
</p>

<div class="anchor">⚓</div>

<div class="infobox">
  <p>This is an information box.</p>
</div>

<p>
  Nisi quis eleifend quam adipiscing vitae proin sagittis nisl rhoncus. In arcu
  cursus euismod quis viverra nibh cras pulvinar. Vulputate ut pharetra sit amet
  aliquam.
</p>

<p>
  Malesuada nunc vel risus commodo viverra maecenas accumsan lacus. Vel elit
  scelerisque mauris pellentesque pulvinar pellentesque habitant morbi
  tristique. Porta lorem mollis aliquam ut porttitor. Turpis cursus in hac
  habitasse platea dictumst quisque. Dolor sit amet consectetur adipiscing elit.
  Ornare lectus sit amet est placerat. Nulla aliquet porttitor lacus luctus
  accumsan.
</p>
```

```
<form>
  <label for="position-area-select">Choose a position-area:</label>
  <select id="position-area-select" name="position-area-select">
    <option>top</option>
    <option>bottom</option>
    <option>left</option>
    <option>right</option>
    <option>start</option>
    <option>end</option>
    <option>top left</option>
    <option>top right</option>
    <option>bottom left</option>
    <option>bottom right</option>
    <option>top span-left</option>
    <option>bottom span-right</option>
    <option>start span-start</option>
    <option>end span-end</option>
    <option>center</option>
    <option>center span-all</option>
    <option>bottom center</option>
    <option>end span-all</option>
  </select>
</form>
```

```
.anchor {
  font-size: 1.8rem;
  color: white;
  text-shadow: 1px 1px 1px black;
  background-color: hsl(240 100% 75%);
  width: fit-content;
  border-radius: 10px;
  border: 1px solid black;
  padding: 3px;
}

.anchor {
  anchor-name: --my-anchor;
}

body {
  width: 50%;
  margin: 0 auto;
}

form {
  background: white;
  border: 1px solid black;
  padding: 5px;
}

select {
  display: block;
  margin-top: 5px;
}

form {
  position: fixed;
  top: 0;
  right: 2px;
}
```

The infobox is given fixed positioning and associated with the anchor using CSS. When loaded, it is set to be tethered to the anchor with `position-area: top;`, which causes it to be positioned at the top of the position-area grid. This will be overridden once you select different values from the `<select>` menu.

```
.infobox {
  color: darkblue;
  background-color: azure;
  border: 1px solid #dddddd;
  padding: 10px;
  border-radius: 10px;
  font-size: 1rem;
}
```

```
.infobox {
  position: fixed;
  position-anchor: --my-anchor;
  position-area: top;
}
```

We also include a short script to apply new `position-area` values chosen from the `<select>` menu to the infobox:

```
const infobox = document.querySelector(".infobox");
const selectElem = document.querySelector("select");

selectElem.addEventListener("change", () => {
  const area = selectElem.value;

  // Set the position-area to the value chosen in the select box
  infobox.style.positionArea = area;
});
```

Try selecting new `position-area` values from the `<select>` menu to see the effect they have on the position of the infobox:

Positioned element width

In the above example, we did not explicitly size the positioned element in either dimension. We deliberately omitted sizing to allow you to observe the behavior this causes.

When a positioned element is placed into `position-area` grid cells without explicit sizing, it aligns with the grid area specified and behaves as if `width` were set to `max-content`. It is sized according to its containing block size, which is the width of its content. This size was imposed by setting `position: fixed`. Auto-sized absolutely and fixed-positioned elements are automatically sized, stretching as wide as needed to fit the

text content, while constrained by the edge of the viewport. In this case, when placed on the left side of the grid with any `left` or `inline-start` value, the text wraps. If the anchored element's `max-content` size is narrower or shorter than its anchor, they won't grow to match the size of the anchor.

If the positioned element is centered vertically, such as with `position-area: bottom center`, it will align with the grid cell specified and the width will be the same as the anchor element. In this case, its minimum height is the anchor element's containing block size. It will not overflow, as the `min-width` is `min-content`, meaning it will be at least as wide as its longest word.

Centering on the anchor using <code>anchor-center</code>

While you can center the anchor-positioned element using `position-area`'s `center` values, inset properties combined with the `anchor()` function provide more control over the exact position. CSS anchor positioning provides a way to center an anchor-positioned element relative to its anchor when inset properties, rather than `position-area`, are used to tether.

The properties `justify-self`, `align-self`, `justify-items`, and `align-items` (and their `place-items` and `place-self` shorthands) exist to allow developers to easily align elements in the inline or block direction inside various layout systems, for example along the main or cross axis in the case of flex children. CSS anchor positioning provides an additional value for these properties, `anchor-center`, which aligns a positioned element with the center of its default anchor.

This example uses the same HTML and base CSS as the previous example. The infobox is given fixed positioning and tethered to the anchor's bottom edge. `justify-self: anchor-center` is then used to make sure it is centered horizontally on the anchor's center:

```
<p>
  Lorem ipsum dolor sit amet, consectetur adipiscing elit, sed do eiusmod tempor
  incididunt ut labore et dolore magna aliqua. Dui nunc mattis enim ut tellus
  elementum sagittis vitae et.
</p>

<div class="anchor">⚓</div>

<div class="infobox">
  <p>This is an information box.</p>
</div>

<p>
  Nisi quis eleifend quam adipiscing vitae proin sagittis nisl rhoncus. In arcu
  cursus euismod quis viverra nibh cras pulvinar. Vulputate ut pharetra sit amet
  aliquam.
</p>

<p>
  Malesuada nunc vel risus commodo viverra maecenas accumsan lacus. Vel elit
  scelerisque mauris pellentesque pulvinar pellentesque habitant morbi
  tristique. Porta lorem mollis aliquam ut porttitor. Turpis cursus in hac
  habitasse platea dictumst quisque. Dolor sit amet consectetur adipiscing elit.
  Ornare lectus sit amet est placerat. Nulla aliquet porttitor lacus luctus
  accumsan.
</p>
```

```
.anchor {
  font-size: 1.8rem;
  color: white;
  text-shadow: 1px 1px 1px black;
  background-color: hsl(240 100% 75%);
  width: fit-content;
  border-radius: 10px;
  border: 1px solid black;
  padding: 3px;
  anchor-name: --my-anchor;
}

body {
  width: 50%;
  margin: 0 auto;
}

.infobox {
  color: darkblue;
  background-color: azure;
  border: 1px solid #dddddd;
  padding: 10px;
  border-radius: 10px;
  font-size: 1rem;
}
```

```
.infobox {
  position: fixed;
  position-anchor: --my-anchor;
  top: calc(anchor(bottom) + 5px);
  justify-self: anchor-center;
}
```

This centers the anchor-positioned element at the bottom of its anchor:

Sizing elements based on anchor size

As well as positioning an element relative to its anchor's position, you can also size an element relative to its anchor's size using the `anchor-size()` function within a sizing property value.

Sizing properties that can accept an `anchor-size()` value include:

- `width`
- `height`
- `min-width`
- `min-height`
- `max-width`
- `max-height`
- `block-size`
- `inline-size`
- `min-block-size`
- `min-inline-size`
- `max-block-size`
- `max-inline-size`

`anchor-size()` functions resolve to `<length>` values. Their syntax looks like this:

```
anchor-size(<anchor-name> <anchor-size>, <length-percentage>)
```

`<anchor-name>`

The `<dashed-ident>` name set as the value of the `anchor-name` property of the anchor element you want to size the element relative to. If omitted, the element's **default anchor**, which is the anchor referenced in the `position-anchor` property, is used.

`<anchor-size>`

Specifies the dimension of the anchor element that the positioned element will be sized relative to. This can be expressed using physical (`width` or `height`) or logical (`inline`, `block`, `self-inline`, or `self-block`) values.

`<length-percentage>`

Specifies the size to use as a fallback value if the element is not absolutely or fixed positioned, or the anchor element doesn't exist.

The most common `anchor-size()` functions you'll use will just refer to a dimension of the default anchor. You can also use them inside `calc()` functions, to modify the size applied to the positioned element.

For example, this rule sizes the positioned element's width equal to the default anchor element's width:

```
.elem {
  width: anchor-size(width);
}
```

This rule sizes the positioned element's inline size to 4 times the anchor element's inline size, with the multiplication being done inside a `calc()` function:

```
.elem {
  inline-size: calc(anchor-size(self-inline) * 4);
}
```

Let's look at an example. The HTML and base CSS are the same as in the previous examples, except that the anchor element is given a `tabindex="0"` attribute to make it focusable. The infobox is given fixed positioning and associated with the anchor in the same way as before. However, this time around we tether it to the right of the anchor using a `position-area`, and give it a width five times the width of the anchor's width:

```
<p>
  Lorem ipsum dolor sit amet, consectetur adipiscing elit, sed do eiusmod tempor
  incididunt ut labore et dolore magna aliqua. Dui nunc mattis enim ut tellus
  elementum sagittis vitae et.
</p>

<div class="anchor" tabindex="0">⚓</div>

<div class="infobox">
  <p>This is an information box.</p>
</div>

<p>
  Nisi quis eleifend quam adipiscing vitae proin sagittis nisl rhoncus. In arcu
  cursus euismod quis viverra nibh cras pulvinar. Vulputate ut pharetra sit amet
  aliquam.
</p>

<p>
  Malesuada nunc vel risus commodo viverra maecenas accumsan lacus. Vel elit
  scelerisque mauris pellentesque pulvinar pellentesque habitant morbi
  tristique. Porta lorem mollis aliquam ut porttitor. Turpis cursus in hac
  habitasse platea dictumst quisque. Dolor sit amet consectetur adipiscing elit.
  Ornare lectus sit amet est placerat. Nulla aliquet porttitor lacus luctus
  accumsan.
</p>
```

```
.anchor {
  font-size: 1.8rem;
  color: white;
  text-shadow: 1px 1px 1px black;
  background-color: hsl(240 100% 75%);
  width: fit-content;
  border-radius: 10px;
  border: 1px solid black;
  padding: 3px;
}

.anchor {
  anchor-name: --my-anchor;
}

body {
  width: 50%;
  margin: 0 auto;
}

.infobox {
  color: darkblue;
  background-color: azure;
  border: 1px solid #dddddd;
  padding: 10px;
  border-radius: 10px;
  font-size: 1rem;
}
```

```
.infobox {
  position: fixed;
  position-anchor: --my-anchor;
  position-area: right;
  margin-left: 5px;
  width: calc(anchor-size(width) * 5);
}
```

In addition, we increase the anchor element's `width` on `:hover` and `:focus`, and give it a `transition` so that it animates when the state changes.

```
.anchor {
  text-align: center;
  width: 30px;
  transition: 1s width;
}

.anchor:hover,
.anchor:focus {
  width: 50px;
}
```

Hover over or tab to the anchor element — the positioned element grows as the anchor grows, demonstrating that the anchor-positioned element's size is relative to its anchor:

Other uses of <code>anchor-size()</code>

You can also use `anchor-size()` in physical and logical inset and margin properties. The sections below explore these uses in more detail, before providing a usage example.

Setting element position based on anchor size

You can use the `anchor-size()` function within an inset property value to position elements based on their anchor element's size, for example:

```
left: anchor-size(width);
inset-inline-end: anchor-size(--my-anchor height, 100px);
```

This doesn't position an element relative to the position of its anchor like the `anchor()` function or `position-area` property do (see Positioning elements relative to their anchor, above); the element won't change its position when its anchor does. Instead, the element will be positioned according to the normal rules of `absolute` or `fixed` positioning.

This can be useful in some situations. For example, if your anchor element can only move vertically, and always remains next to the edge of its closest positioned ancestor horizontally, you could use `left: anchor-size(width)` to cause the anchor-positioned element to always be positioned to the right of its anchor, even if the anchor width changes.

Setting element margin based on anchor size

You can use the `anchor-size()` function within a `margin-*` property value to set element margins based on their anchor element's size, for example:

```
margin-left: calc(anchor-size(width) / 4);
margin-block-start: anchor-size(--my-anchor self-block, 20px);
```

This can be useful in cases where you want to set an anchor-positioned element's margin to be always equal to the same percentage of the anchor element's width, even when the width changes.

<code>anchor-size()</code> position and margin example

Let's look at an example where we set an anchor-positioned element's margin and position relative to the anchor element's width.

In the HTML, we specify two `<div>` elements, one `anchor` element and one `infobox` element that we'll position relative to the anchor. We give the anchor element a `tabindex` attribute so that it can be focused via the keyboard. We also include filler text to make the `<body>` tall enough to require scrolling, but this has been hidden for the sake of brevity.

```
<p>Lorem ipsum dolor sit amet, consectetur adipiscing elit.</p>

<p>
  Nisi quis eleifend quam adipiscing vitae proin sagittis nisl rhoncus. In arcu
  cursus euismod quis viverra nibh cras pulvinar.
</p>
```

```
<div class="anchor" tabindex="0">⚓</div>

<div class="infobox">
  <p>Infobox.</p>
</div>
```

```
<p>Vulputate ut pharetra sit amet aliquam.</p>

<p>
  Malesuada nunc vel risus commodo viverra maecenas accumsan lacus. Vel elit
  scelerisque mauris pellentesque pulvinar pellentesque habitant morbi
  tristique. Porta lorem mollis aliquam ut porttitor. Turpis cursus in hac
  habitasse platea dictumst quisque. Dolor sit amet consectetur adipiscing elit.
  Ornare lectus sit amet est placerat. Nulla aliquet porttitor lacus luctus
  accumsan.
</p>
```

In the CSS, we first declare the `anchor` `<div>` as an anchor element by giving it an `anchor-name`. The positioned element has its `position` property set to `absolute`, and is associated with the anchor element via its `position-anchor` property. We also set absolute `height` and `width` dimensions on the anchor and infobox, and include a `transition` on the anchor so that width changes are smoothly animated when its state changes:

```
.anchor {
  font-size: 2rem;
  color: white;
  text-shadow: 1px 1px 1px black;
  background-color: hsl(240 100% 75%);
  text-align: center;
  align-content: center;
  outline: 1px solid black;
}

body {
  width: 80%;
  margin: 0 auto;
  position: relative;
}

.infobox {
  align-content: center;
  color: darkblue;
  background-color: azure;
  outline: 1px solid #dddddd;
  font-size: 1rem;
```

```
  text-align: center;
}
```

```
.anchor {
  anchor-name: --my-anchor;
  width: 100px;
  height: 100px;
  transition: 1s all;
}

.infobox {
  position-anchor: --my-anchor;
  position: absolute;
  height: 100px;
  width: 100px;
}
```

Now onto the most interesting part. Here we set the anchor's `width` to `300px` when it is hovered or focused. We then set the infobox's:

- `top` value to `anchor(top)`. This causes the top of the infobox to always stay in line with the top of the anchor.
- `left` value to `anchor-size(width)`. This causes the left of the infobox to be positioned the specified distance away from the left edge of its nearest positioned ancestor. In this case, the specified distance is equal to the anchor element's width and the nearest positioned ancestor is the `<body>` element, so the infobox appears to the right of the anchor.
- `margin-left` value to `calc(anchor-size(width)/4)`. This cases the infobox to always have a left margin separating it and the anchor, equal to a quarter of the anchor's width.

```
.anchor:hover,
.anchor:focus {
  width: 300px;
}

.infobox {
  top: anchor(top);
  left: anchor-size(width);
  margin-left: calc(anchor-size(width) / 4);
}
```

The rendered result is as follows:

Try tabbing to the anchor or hovering over it with the mouse pointer, and note how the infobox's position and left margin grow in proportion to the anchor element's width.

CSS animation triggers

The **CSS animation triggers** module provides functionality to trigger standard time-based CSS animations when a specific timeline trigger occurs.

Scroll-triggered animations allow you to control when a regular time-based animation starts, pauses, or stops based on when a trigger activates or deactivates, without using JavaScript. This could include when a scrolling element enters or leaves a timeline range.

These ranges normally come from view progress timelines, enabling, for example, an animation to start when an element enters a scrollport and pause when it leaves the scrollport. Properties let you change the timeline range and control the active and activation ranges. Triggers can specify different actions when entering versus exiting the timeline range, allowing control over animation playback.

The animation triggers module also defines **event triggers**. When supported, these will activate timeline-based animations when specific DOM events occur.

Animation triggers in action

This example demonstrates scroll-triggered animations. Scroll the box up and down — the appearance of the "bouncer" text will trigger the ball's animation, and its disappearance will trigger the same animation in reverse. Scroll further, and the same process will repeat when the "another bouncer" text appears and then disappears from the scrollport.

```
<section>
  <div>
    <p>scroll down</p>
    <p id="trigger">bouncer</p>
    <p>keep scrolling</p>
    <p>keep scrolling</p>
    <p>keep scrolling</p>
    <p id="trigger2">another bouncer</p>
    <p>scroll up</p>
  </div>
</section>

<span id="ball"><span></span></span>
```

```
#ball,
#ball span {
  animation:
    move-right 2s 1 ease-out both,
    move-right 2s 1 ease-out forwards;
  animation-trigger:
    --t play-forwards play-backwards,
    --t2 play-forwards play-backwards;
}
#ball span {
  animation-name: bounce, bounce;
}

#trigger {
  timeline-trigger-name: --t;
  timeline-trigger-source: view();
}
#trigger2 {
  timeline-trigger-name: --t2;
  timeline-trigger-source: view();
}
```

```
html {
  font-family: sans-serif;
  font-size: 1.3rem;
}

* {
  box-sizing: border-box;
}

@layer scroller {
  section {
    border: solid;
    width: 200px;
    height: 250px;
    margin-top: 50px;
    overflow: scroll;
  }
  p {
    text-align: center;
    font-size: 1.5rem;
    margin: 100% 0;
  }
  #trigger,
  #trigger2 {
    padding: 0;
    color: red;
  }
}

@layer animation-setup {
  #ball {
    position: fixed;
    top: 96vh;
  }
  #ball span {
    background: red;
    border-radius: 50%;
    height: 5vw;
    display: block;
    aspect-ratio: 1/1;
  }

  @keyframes move-right {
    from {
      transform: translateX(0);
    }
    to {
      transform: translateX(90vw);
    }
  }

    44%,
    51%,
    58%,
    63%,
    68%,
    72%,
    76%,
    100% {
      transform: translateY(0);
      animation-timing-function: ease-out;
    }
    0%,
    17%,
    30%,
    40%,
    48%,
    55%,
    61%,
    66%,
    70%,
    74% {
      animation-timing-function: ease-in;
    }
    0% {
      transform: translateY(-96vh);
    }
    17% {
      transform: translateY(-57.6vh);
    }
    30% {
      transform: translateY(-34.56vh);
    }
    40% {
      transform: translateY(-20.74vh);
    }
    48% {
      transform: translateY(-12.44vh);
    }
    55% {
      transform: translateY(-7.46vh);
    }
    61% {
      transform: translateY(-4.48vh);
    }
    66% {
      transform: translateY(-2.69vh);
    }
```

```
    70% {
      transform: translateY(-1.61vh);
    }
    74% {
      transform: translateY(-0.97vh);
    }
  }
}
```

```
@supports not (timeline-trigger-source: view()) {
  body::before {
    content: "Your browser does not support scroll-triggered animations.";
    background-color: wheat;
    text-align: center;
    padding: 1rem 0;

    z-index: 1;
    position: fixed;
    inset: 40% 0 auto;
  }
}
```

We defined the animation triggers by specifying a `timeline-trigger-name` and `timeline-trigger-source` on the "bouncer" elements. The ball has a bouncing `animation` set on it twice. It also has an `animation-trigger` property set: this references the names of both triggers and the actions to perform when the animations are activated and deactivated. Activation and deactivation are caused by the "bouncer" elements coming into and out of view.

Reference

Properties

- `animation-trigger`
- `timeline-trigger` shorthand
- `timeline-trigger-activation-range` shorthand
  - `timeline-trigger-activation-range-end`
  - `timeline-trigger-activation-range-start`
- `timeline-trigger-active-range` shorthand
  - `timeline-trigger-active-range-end`
  - `timeline-trigger-active-range-start`
- `timeline-trigger-name`
- `timeline-trigger-source`
- `trigger-scope`

The CSS animation triggers module also introduces the `event-trigger`, `event-trigger-name`, and `event-trigger-source` properties. Currently, no browsers support these features.

Using CSS scroll-triggered animations

CSS **scroll-triggered animations** provide a declarative mechanism to start, pause, stop, or reverse an element's `DocumentTimeline`-based CSS animation when the user scrolls it (or a different element) to a specified offset within a scrollport.

This article covers how to create CSS scroll-triggered animations.

Scroll-triggered animation concepts

A common UI pattern involves triggering animations on a web page when the user scrolls to a certain place in the content, for example, to pull in additional UI elements or draw the user's attention to certain details.

CSS scroll-triggered animations enable defining scroll-based triggers that start and stop regular time-based CSS animations. You can define trigger positions inside a scroll container so that, when a tracked element reaches those positions within the scrollport, they toggle the play state of an animation applied to that element, or to a completely different element.

> **Note:** Scroll-triggered animations provide an alternative to using JavaScript features — such as frameworks or the Intersection Observer API — to trigger animations on scroll. CSS scroll-triggered animations are more performant and, arguably, simpler to implement.

Scroll-triggered versus scroll-driven animations

Scroll-triggered animations are similar to CSS scroll-driven animations, but they are different:

- Scroll-triggered animations are regular time-based animations that play when a trigger becomes active; they observe the `animation-delay` each time the animation starts, and always complete each iteration in the amount of time defined by the `animation-duration`, regardless of how fast the user scrolls.
- With scroll-driven animations, the normal, time-based animation timeline is replaced by a scroll-based timeline, meaning that the animation progresses forwards and backwards as you scroll towards the start and end of the content, respectively, with faster scrolling resulting in a faster animation. Scroll-driven animations ignore the `animation-duration` and `animation-delay` properties.

Scroll-triggered animation basics

Let's walk through a basic example to show you how a scroll-triggered animation works. An image caption will fade in and out when the image it is captioning is scrolled into and out of view. In this case:

- The `<figcaption>` element has a `@keyframes` animation set on it: a fade-in effect. This animation is the *triggered animation*.
- For the *animation actions*, we specify that the animation should play forwards when the trigger is *activated*, fading the caption in, and play backwards when the trigger is *deactivated*, fading the caption out.
- The *animation triggers* are defined on the `<img>` element. The activation is triggered when the `<img>` starts entering the scrollport and the deactivation occurs when the `<img>` fully exits the scrollport, meaning the full scrollport is the *timeline range*, the `<img>` is the *tracked element*, and the `<figcaption>` is the animated element.
- We'll set an anonymous view progress timeline as the *trigger source* on the `<img>` element, created using the `view()` function.

As the content is scrolled up and down, the caption's animation will start as soon as the `<img>` begins to appear inside the scrollport, with the animation reversing when the `<img>` exits the scrollport. This basic example doesn't create the effect we want, but it's a good start that we can improve on as we learn about more features.

The HTML features several paragraphs of content with a `<figure>` element included in the middle of them, which contains the `<img>` and `<figcaption>`. For the sake of brevity, we are not showing the full source.

```

```
<h1>Information about Cairns</h1>

<p>
  The countryside surrounding Cairns, located in eastern Australia, is a
  breathtakingly beautiful region characterized by diverse landscapes, lush
  greenery, and unique natural wonders.
</p>

<p>
  Nestled between the Great Dividing Range and the sparkling Coral Sea, this
  area offers a stunning blend of tropical rainforests, pristine beaches, and
  majestic mountain ranges.
</p>

<p>
  As you venture away from the city, you'll be greeted by the verdant
  rainforests of the Wet Tropics World Heritage Area. Towering ancient trees,
  vibrant ferns, and cascading waterfalls create a serene and magical
  atmosphere.
</p>
<p>
  Exploring the lush undergrowth, you may encounter unique wildlife such as
  colorful birds, tree-dwelling mammals, and rare reptiles. The sounds of
  chirping birds and rushing water add to the symphony of nature, providing an
  immersive experience in this captivating wilderness.
</p>

<p>
  Traveling further, you'll discover the Atherton Tablelands, a plateau renowned
  for its fertile farmlands, rolling hills, and picturesque lakes. This
  agricultural heartland is dotted with quaint rural towns and farms producing
  an array of fresh produce.
</p>
<p>
  Fields of sugar cane, banana plantations, and dairy farms stretch as far as
  the eye can see, creating a patchwork of vibrant green hues against the
  backdrop of distant mountains. The region is also famous for its waterfalls,
  such as Millaa Millaa Falls, where crystal-clear water tumbles down verdant
  cliffs, offering a refreshing retreat.
</p>

<figure>
  <img
    src="https://mdn.github.io/shared-assets/images/examples/learn/gallery/pic5.jpg"
    alt="A butterfly with red, white, and gold wing sections, sitting in a leaf" />
  <figcaption>A beautiful butterfly seen in the Jungle near Cairns</figcaption>
</figure>
```

```
<p>
  No visit to the countryside surrounding Cairns is complete without exploring
  the stunning beaches that line the Coral Sea. From Palm Cove to Mission Beach,
  the coastline is adorned with golden sands, swaying palm trees, and azure
  waters. These idyllic beaches provide the perfect setting for relaxation,
  swimming, and water sports.
</p>
<p>
  Snorkeling enthusiasts can also discover the wonders of the Great Barrier
  Reef, a UNESCO World Heritage Site, which lies just off the coast. This
  vibrant underwater ecosystem teems with an incredible diversity of marine
  life, including colorful coral formations, tropical fish, and sea turtles.
</p>

<p>
  Lastly, the surrounding countryside is home to an impressive array of national
  parks and mountains. Barron Gorge National Park, for instance, showcases
  rugged terrain, deep gorges, and thundering waterfalls.
</p>
<p>
  You can embark on hiking trails that lead to breathtaking viewpoints, offering
  panoramic vistas of the surrounding rainforest-clad mountains and valleys.
  Further west, the towering peaks of the Great Dividing Range present
  opportunities for adventurous hiking and exploring scenic vistas, including
  the iconic Walshs Pyramid near Gordonvale.
</p>
```

We'll start by defining `@keyframes` for the `fade-in` animation we'll apply to our `<figcaption>`.

```
@keyframes fade-in {
  from {
    opacity: 0;
  }

  to {
    opacity: 1;
  }
}
```

```
body {
  width: 80%;
  margin: 0 auto;
  font-family: "Helvetica", "Arial";
  font-size: 1.3rem;
}

figure {
  display: block;
  margin: 0 auto;
  max-width: 60%;
  position: relative;
}

img {
  max-width: 100%;
  border: 3px solid black;
}

h1 {
  font-size: 3rem;
}

p {
  line-height: 1.5;
}

figcaption {
  font-size: 1rem;
  padding: 5px;
  position: absolute;
  top: 5px;
  left: 5px;
  border: 3px solid black;
  background: white;
}
```

The first declaration block applies the animation and an animation trigger, along with the animation actions, to the `<figcaption>` element:

1. We use the `animation` shorthand to apply the `fade-in` animation to `<figcaption>`. By itself, without triggers, this would cause the `<figcaption>` to fade into view as soon as the page loads.
2. We use the `animation-trigger` property to delay the start of the animation until the `<img>` element is scrolled into view by identifying which element will provide the triggers, and what those trigger's actions will be. The `animation-trigger` property value components include:
    - A `<dashed-ident>`, `--t`, which is the identifier set as the value of the `timeline-trigger-name` property on the triggering element.
    - Two `<animation-action>` values, which specify how the animation should behave when the trigger is activated and deactivated (the animation actions). When the trigger is activated, we set the `<figcaption>` element's animation to play forwards. When the trigger is deactivated, we set the `<figcaption>` element's animation to play backwards.

```
figcaption {
  animation: fade-in 1s ease-in both;
  animation-trigger: --t play-forwards play-backwards;
}
```

The second declaration block creates the animation trigger:

1. We use the `timeline-trigger-name` property to give the `<img>` element an identifying name for triggers created on it. This is the same dashed identifier as the trigger name referenced in the `<figcaption>` element's `animation-trigger` property value.
2. We use the `timeline-trigger-source` property to create the animation trigger type. Specifying the `view()` function means our trigger type is an anonymous view progress timeline, which has a default activation range equal to the `cover` timeline range.

```
img {
  timeline-trigger-name: --t;
  timeline-trigger-source: view();
}
```

By default, the `ViewTimeline` created by the `view()` function tracks the position of the `<img>` element across the block-axis of the nearest parent scroller. The element that is tracked, in this case the `<img>`, is the **subject** or the **tracked element**.

By default, the triggers are activated and deactivated when the tracked element is scrolled to the start and end of the timeline range respectively, in the block direction, causing the `<figcaption>` animation to play forwards and play backwards. Activation occurs when the tracked element enters the **activation range**, and deactivation occurs when the tracked element leaves the **active range**. When the `timeline-trigger-source` is set to `view()`, the default activation and active ranges resolve to `cover`, which is from the point when the tracked element's start border edge starts to enter the scrollport to the point when the tracked element's end border edge completely exits the scrollport.

The example renders like so:

Note how the caption starts to fade in as soon as any part of the image becomes visible in the scrollport, whether you are moving it in from the bottom or the top. It doesn't fade out again until the entire image has moved out of the scrollport, so you won't be able to see the fading out effect; if you scroll the image back into view, the caption will fade in again.

Creating the trigger on the same element

In the previous example, the trigger was defined on the `<img>` element, and the `<figcaption>` was animated. It is possible to define the trigger on the animated element itself. Let's modify the previous example to create the trigger on the animated `<figcaption>` element.

The HTML is identical to the previous example. The CSS differs only in where the `timeline-trigger-*` properties are set.

This time, the `animation`, `animation-trigger`, `timeline-trigger-name`, and `timeline-trigger-source` properties are all set on the `<figcaption>` element — it will animate when it appears in the scrollport. In the previous example, the `<figcaption>` was the animated element and the `<img>` was the tracked element. Now the caption plays both roles.

```
figcaption {
  animation: fade-in 1s ease-in both;
  animation-trigger: --t play-forwards play-backwards;
  timeline-trigger-name: --t;
  timeline-trigger-source: view();
}
```

The updated rendering looks like this:

In this case, the `<figcaption>` fades into view when it, rather than the image, first enters into the scrollport.

Adjusting the trigger activation range

In the previous examples, the trigger activates (`fade-in` starts) as soon as a block edge of the tracked element enters the scrollport at one edge, and deactivates (fade-out starts: `fade-in` is played backwards) when the tracked element has finished exiting the scrollport at the opposite edge. As a result, the fade out is never visible. This is because the default activation and active ranges (see `<timeline-range-name>`) when using `view()` as the `timeline-trigger-source` are both `cover`.

To make the fade out animation visible, we can offset the start and end of the activation range using the `timeline-trigger-activation-range-start` and `timeline-trigger-activation-range-end` properties, respectively, or the `timeline-trigger-activation-range` shorthand to set both values in a single declaration. Each of these properties can take the following values:

- The `normal` default value.
- A `<length-percentage>` value to specify a point along the default range.
- A `<timeline-range-name>` keyword specifying a named range.
- A `timeline-range-name` and a `<length-percentage>` to specify a point along the named range.

Percentages are relative to the length of the `<timeline-range-name>`, which resolves to `cover` for our view progress timeline. Had we set `scroll()` as our `timeline-trigger-source`, the default `<timeline-range-name>` would have resolved to `scroll`. See Timeline range names to learn about the `<timeline-range-name>` values.

The following example will cause the trigger to activate `50%` of the way through the `entry` range (when `50%` of the tracked element has entered the scrollport via one of the scrollport's block edges) and deactivate `0%` of the way through the `exit` range (when `50%` of the tracked element has exited the scrollport's opposite block edge).

```
timeline-trigger-activation-range: entry 50% exit 0%;
```

Let's apply this to our first example so you can see what the effect is. Our `img` declaration block is updated to the following:

```
img {
  timeline-trigger-name: --t;
  timeline-trigger-source: view();
  timeline-trigger-activation-range: entry 50% exit 0%;
}
```

The updated rendering looks like this:

The animation of the `<figcaption>` is now a bit more useful — it only starts to fade into view when a significant portion of the `<img>` has entered the scrollport at its end edge, and it starts to fade out when the `<img>` has started to exit the scrollport at its start edge. When you scroll the content back down again, the trigger reactivates and the fade-in occurs again at the scrollport's start edge, and deactivation occurs again at the scrollport's end edge.

Setting a custom active range

The **active range** is the range within which a trigger will remain activated once activation has occurred. By default, the active range is the same as the activation range; therefore, in the examples we've seen so far, the range for activation and deactivation has been the same.

It is possible to set a different active range from the activation range using the `timeline-trigger-active-range-start` and `timeline-trigger-active-range-end` properties, or the `timeline-trigger-active-range` shorthand to set both values in a single declaration.

You might want to do this to extend the time an animation has to complete — for example, if you want the animation trigger to activate only within a small range but stay active over a larger range. Only when the tracked element moves out of the active range does the trigger become inactive; after that, you can activate it again by moving the subject back into the activation range.

Let's build on our previous examples to demonstrate the effect of the active range. The HTML is the same, except we've included two identical `<figure>` elements with classes of `.one` and `.two`, placed next to one another using flexbox, meaning they'll come in and go out of view at the same time as each other. In each case, the `<img>` will be the tracked element for its sibling animated `<figcaption>`.

```
<div class="figure-wrapper">
  <figure class="one">
    <img
      src="https://mdn.github.io/shared-assets/images/examples/learn/gallery/pic5.jpg"
      alt="A butterfly with red, white, and gold wing sections, sitting in a leaf" />
    <figcaption>
      A beautiful butterfly seen in the Jungle near Cairns
```

```
    </figcaption>
  </figure>

  <figure class="two">
    <img
      src="https://mdn.github.io/shared-assets/images/examples/learn/gallery/pic5.jpg"
      alt="A butterfly with red, white, and gold wing sections, sitting in a leaf" />
    <figcaption>
      A beautiful butterfly seen in the Jungle near Cairns
    </figcaption>
  </figure>
</div>
```

```
<h1>Information about Cairns</h1>

<p>
  The countryside surrounding Cairns, located in eastern Australia, is a
  breathtakingly beautiful region characterized by diverse landscapes, lush
  greenery, and unique natural wonders.
</p>

<p>
  Nestled between the Great Dividing Range and the sparkling Coral Sea, this
  area offers a stunning blend of tropical rainforests, pristine beaches, and
  majestic mountain ranges.
</p>

<p>
  As you venture away from the city, you'll be greeted by the verdant
  rainforests of the Wet Tropics World Heritage Area. Towering ancient trees,
  vibrant ferns, and cascading waterfalls create a serene and magical
  atmosphere.
</p>
<p>
  Exploring the lush undergrowth, you may encounter unique wildlife such as
  colorful birds, tree-dwelling mammals, and rare reptiles. The sounds of
  chirping birds and rushing water add to the symphony of nature, providing an
  immersive experience in this captivating wilderness.
</p>

<p>
  Traveling further, you'll discover the Atherton Tablelands, a plateau renowned
  for its fertile farmlands, rolling hills, and picturesque lakes. This
  agricultural heartland is dotted with quaint rural towns and farms producing
  an array of fresh produce.
</p>
<p>
  Fields of sugar cane, banana plantations, and dairy farms stretch as far as
  the eye can see, creating a patchwork of vibrant green hues against the
  backdrop of distant mountains. The region is also famous for its waterfalls,
  such as Millaa Millaa Falls, where crystal-clear water tumbles down verdant
  cliffs, offering a refreshing retreat.
</p>

<div class="figure-wrapper">
  <figure class="one">
    <img
      src="https://mdn.github.io/shared-assets/images/examples/learn/gallery/pic5.jpg"
      alt="A butterfly with red, white, and gold wing sections, sitting in a leaf" />
    <figcaption>
      A beautiful butterfly seen in the Jungle near Cairns
    </figcaption>
  </figure>

  <figure class="two">
    <img
      src="https://mdn.github.io/shared-assets/images/examples/learn/gallery/pic5.jpg"
      alt="A butterfly with red, white, and gold wing sections, sitting in a leaf" />
    <figcaption>
      A beautiful butterfly seen in the Jungle near Cairns
    </figcaption>
  </figure>
</div>

<p>
  No visit to the countryside surrounding Cairns is complete without exploring
  the stunning beaches that line the Coral Sea. From Palm Cove to Mission Beach,
  the coastline is adorned with golden sands, swaying palm trees, and azure
  waters. These idyllic beaches provide the perfect setting for relaxation,
  swimming, and water sports.
</p>
<p>
  Snorkeling enthusiasts can also discover the wonders of the Great Barrier
  Reef, a UNESCO World Heritage Site, which lies just off the coast. This
  vibrant underwater ecosystem teems with an incredible diversity of marine
  life, including colorful coral formations, tropical fish, and sea turtles.
</p>

<p>
  Lastly, the surrounding countryside is home to an impressive array of national
  parks and mountains. Barron Gorge National Park, for instance, showcases
  rugged terrain, deep gorges, and thundering waterfalls.
</p>
<p>
  You can embark on hiking trails that lead to breathtaking viewpoints, offering
  panoramic vistas of the surrounding rainforest-clad mountains and valleys.
  Further west, the towering peaks of the Great Dividing Range present
  opportunities for adventurous hiking and exploring scenic vistas, including
  the iconic Walshs Pyramid near Gordonvale.
</p>
```

We apply the same `animation` to both `<figcaption>` elements as in previous examples, but their `animation-trigger` property values reference two different `timeline-trigger-name` values.

```
figcaption {
  animation: fade-in 0.4s ease-in both;
}

.one figcaption {
  animation-trigger: --t1 play-forwards play-backwards;
}

.two figcaption {
  animation-trigger: --t2 play-forwards play-backwards;
}
```

We set the same `timeline-trigger-source` and the same `timeline-trigger-activation-range` on both `<img>` elements. The `timeline-trigger-name` for each `<img>` element reference the two different dashed identifiers in the previous code block, which means the trigger created on each `<img>` acts as the trigger for the animation on its own sibling `<figcaption>`.

The `timeline-trigger-activation-range: contain 40% contain 60%` declaration means that the trigger activates — and thus the animation starts playing — when the tracked element reaches a narrow range, the middle `20%` of the scrollport, and deactivates when the subject exits that narrow range.

By default, the activation range is the same as the active range. However, we also set a `timeline-trigger-active-range` range of `entry 50% exit 100%` on the second `<img>`. This means that, once faded in, the second `<figcaption>` will only fade out again when the second `<img>` scrolls to `exit 100%`, which is when it has completely left the scrollport.

```
img {
  timeline-trigger-source: view();
  timeline-trigger-activation-range: contain 40% contain 60%;
}

.one img {
  timeline-trigger-name: --t1;
}

.two img {
  timeline-trigger-name: --t2;
  timeline-trigger-active-range: entry 50% exit 100%;
}
```

> **Note:** To have an effect, the `timeline-trigger-active-range` must be set to a larger range than the `timeline-trigger-activation-range`.

```
.figure-wrapper {
  display: flex;
  gap: 20px;
}

figcaption {
  left: 5px;
  right: -1px;
}
```

This example renders like so:

Scroll the images into view, and then scroll them carefully up and down. Note how both captions fade into view at the same time, at a point roughly one third up the embedded page. The first caption fades out slightly further up, whereas the second caption doesn't fade out until it has been moved completely out of the scrollport. This is because both `<img>` triggers have the same *activation* range, while the second one has a much larger *active* range applied to it than the activation range.

The timeline-trigger shorthand

So far, we've written all the CSS for our scroll-triggered animation as a mixture of shorthand and longhand properties, to effectively explain each of the properties and their values. However, this is cumbersome and wordy. Now that you've understood the concepts, we can use the `timeline-trigger` shorthand to create the shortest possible equivalent. You'll likely opt for this shorthand in your future projects.

Taking these declarations as an example:

```
img {
  timeline-trigger-name: --t;
  timeline-trigger-source: view();
  timeline-trigger-activation-range: contain 25% contain 75%;
  timeline-trigger-active-range: entry 0% exit 100%;
}
```

We can rewrite these in a single line of CSS using the `timeline-trigger` shorthand:

```
img {
  timeline-trigger: --t view() contain 25% contain 75% / entry 0% exit 100%;
}
```

Adjusting the animation's action

All the examples so far in this guide have triggered the `fade-in` animation, causing the caption to fade in and fade out. The forwards and backwards play is controlled by the `animation-trigger` declaration set on the animated element:

```
animation-trigger: --t play-forwards play-backwards;
```

The `<animation-action>` values `play-forwards` and `play-backwards` specify that the animation plays forwards when the trigger activates, and backwards when the trigger deactivates. The first value is the animation activation action, and the second value is the animation deactivation action.

If we set the following `animation` declaration on the same element:

```
animation: fade-in 1s ease-in both;
```

The animation only happens once when the trigger is activated, and once in reverse when it is deactivated: we didn't specify an `animation-iteration-count` in our `animation` shorthand, therefore the default value, `1`, is used.

There are other `animation-action` values that can be set to produce different effects. For example:

- `play-once` causes the animation to play only once. Once finished, it won't play again on subsequent activations or deactivations.

- `play` causes the animation to play, in whatever direction it was previously playing in. In contrast, `play-forwards` and `play-backwards` interact with the animation's `playbackRate`, setting it to its absolute positive value or its absolute positive value multiplied by `-1`, respectively. This results in the animation playing forwards or backwards. Note that the `animation-direction` value is not affected.
- `pause` causes the animation to pause. For example, you could set an animation's iteration count to `infinite`, and set the corresponding `animation-trigger` to `--t play pause`: This would cause the animation to play when the trigger is activated, and pause when it deactivates.
- `reset` has the same effect as `pause`, except that additionally it sets the animation progress back to `0`.

Some of these values are designed to be used together. For example, `play-forwards play-backwards` is intended for use in cases where you want to alternate the direction of play in the animation's end visual effect, causing a UI element to "animate in" when it appears on-screen and then "animate out" again when it goes off-screen. On the other hand, `play pause` is common for animating an element as it appears, then pausing the animation as it starts to go off-screen.

Let's look at a brief example — we'll take our first example and change it so that our `<figure>` fades in only once, when has completely entered the scrollport, and doesn't fade out or animate again until the page is reloaded.

We set the `animation-trigger` property's `animation-action` to `play-once` so that the animation only plays once when the `<figure>` first enters the activation range. We've also set the `timeline-trigger-activation-range` to `contain` so that the animation only plays when the `<figure>` is completely on-screen — it only plays once, so we don't want you to miss it.

```
figure {
  animation: fade-in 1s ease-in both;
  animation-trigger: --t play-once;

  timeline-trigger: --t view() contain;
}
```

This example renders like so:

When you first scroll the `<figure>` on-screen, it will fade in. After that, it will stay at `100%` opacity regardless of how many times you scroll it up and down the scrollport. You can only get it to fade in again by refreshing the page (or reloading the embedded example's `<iframe>`).

Trigger scope

If multiple triggers use the same `timeline-trigger-name`, because of how triggers are determined by the browser by default, the triggers will be associated with the last element in the HTML source order that has that `timeline-trigger-name` value. This is likely not the desired behavior.

For example, if a document contains multiple repeated components, each containing a scroll-triggered animation where the animated element and tracked element are different elements, all of the animated elements will have their animations controlled by the last component's trigger, unless you use a different `timeline-trigger-name` in each component, or scope the name by subtree.

The `trigger-scope` property limits the visibility, or "scope", of a `timeline-trigger-name` value to a specific subtree. The result is that each animated element can only have its animation triggered by a trigger created within the same scoped subtree. See the `trigger-scope` reference page for details of how this works and a `trigger-scope` example.

Multiple scroll-triggered animations

In previous examples, we set only a single scroll-triggered animation on an element; however, all of the `animation-*` and `timeline-trigger-*` properties discussed in this guide accept a comma separated list of values to enable triggering multiple animations from multiple triggers. In this section we'll build a slightly more complex example with multiple scroll-triggered animations on the same element.

The `animation-trigger` property works in exactly the same way as the `animation` shorthand property and the other animation longhand properties with regards to setting multiple values. If multiple `animation-name` values are set, but only a single `animation-trigger` value is set, the `animation-trigger` will apply to all the animations. If two `animation-trigger` values are set, they will cycle between the animations until all of them have an `animation-trigger` value set. And so on.

This example progressively animates an element — applying further animations when new triggers are activated as the page scrolls. As the user scrolls, the element first slides in from the right of the screen, then reveals its contents, then slides down the screen and changes its background color.

The HTML is similar to previous examples except that we have included a `<section>` element at the top containing some highlighted content, and some empty `<div>` elements interspersed throughout our main content that will have triggers defined on them to trigger our animations.

```
<section>
  <h2>This content is animated!</h2>

  the iconic Walshs Pyramid near Gordonvale.
</p>

<div id="three"></div>

<p>
  Walshs Pyramid is located within Wooroonooran National Park south of Cairns,
  Queensland, Australia. An annual footrace to its summit is held on the third
  Saturday in August. For experienced hikers, the ascent and descent can take 4
  to 6 hours. The vegetation on the mountain is fairly dense with exposed rocks
  which can make the surface very slippery after rain.
</p>
```

Initially, the highlighted content `<section>` is hidden off-screen. Our CSS starts by styling the `<section>` element, giving it a `position` of `fixed` and positioning it near the top-left of the scrollport. We also define the initial styles that we will be animating from and returning to. We then set three `animation` values, which will make the `<section>` element `slide-from-right`, then `reveal` its contents, then `slide-down` the screen and change its background color. We also set an `animation-trigger` for each one of the animations so that they will be triggered by different triggers being activated.

We want the finished state of each animation to apply throughout, after it is reached, therefore it is important to set appropriate `animation-fill-mode` values on the animations and `<animation-action>` values on the `animation-trigger` values to achieve this. We had to set an `animation-fill-mode` of `forwards` rather than `both` on the last animation because there is no `from` keyframe.

```
body {
  overflow-x: hidden;
  font-family: "Helvetica", "Arial";
  font-size: 1.3rem;
  width: 80%;
  margin: 0 auto;
}

h1 {
  font-size: 3rem;
}

h2 {
  font-size: 2rem;
}

p {
  font-size: 1.5rem;
  line-height: 1.5;
}

section {
  background: red;
```

```
  color: #ffffff00;
  padding: 10px;
  width: 400px;
  height: 50px;
}

section p {
  font-size: 1.2rem;
}
```

```
section {
  position: fixed;
  left: 1em;
  top: 1em;
  height: 240px;
  background: red;
  width: 400px;
  transform-origin: top;

  animation:
    slide-from-right 1s both,
    reveal 1s both,
    slide-down 1s forwards;

  animation-trigger:
    --t1 play-forwards pause,
    --t2 play-forwards pause,
    --t3 play-forwards pause;
}
```

Next, we create triggers on the `<div>` elements, setting their `timeline-trigger-name` equal to the identifiers specified in the `<section>` elements' `animation-trigger` property values. This means that as the user scrolls, when each tracked `<div>` enters the scrollport, a different animation is activated. In this case, our tracked elements are invisible — they don't contain any useful content and are only here to create the triggers.

```
#one {
  timeline-trigger: --t1 view();
}

#two {
  timeline-trigger: --t2 view();
}

#three {
  timeline-trigger: --t3 view();
}
```

Finally, we define the animation `@keyframes` referenced in the `<section>` element's `animation` property earlier on.

```
@keyframes slide-from-right {
  from {
    translate: 400%;
  }
  to {
    translate: 0;
  }
}

@keyframes reveal {
  from {
    color: #ffffff00;
    transform: scaleY(0.2);
  }
  to {
    color: white;
    transform: scaleY(1);
  }
}

@keyframes slide-down {
  to {
    translate: 0 100%;
    background: blue;
  }
}
```

```
@supports not (timeline-trigger-name: --t) {
  body::before {
    content: "Your browser does not support scroll-triggered animations.";
    background-color: wheat;
    text-align: center;
    padding: 1rem 0;

    z-index: 1;
    position: fixed;
    inset: 40% 0 auto;
  }
}
```

This example renders as follows:

Try carefully scrolling the example, and note how each animation is applied to the `<section>` when each `<div>` is scrolled to.

Multiple triggers for the same animation

If you have an animated element, and you want to define triggers on multiple different elements that all trigger the same animation, you need to specify the same named animation multiple times on the animated element, and then give each instance of that animation a different trigger. See Multiple triggers for the same animation for more information.

CSS animations

The **CSS animations** module lets you animate the values of CSS properties, such as background-position and transform, over time by using keyframes. Each keyframe describes how the animated element should render at a given time during the animation sequence. You can use the properties in the animations module to control the duration, number of repetitions, delayed start, and other aspects of an animation.

Animations in action

To view the animation in the box below, click the checkbox 'Play the animation' or hover the cursor over the box. When the animation is active, the cloud at the top changes shape, snowflakes fall, and the snow level at the bottom rises. To pause the animation, uncheck the checkbox or move your cursor away from the box.

```
<!-- See aria-label: https://developer.mozilla.org/en-US/docs/Web/Accessibility/ARIA/Reference/Attributes/aria-label -->
<input
  type="checkbox"
  id="animate"
  aria-label="Toggle the play state of the animation" />
<label for="animate">the animation</label>
<div class="root">
  <i></i><i></i><i></i>
```

```
}
i:nth-of-type(5n + 4) {
  animation-timing-function: linear;
}
i:nth-of-type(11n) {
  animation-timing-function: cubic-bezier(0.2, 0.3, 0.8, 0.9);
}
i:nth-of-type(7n) {
  opacity: 0.5;
}
i:nth-of-type(7n + 2) {
  opacity: 0.3;
}
i:nth-of-type(7n + 4) {
  opacity: 0.7;
}
i:nth-of-type(7n + 6) {
  opacity: 0.6;
  animation-timing-function: ease-in;
  transform-origin: left 10px;
}
i:nth-of-type(7n + 1) {
  opacity: 0.8;
}

.root {
  height: 580px;
  background-color: skyblue;
  border: 1px solid darkgrey;
  position: relative;
  overflow: hidden;
}
.ground,
.cloud {
  position: absolute;
  top: 0;
  right: 0;
  left: 0;
  background-repeat: no-repeat;
}
.cloud {
  width: 100%;
  height: 150px;
  background: white;
  border-radius: 0 0 90px 33% / 0 0 45px 50px;
  box-shadow:
    5px 15px 15px white,
    -5px 15px 15px white,
    0 20px 20px rgb(125 125 125 / 0.5);
  animation:
    clouds ease 5s alternate infinite 0.2s,
    wind ease-out 4s alternate infinite;
}
.ground {
  bottom: 0;
  background-image: linear-gradient(to top, white 97%, 99%, #bbbbbb 100%);
  background-position: center 580px;
  animation: snowfall linear 300s forwards;
  border: 1px solid grey;
  /* Put the ground into a 3D rendering context (because the snow flakes are in a 3d rendering context) */
  transform: translate3d(0, 0, 0);
}

@keyframes snowfall {
  from {
    background-position: center 580px;
  }
  to {
    background-position: center 280px;
  }
}

@keyframes clouds {
  from {
    border-radius: 0 0 90px 33% / 0 0 45px 50px;
  }
  to {
    border-radius: 0 0 40px 50% / 0 0 55px 80px;
  }
}

@keyframes wind {
  from {
    height: 150px;
  }
  to {
    height: 100px;
  }
}

@keyframes falling {
  from {
    transform: translate(0, -50px) rotate(0deg) scale(0.9, 0.9);
  }
  to {
    transform: translate(30px, 600px) rotate(360deg) scale(1.1, 1.1);
  }
}

/* By default, the animations are paused. */
i,
div[class] {
  animation-play-state: paused;
```

```
}
/* When the div is hovered, the animation plays. Also,
when the input is checked, the animation coming after the checked checkbox plays */
div:hover *,
input:checked ~ div * {
  animation-play-state: running;
}

/* Change the content of the label that comes right after the input. Included aria-label on the label to improve accessibility. */
input + label::before {
  content: "Play ";
}
input:checked + label::before {
  content: "Pause ";
}
```

This sample animation uses `animation-iteration-count` to make the flakes fall repeatedly, `animation-direction` to make the cloud move back and forth, `animation-fill-mode` to raise the snow level in response to the cloud movement, and `animation-play-state` to pause the animation.

Click "Play" in the example above to see or edit the code for the animation in the MDN Playground.

Animatable CSS properties

CSS Animations and Transitions rely on the concept of **animatable** properties, and all CSS properties are animatable unless otherwise specified. Each property's *animation type* determines how values combine - interpolate, add, or accumulate - for this property. Transitions only involve interpolation, whereas animations may use all three combination methods.

> **Note:** The animation type for each CSS property is listed in its "Formal definition" table (E.g., `color`).

> **Note:** The interpolation method for each CSS data type is described in its "Interpolation" section (E.g., `<length>`).

Animation types

There are mainly four animation types as defined in the Web Animations specification:

Not animatable

: The property is not animatable. It is not processed when listed in an animation keyframe and is unaffected by transitions.

> **Note:** An animation effect targeting only properties that are not animatable will still exhibit the usual behavior for an animation effect (E.g., firing the `animationstart` event).

Discrete

: The property's values are not additive, and interpolation swaps from the start value to the end value at `50%`. Specifically, denoting by `p` the progress value:

- If `p < 0.5`, then `V_result = V_start`;
- If `p ≥ 0.5`, then `V_result = V_end`.

By computed value

: Corresponding individual components of the computed values are combined using the indicated procedure for that value type. If the number of components or the types of corresponding components do not match, or if any component value uses discrete animation and the two corresponding values do not match, then the property values combine as discrete.

Repeatable list

: Same as by computed value except that if the two lists have differing numbers of items, they are first repeated to the least common multiple numbers of items. Each item is then combined by computed value. If a pair of values cannot be combined or any component value uses discrete animation, then the property values combine as discrete.

Some properties have specific interpolation behavior not covered by these four types. In this case, refer to the property's "Interpolation" section (E.g., `visibility`).

Animating custom properties

For custom properties registered using the `registerProperty()` method, the animation type is by computed value, with the computed value type determined by the property's syntax definition.

For unregistered custom properties, the animation type is discrete.

Using CSS animations

CSS animations make it possible to animate transitions from one CSS style configuration to another. Animations consist of two components: a style describing the CSS animation and a set of keyframes that indicate the start and end states of the animation's style, as well as possible intermediate waypoints.

There are three key advantages to CSS animations over traditional script-driven animation techniques:

1. You can create basic animations with a few lines of CSS; no JavaScript required.
2. The animations run well, even under moderate system load. Simple animations can often perform poorly in JavaScript. The rendering engine can use frame-skipping and other techniques to keep the performance as smooth as possible.
3. Letting the browser control the animation sequence lets the browser optimize performance and efficiency by, for example, reducing the update frequency of animations running in tabs that aren't currently visible.

Configuring an animation

To create a CSS animation sequence, you style the element you want to animate with the `animation` property or its sub-properties. This lets you configure the timing, duration, and other details of how the animation sequence should progress. This does **not** configure the actual appearance of the animation, which is done using the `@keyframes` at-rule as described in the Defining animation sequence using keyframes section below.

The sub-properties of the `animation` property are:

`animation-composition`

Specifies the composite operation to use when multiple animations affect the same property simultaneously. This property is not part of the `animation` shorthand property.

`animation-delay`

Specifies the delay between an element loading and the start of an animation sequence and whether the animation should start immediately from its beginning or partway through the animation.

`animation-direction`

Specifies whether an animation's first iteration should be forward or backward and whether subsequent iterations should alternate direction on each run through the sequence or reset to the start point and repeat.

`animation-duration`

Specifies the length of time in which an animation completes one cycle.

`animation-fill-mode`

Specifies how an animation applies styles to its target before and after it runs.

> **Note:** In the case of animation forwards fill mode, animated properties behave as if included in a set `will-change` property value. If a new stacking context was created during the animation, the target element retains the stacking context after the animation has finished.

`animation-iteration-count`

Specifies the number of times an animation should repeat.

`animation-name`

Specifies the name of the `@keyframes` at-rule describing an animation's keyframes.

`animation-play-state`

Specifies whether to pause or play an animation sequence.

`animation-timeline`

Specifies the timeline that is used to control the progress of a CSS animation.

`animation-timing-function`

Specifies how an animation transitions through keyframes by establishing acceleration curves.

Defining an animation sequence using keyframes

After you've configured the animation's timing, you need to define the appearance of the animation. This is done by establishing one or more keyframes using the `@keyframes` at-rule. Each keyframe describes how the animated element should render at a given time during the animation sequence.

Since the timing of the animation is defined in the CSS style that configures the animation, keyframes use a `<percentage>` to indicate the time during the animation sequence at which they take place. 0% indicates the first moment of the animation sequence, while 100% indicates the final state of the animation. Because these two times are so important, they have special aliases: `from` and `to`. Both are optional. If `from`/`0%` or `to`/`100%` is not specified, the browser starts or finishes the animation using the computed values of all attributes.

You can optionally include additional keyframes that describe intermediate steps between the start and end of the animation.

Using the animation shorthand

The `animation` shorthand is useful for saving space. As an example, some of the rules we've been using through this article:

```
p {
  animation-duration: 3s;
  animation-name: slide-in;
  animation-iteration-count: infinite;
  animation-direction: alternate;
}
```

...could be replaced by using the `animation` shorthand.

```
p {
  animation: 3s infinite alternate slide-in;
}
```

To learn more about the sequence in which different animation property values can be specified using the `animation` shorthand, see the `animation` reference page.

Setting multiple animation property values

The CSS animation longhand properties can accept multiple values, separated by commas. This feature can be used when you want to apply multiple animations in a single rule and set different durations, iteration counts, etc., for each of the animations. Let's look at some quick examples to explain the different permutations.

In this first example, there are three duration and three iteration count values. So each animation is assigned a value of duration and iteration count with the same position as the animation name. The `fadeInOut` animation is assigned a duration of `2.5s` and an iteration count of `2`, and the `bounce` animation is assigned a duration of `1s` and an iteration count of `5`.

```
animation-name: fadeInOut, moveLeft300px, bounce;
animation-duration: 2.5s, 5s, 1s;
animation-iteration-count: 2, 1, 5;
```

In this second example, three animation names are set, but there's only one duration and iteration count. In this case, all three animations are given the same duration and iteration count.

```
animation-name: fadeInOut, moveLeft300px, bounce;
animation-duration: 3s;
animation-iteration-count: 1;
```

In this third example, three animations are specified, but only two durations and iteration counts. In such cases where there are not enough values in the list to assign a separate one to each animation, the value assignment cycles from the first to the last item in the available list and then cycles back to the first item. So, `fadeInOut` gets a duration of `2.5s`, and `moveLeft300px` gets a duration of `5s`, which is the last value in the list of duration values. The duration value assignment now resets to the first value; `bounce`, therefore, gets a duration of `2.5s`. The iteration count values (and any other property values you specify) will be assigned in the same way.

```
animation-name: fadeInOut, moveLeft300px, bounce;
animation-duration: 2.5s, 5s;
animation-iteration-count: 2, 1;
```

If the mismatch in the number of animations and animation property values is inverted, say there are five `animation-duration` values for three `animation-name` values, then the extra or unused animation property values, in this case, two `animation-duration` values, don't apply to any animation and are ignored.

Examples

Making text slide across the browser window

This basic example styles a `<p>` element using the `translate` and `scale` transition properties so that the text slides in from off the right edge of the browser window.

```
p {
  animation-duration: 3s;
  animation-name: slide-in;
}

@keyframes slide-in {
  from {
    translate: 150vw 0;
    scale: 200% 1;
  }

  to {
    translate: 0 0;
    scale: 100% 1;
  }
}
```

In this example, the style for the `<p>` element specifies that the animation should take 3 seconds to execute from start to finish, using the `animation-duration` property and that the name of the `@keyframes` at-rule defining the keyframes for the animation sequence is `slide-in`.

In this case, we have just two keyframes. The first occurs at `0%` (using the alias `from`). Here, we configure the `translate` property of the element to be at `150vw` (that is, beyond the far right edge of the containing element), and the `scale` of the element to be 200% (or two times its default inline size), causing the paragraph to be twice as wide as its `<body>` containing block. This causes the first frame of the animation to have the header drawn off the right edge of the browser window.

The second keyframe occurs at `100%` (using the alias `to`). The `translate` property is set to `0%` and the `scale` of the element is set to `1`, which is `100%`. This causes the header to finish its animation in its default state, flush against the left edge of the content area.

```
<p>
  The Caterpillar and Alice looked at each other for some time in silence: at
  last the Caterpillar took the hookah out of its mouth, and addressed her in a
  languid, sleepy voice.
</p>
```

> **Note:** Reload page to see the animation.

Adding another keyframe animation

Let's add another keyframe to the previous example's animation. Let's say we want Alice's name to turn pink and grow and then shrink back to its original size and color as it moves from right to left. While we could change the `font-size`, changing any properties that impact the box model negatively impacts performance. Instead, we wrap her name in a `<span>` and then scale and assign a color to that separately. That requires adding a second animation impacting only the `<span>`:

```
@keyframes grow-shrink {
  25%,
  75% {
    scale: 100%;
  }

  50% {
    scale: 200%;
    color: magenta;
  }
}
```

The full code now looks like this:

```
p {
  animation-duration: 3s;
  animation-name: slide-in;
}
p span {
  display: inline-block;
  animation-duration: 3s;
  animation-name: grow-shrink;
}

@keyframes slide-in {
  from {
    translate: 150vw 0;
    scale: 200% 1;
  }

  to {
    translate: 0 0;
    scale: 100% 1;
  }
}

@keyframes grow-shrink {
  25%,
  75% {
    scale: 100%;
  }

  50% {
```

```
    scale: 200%;
    color: magenta;
  }
}
```

We've added a `<span>` around "Alice":

```
<p>
  The Caterpillar and <span>Alice</span> looked at each other for some time in
  silence: at last the Caterpillar took the hookah out of its mouth, and
  addressed her in a languid, sleepy voice.
</p>
```

This tells the browser the name should be normal for the first and last 25% of the animation, but turn pink while being scaled up and back again in the middle. We set the spans's `display` property to `inline-block` as the `transform` properties do not affect non-replaced inline-level content.

> **Note:** Reload page to see the animation.

Repeating the animation

To make the animation repeat itself, use the `animation-iteration-count` property to indicate how many times to repeat the animation. In this case, let's use `infinite` to have the animation repeat indefinitely:

```
p {
  animation-duration: 3s;
  animation-name: slide-in;
  animation-iteration-count: infinite;
}
```

```
@keyframes slide-in {
  from {
    translate: 150vw 0;
    scale: 200% 1;
  }

  to {
    translate: 0 0;
    scale: 100% 1;
  }
}
```

```
<p>
  The Caterpillar and Alice looked at each other for some time in silence: at
  last the Caterpillar took the hookah out of its mouth, and addressed her in a
  languid, sleepy voice.
</p>
```

Making the animation move back and forth

That made it repeat, but it's very odd having it jump back to the start each time it begins animating. What we really want is for it to move back and forth across the screen. That's easily accomplished by setting `animation-direction` to `alternate`:

```
p {
  animation-duration: 3s;
  animation-name: slide-in;
  animation-iteration-count: infinite;
  animation-direction: alternate;
}
```

```
@keyframes slide-in {
  from {
    translate: 150vw 0;
    scale: 200% 1;
  }

  to {
    translate: 0 0;
    scale: 100% 1;
  }
}
```

```
<p>
  The Caterpillar and Alice looked at each other for some time in silence: at
  last the Caterpillar took the hookah out of its mouth, and addressed her in a
  languid, sleepy voice.
</p>
```

Using animation events

You can get additional control over animations — as well as useful information about them — by making use of animation events. These events, represented by the `AnimationEvent` object, can be used to detect when animations start, finish, and begin a new iteration. Each event includes the time at which it occurred as well as the name of the animation that triggered the event.

We'll modify the sliding text example to output some information about each animation event when it occurs, so we can get a look at how they work.

We've included the same keyframe animation as the previous example. This animation will last 3 seconds, be called "slide-in", repeat 3 times, and travel in an alternate direction each time. In the `@keyframes`, the scale and translation are manipulated along the x-axis to make the element slide across the screen.

```
.slide-in {
  animation-duration: 3s;
  animation-name: slide-in;
  animation-iteration-count: 3;
  animation-direction: alternate;
}
```

```
@keyframes slide-in {
  from {
```

```
    translate: 150vw 0;
    scale: 200% 1;
  }

  to {
    translate: 0 0;
    scale: 100% 1;
  }
}
```

Adding the animation event listeners

We'll use JavaScript code to listen for all three possible animation events. This code configures our event listeners; we call it when the document is first loaded in order to set things up.

```
const element = document.getElementById("watch-me");
element.addEventListener("animationstart", listener);
element.addEventListener("animationend", listener);
element.addEventListener("animationiteration", listener);

element.className = "slide-in";
```

This is pretty standard code; you can get details on how it works in the documentation for `eventTarget.addEventListener()`. The last thing this code does is set the `class` on the element we'll be animating to "slide-in"; we do this to start the animation.

Why? Because the `animationstart` event fires as soon as the animation starts, and in our case, that happens before our code runs. So we'll start the animation ourselves by setting the class of the element to the style that gets animated after the fact.

Receiving the events

The events get delivered to the `listener()` function, which is shown below.

```
function listener(event) {
  const l = document.createElement("li");
  switch (event.type) {
    case "animationstart":
      l.textContent = `Started: elapsed time is ${event.elapsedTime}`;
      break;
    case "animationend":
      l.textContent = `Ended: elapsed time is ${event.elapsedTime}`;
      break;
    case "animationiteration":
      l.textContent = `New loop started at time ${event.elapsedTime}`;
      break;
  }
  document.getElementById("output").appendChild(l);
}
```

This code, too, is very simple. It looks at the `event.type` to determine which kind of animation event occurred, then adds an appropriate note to the `<ul>` (unordered list) we're using to log these events.

The output, when all is said and done, looks something like this:

- Started: elapsed time is 0
- New loop started at time 3.01200008392334
- New loop started at time 6.00600004196167
- Ended: elapsed time is 9.234000205993652

Note that the times are very close to, but not exactly, those expected given the timing established when the animation was configured. Note also that after the final iteration of the animation, the `animationiteration` event isn't sent; instead, the `animationend` event is sent.

Just for the sake of completeness, here's the HTML that displays the page content, including the list into which the script inserts information about the received events:

```
<h1 id="watch-me">Watch me move</h1>
<p>
  This example shows how to use CSS animations to make <code>H1</code>
  elements move across the page.
</p>
<p>
  In addition, we output some text each time an animation event fires, so you
  can see them in action.
</p>
<ul id="output"></ul>
```

And here's the live output.

> **Note:** Reload page to see the animation.

Animating display and content-visibility

This example demonstrates how `display` and `content-visibility` can be animated. This behavior is useful for creating entry/exit animations where you want to for example remove a container from the DOM with `display: none`, but have it fade out smoothly with `opacity` rather than disappearing immediately.

Supporting browsers animate `display` and `content-visibility` with a variation on the discrete animation type. This generally means that properties will flip between two values 50% of the way through animating between the two.

There is an exception, however, which is when animating to/from `display: none` or `content-visibility: hidden` to a visible value. In this case, the browser will flip between the two values so that the animated content is shown for the entire animation duration.

So for example:

- When animating `display` from `none` to `block` (or another visible `display` value), the value will flip to `block` at `0%` of the animation duration so it is visible throughout.
- When animating `display` from `block` (or another visible `display` value) to `none`, the value will flip to `none` at `100%` of the animation duration so it is visible throughout.

HTML

The HTML contains two `<p>` elements with a `<div>` in between that we will animate from `display` `none` to `block`.

```
<p>
  Click anywhere on the screen or press any key to toggle the
  <code>&lt;div&gt;</code> between hidden and showing.
</p>

<div>
  This is a <code>&lt;div&gt;</code> element that animates between
  <code>display: none; opacity: 0</code> and
  <code>display: block; opacity: 1</code>. Neat, huh?
</div>

<p>
  This is another paragraph to show that <code>display: none;</code> is being
  applied and removed on the above <code>&lt;div&gt; </code>. If only its
  <code>opacity</code> was being changed, it would always take up the space in
  the DOM.
</p>
```

CSS

```
html {
  height: 100vh;
}

div {
  font-size: 1.6rem;
  padding: 20px;
  border: 3px solid red;
  border-radius: 20px;
  width: 480px;
  opacity: 0;
  display: none;
}

/* Animation classes */

div.fade-in {
  display: block;
  animation: fade-in 0.7s ease-in forwards;
}

div.fade-out {
  animation: fade-out 0.7s ease-out forwards;
}

/* Animation keyframes */

@keyframes fade-in {
  0% {
    opacity: 0;
    display: none;
  }

  100% {
    opacity: 1;
    display: block;
  }
}

@keyframes fade-out {
  0% {
    opacity: 1;
    display: block;
  }

  100% {
    opacity: 0;
    display: none;
  }
}
```

Note the inclusion of the `display` property in the keyframe animations.

JavaScript

Finally, we include a bit of JavaScript to set up event listeners to trigger the animations. Specifically, we add the `fade-in` class to the `<div>` when we want it to appear, and `fade-out` when we want it to disappear.

```
const divElem = document.querySelector("div");
const htmlElem = document.querySelector(":root");

htmlElem.addEventListener("click", showHide);
document.addEventListener("keydown", showHide);

function showHide() {
  if (divElem.classList[0] === "fade-in") {
    divElem.classList.remove("fade-in");
    divElem.classList.add("fade-out");
  } else {
    divElem.classList.remove("fade-out");
    divElem.classList.add("fade-in");
  }
}
```

Result

The code renders as follows:

CSS backgrounds and borders

The **CSS backgrounds and borders** module provides properties for adding backgrounds, borders, rounded corners, and box shadows to elements.

You can add different types of border styles, including borders made of images of any image type, from raster images to CSS gradients. Borders can be square or rounded, and a different radius can be set for each corner. Elements can be rounded whether or not they have a visible border.

Box shadows include inset and outset shadow, single or multiple shadows, and solid or allowed to fade to transparent. An outer box-shadow casts a shadow as if the border-box of the element were opaque. An inner box-shadow casts a shadow as if everything outside the padding edge were opaque. The shadow can be solid or include a spread distance with the shadow color transitioning to transparent.

The properties in this module also let you define whether cells inside a `<table>` should have shared or separate borders.

Backgrounds, borders, and box shadows in action

This sample of borders, backgrounds, and box shadows consists of centered background images made of linear and radial gradients. A series of box shadows make the border appear to "pop". The element on the left has a border image set. The element on the right has a rounded dotted border.

```
<article>
  <div></div>
  <div></div>
</article>
```

```
article {
  display: flex;
  gap: 10px;
}
div {
  color: #58ade3;
  height: 320px;
  width: 240px;
  padding: 20px;
  margin: 10px;
  border: dotted 15px; /* defaults to `currentColor` */
  border-radius: 100px 0;
  background-image:
    radial-gradient(
      circle,
      transparent 60%,
      currentColor 60% 70%,
      transparent 70%
    ),
    linear-gradient(45deg, currentColor, white),
    linear-gradient(transparent, transparent);
  /* the third transparent background image was added to provide space for the background color to show through */
  background-color: currentColor;
  background-position: center;
  background-size:
    60px 60px,
    120px 120px;
  background-clip: content-box, content-box, padding-box;
  box-shadow:
    inset 5px 5px 5px rgb(0 0 0 / 0.4),
    inset -5px -5px 5px rgb(0 0 0 / 0.4),
    5px 5px 5px rgb(0 0 0 / 0.4),
    -5px -5px 5px rgb(0 0 0 / 0.4);
}
div:first-of-type {
  border-radius: 0;
  border-image-source: repeating-conic-gradient(
    from 3deg at 25% 25%,
    currentColor 0 3deg,
    transparent 3deg 6deg
  );
  border-image-slice: 30;
}
```

The background images are defined with `background-image`. The images are centered with `background-position`. Different values of the `background-clip` property for the multiple background images are used to make the background images stay within the content box. The background color gets clipped to the padding box preventing the background from appearing through the transparent sections for the `border-image` and the `dotted border`. The rounded corners in the element on the right are created using the `border-radius` property. A single `box-shadow` declaration is used to set all the shadows, both inset and outset.

Box-shadow generator

This tool lets you construct CSS `box-shadow` effects, to add box shadow effects to your CSS objects.

The box-shadow generator enables you to add one or more box shadows to an element.

On opening the tool, you'll find a rectangle in the top-right section of the tool. That's the element you're going to be applying shadows to. When this element is selected (as it is, when you first load the page) you can apply some basic styling to it:

- Set the element's `color` using the color picker tool.
- Give the element a `border` using the "border" checkbox.
- Use the sliders to set the element's `top`, `left`, `width`, and `height` properties.

To add a box shadow, click the "+" button at the top-left. This adds a shadow, and lists it in the column on the left. Now you can set the values of the new shadow:

- Set the shadow's `color` using the color picker tool.
- Set the shadow to be inset using the "inset" checkbox.
- Use the sliders to set the element's position, blur, and spread.

To add another shadow, click "+" again. Now any values you set will apply to this new shadow. Change the order in which these two shadows are applied using the ↑ and ↓ buttons at the top-left. Select the first shadow again by clicking it in column on the left. To update the element's own styles, select it by clicking the button labeled "element" along the top.

You can add `::before` and `::after` pseudo-elements to the element, and give them box shadows as well. To switch between the element and its pseudo-elements, use the buttons along the top labeled "element", "::before", and "::after".

The box at the bottom-right contains the CSS for the element and any `::before` or `::after` pseudo-elements.

Resizing background images with background-size

The **`background-size`** CSS property lets you resize the background image of an element, overriding the default behavior of tiling the image at its full size by specifying the width and/or height of the image. By doing so, you can scale the image upward or downward as desired.

Tiling a large image

Let's consider a large image, a 2982x2808 Firefox logo image. We want (for some reason likely involving horrifyingly bad site design) to tile four copies of this image into a 300x300-pixel element. To do this, we can use a fixed `background-size` value of 150 pixels.

HTML

```
<div class="tiledBackground"></div>
```

CSS

```
.tiledBackground {
  background-image: url("https://www.mozilla.org/media/img/logos/firefox/logo-quantum.9c5e96634f92.png");
  background-size: 150px;
  width: 300px;
  height: 300px;
  border: 2px solid;
  color: pink;
}
```

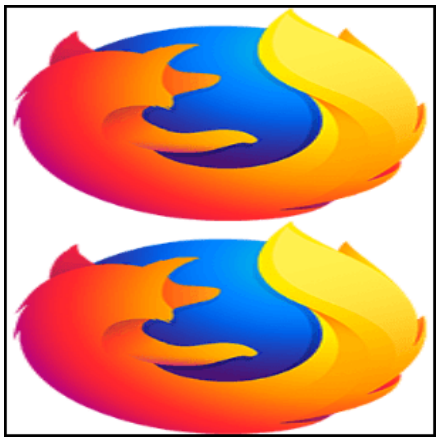
Result

Stretching an image

You can also specify both the horizontal and vertical sizes of the image, like this:

```
background-size: 300px 150px;
```

The result looks like this:



Scaling an image up

On the other end of the spectrum, you can scale an image up in the background. Here we scale a 32x32 pixel favicon to 300x300 pixels:

```
.square2 {
  background-image: url("favicon.png");
  background-size: 300px;
  width: 300px;
  height: 300px;
  border: 2px solid;
  text-shadow: white 0px 0px 2px;
  font-size: 16px;
}
```

As you can see, the CSS is actually essentially identical, save the name of the image file.

Special values: <code>contain</code> and <code>cover</code>

In addition to `<length>` values, the `background-size` CSS property offers two special size values, `contain` and `cover`. Let's take a look at these.

<code>contain</code>

The `contain` value specifies that, regardless of the size of the containing box, the background image should be scaled so that each side is as large as possible while not exceeding the length of the corresponding side of the container. Try resizing the example below to see this in action.

HTML

```
<div class="bgSizeContain">
  <p>Try resizing this element!</p>
</div>
```

CSS

```
.bgSizeContain {
  background-image: url("https://www.mozilla.org/media/img/logos/firefox/logo-quantum.9c5e96634f92.png");
  background-size: contain;
  width: 160px;
  height: 160px;
  border: 2px solid;
  resize: both;
  overflow: scroll;
}
```

Result

<code>cover</code>

The `cover` value specifies that the background image should be sized so that it is as small as possible while ensuring that both dimensions are greater than or equal to the corresponding size of the container. Try resizing the example below to see this in action.

HTML

```
<div class="bgSizeCover">
  <p>Try resizing this element!</p>
</div>
```

CSS

```
.bgSizeCover {
  background-image: url("https://www.mozilla.org/media/img/logos/firefox/logo-quantum.9c5e96634f92.png");
  background-size: cover;
  width: 160px;
  height: 160px;
  border: 2px solid;
  resize: both;
  overflow: scroll;
}
```

Scaling SVG backgrounds

Given the flexibility of SVG images, there's a lot to keep in mind when using them as background images with the `background-image` property, and even more to keep in mind when scaling them using the `background-size` property. This article describes how scaling of SVG images is handled when using these properties.

The background sizing algorithm

The algorithm used to determine the background size of a background image can, for the most part, be summarized by these four rules. There are some edge cases that aren't covered by these rules, but this covers the majority of cases.

1. If `background-size` specifies a fixed dimension (that is, percentages and relative units are fixed by their context), that dimension wins.
2. If the image has an intrinsic ratio (that is, its width:height ratio is constant, such as 16:9, 4:3, 2.39:1, 1:1, and so forth), the rendered size preserves that ratio.
3. If the image specifies a size, and the size isn't modified by `constrain` or `cover`, that specified size wins.
4. If none of the above cases are met, the image is rendered at the same size as the background area.

It's worth noting that the background sizing algorithm only cares about the image's dimensions and proportions, or lack thereof. An SVG image with fixed dimensions will be treated just like a raster image of the same size.

> **Note:** If you are trying to stretch your SVG to a different aspect ratio with CSS—for example in order to stretch it over the page background—make sure your SVG includes `preserveAspectRatio="none"`. Find out more about `preserveAspectRatio`.

Source image examples

Before diving in to look at the results of using different kinds of SVG source images and seeing how they look when used with `background-size`, it will be helpful to look at a few example source images that have different dimensions and sizing settings, which we will later use as our `background-image` values in our examples. The browser renders `<svg>` images as `300px` wide and `150px` tall by default.

Dimensionless and proportionless

This SVG gradient image is both dimensionless and proportionless. It doesn't care what size it is, nor does it care about remaining at a particular aspect ratio. This would make a good gradient desktop background that would work regardless of your screen size and its aspect ratio.

```
<svg>
  <title>Corner-to-corner gradient</title>
  <defs>
    <linearGradient id="g" x1="0%" x2="100%" y1="0%" y2="100%">
      <stop stop-color="pink" offset="0" />
      <stop stop-color="goldenrod" offset="1" />
    </linearGradient>
  </defs>
  <rect fill="url('#g')" width="100%" height="100%" />
</svg>
```

One specified dimension and proportionless

This image specifies a width of 100 pixels but no height or intrinsic ratio. This is, basically, a thin strip of wallpaper that could be stretched across the entire height of a block.

```
<svg width="100">
  <title>Vertical gradient, with a fixed width</title>
  <defs>
    <linearGradient id="g" x1="0%" x2="0%" y1="0%" y2="100%">
      <stop stop-color="purple" offset="0" />
      <stop stop-color="lime" offset="1" />
    </linearGradient>
  </defs>
  <rect fill="url('#g')" width="100%" height="100%" />
</svg>
```

One specified dimension with intrinsic ratio

This image specifies a 100 pixel height but no width. It also specifies an intrinsic aspect ratio of 3:4. This ensures that its width:height ratio is always 3:4, unless it's deliberately scaled to a disproportionate size (that is, by explicitly specifying both width and height that aren't of that ratio).

This is very much like specifying a specific width and height; since once you have one dimension and a ratio, the other dimension is implied.

```
<svg height="100" viewBox="0 0 3 4" preserveAspectRatio="none">
  <title>Vertical gradient, with a fixed height and intrinsic ratio</title>
  <defs>
    <linearGradient id="g" x1="0%" x2="0%" y1="0%" y2="100%">
      <stop stop-color="teal" offset="0" />
      <stop stop-color="orange" offset="1" />
    </linearGradient>
  </defs>
  <rect fill="url('#g')" width="100%" height="100%" />
</svg>
```

No width or height with intrinsic ratio

This image doesn't specify either a width or a height; instead, it specifies an intrinsic ratio of 1:1. It's always square, and is usable at any size, such as 32x32, 128x128, or 512x512, for example.

```
<svg viewBox="0 0 1 1" preserveAspectRatio="none">
  <title>Intrinsic ratio</title>
  <defs>
    <linearGradient id="g" x1="0%" x2="100%" y1="0%" y2="0%">
      <stop stop-color="navy" offset="0" />
      <stop stop-color="maroon" offset="1" />
    </linearGradient>
  </defs>
  <rect fill="url('#g')" width="100%" height="100%" />
</svg>
```

Scaling examples

Now let's see some examples of what happens as we apply different scaling to these images. In each of the examples below, the enclosing `<div>` elements are 300 pixels wide and 200 pixels tall, with a 2 pixel-wide border. To ensure we display the SVG background image only once for these demonstrations, we set `background-repeat` to `no-repeat`.

```
div {
  width: 300px;
  height: 200px;
  background-repeat: no-repeat;
  border: 2px solid black;
}
```

Specifying fixed lengths for both dimensions

If you use `background-size` to specify fixed lengths for both dimensions, those lengths are always used, per rule 1 above. In other words, the image will always get stretched to the dimensions you specify, regardless of whether or not the source image has specified its dimensions and/or aspect ratio.

No dimensions or intrinsic ratio

In this example, the image has no dimensions or intrinsic ratio set:

```
<div></div>
```

```
div {
  width: 300px;
  height: 200px;
  background-repeat: no-repeat;
  border: 2px solid black;
}
```

```
div {
  background-image: url("no-dimensions-or-ratio.svg");
  background-size: 125px 175px;
}
```

One specified dimension, no intrinsic ratio

In this example, the image has one dimension specified, and no intrinsic ratio set:

```
<div></div>
```

```
div {
  width: 300px;
  height: 200px;
  background-repeat: no-repeat;
  border: 2px solid black;
}
```

```
div {
  background-image: url("100px-wide-no-height-or-ratio.svg");
  background-size: 250px 150px;
}
```

One specified dimension with intrinsic ratio

```
<div></div>
```

In this example, the image has one dimension explicitly set, along with an intrinsic ratio, meaning both dimensions are effectively defined. Setting an absolute height and width for `background-size` overrides the dimensions set in the SVG:

```
div {
  width: 300px;
  height: 200px;
  background-repeat: no-repeat;
  border: 2px solid black;
}
```

```
div {
  background-image: url("100px-height-3x4-ratio.svg");
  background-size: 275px 125px;
}
```

No specified width or height with intrinsic ratio

In this example, the image has an intrinsic ratio but no dimensions set:

```
<div></div>
```

```
div {
  width: 300px;
  height: 200px;
```

```
  background-repeat: no-repeat;
  border: 2px solid black;
}
```

```
div {
  background-image: url("no-dimensions-1x1-ratio.svg");
  background-size: 250px 100px;
}
```

Using contain or cover

Specifying `cover` for `background-size` makes the picture as small as possible while still covering the entire background area. `contain`, on the other hand, makes the image as large as possible while not being clipped by the background area.

For an image with an intrinsic ratio, exactly one size matches the `cover`/fit criteria alone. But if there is no intrinsic ratio specified, `cover`/fit isn't sufficient, so the large/small constraints choose the resulting size.

No dimensions or intrinsic ratio

In this example, the image has no dimensions or intrinsic ratio set. If an image doesn't specify either dimensions or an intrinsic ratio, neither rule 2 nor rule 3 apply, so rule 4 takes over: the background image is rendered covering the entire background area. This satisfies the largest-or-smallest constraint.

```
<div></div>
```

```
div {
  width: 300px;
  height: 200px;
  background-repeat: no-repeat;
  border: 2px solid black;
}
```

```
div {
  background-image: url("no-dimensions-or-ratio.svg");
  background-size: contain;
}
```

One specified dimension, no intrinsic ratio

In this example, with the image having one dimension specified but no intrinsic ratio, rule 4 applies, and the image is scaled to cover the entire background area.

```
<div></div>
```

```
div {
  width: 300px;
  height: 200px;
  background-repeat: no-repeat;
  border: 2px solid black;
}
```

```
div {
  background-image: url("100px-wide-no-height-or-ratio.svg");
  background-size: contain;
}
```

One specified dimension with intrinsic ratio

In these examples, the image has one dimension explicitly set, along with an intrinsic ratio.

Things change when you specify an intrinsic ratio. In this case, rule 1 isn't relevant, so rule 2 is applied: we try to preserve any intrinsic ratio (while respecting `contain` or `cover`). For example, preserving a 3:4 intrinsic aspect ratio for a 300x200 box with `contain` means drawing a 150x200 background.

contain case

```
<div></div>
```

Given this CSS:

```
div {
  width: 300px;
  height: 200px;
  background-repeat: no-repeat;
  border: 2px solid black;
}
```

```
div {
  background-image: url("100px-height-3x4-ratio.svg");
  background-size: contain;
}
```

Notice how the entire image is rendered, fitting as best as possible into the box without clipping any of it away.

cover case

```
<div></div>
```

```
div {
  width: 300px;
  height: 200px;
  background-repeat: no-repeat;
  border: 2px solid black;
}
```

```
div {
  background-image: url("100px-height-3x4-ratio.svg");
  background-size: cover;
}
```

Here, the 3:4 ratio is preserved while still stretching the image to fill the entire box. That causes the bottom of the image to be clipped away.

No dimensions with intrinsic ratio

These example use the image with an intrinsic ratio set but no defined dimensions. When using an image with no intrinsic dimensions but an intrinsic ratio, things work similarly.

contain case

```
<div></div>
```

```
div {
  width: 300px;
  height: 200px;
  background-repeat: no-repeat;
  border: 2px solid black;
}
```

```
div {
  background-image: url("no-dimensions-1x1-ratio.svg");
  background-size: contain;
}
```

Notice that the image is sized to fit the smallest dimension while preserving the 1:1 aspect ratio.

cover case

```
<div></div>
```

```
div {
  width: 300px;
  height: 200px;
  background-repeat: no-repeat;
  border: 2px solid black;
}
```

```
div {
  background-image: url("no-dimensions-1x1-ratio.svg");
  background-size: cover;
}
```

Here, the image is sized so that it fills the largest dimension. The 1:1 aspect ratio has been preserved, although with this source image, that can be difficult to see.

Automatic sizing using "auto" for both dimensions

If `background-size` is set to `auto` or `auto auto`, rule 2 says that rendering must preserve any intrinsic ratio that's provided.

No dimensions or intrinsic ratio

When auto-sizing background images with no intrinsic ratio or dimensions specified, rule 4 takes effect, and the image is rendered to fill the background area.

```
<div></div>
```

```
div {
  width: 300px;
  height: 200px;
  background-repeat: no-repeat;
  border: 2px solid black;
}
```

```
div {
  background-image: url("no-dimensions-or-ratio.svg");
  background-size: auto auto;
}
```

One dimension and no intrinsic ratio

If no intrinsic ratio is specified, but at least one dimension is specified, rule 3 takes effect, and we render the image obeying those dimensions.

```
<div></div>
```

```
div {
  width: 300px;
  height: 200px;
  background-repeat: no-repeat;
  border: 2px solid black;
}
```

```
div {
  background-image: url("100px-wide-no-height-or-ratio.svg");
  background-size: auto auto;
}
```

Note here that the width, which is specified in the source SVG at 100 pixels, is obeyed, while the height fills the background area since it's not specified (either explicitly or by an intrinsic ratio).

One dimension and an intrinsic ratio

If we have an intrinsic ratio with a fixed dimension, that fixes both dimensions in place. As previously mentioned, knowing one dimension and a ratio is the same as specifying both dimensions explicitly.

```
<div></div>
```

```
div {
  width: 300px;
  height: 200px;
  background-repeat: no-repeat;
  border: 2px solid black;
}
```

```
div {
  background-image: url("100px-height-3x4-ratio.svg");
  background-size: auto auto;
}
```

Since this image has an explicit height of `100px`. With the 3:4 ratio set in the SVG, in the case of `auto`, the image's width is 75 pixels.

No fixed dimensions with intrinsic ratio

When an intrinsic ratio is specified, but no dimensions, rule 4 is applied — except that rule 2 also applies. The image is therefore rendered just like for the `contain` case.

```
<div></div>
```

```
div {
  width: 300px;
  height: 200px;
  background-repeat: no-repeat;
  border: 2px solid black;
}
```

```
div {
  background-image: url("no-dimensions-1x1-ratio.svg");
  background-size: auto auto;
}
```

Using "auto" and one specific length

Given rule 1, specified dimensions are always used, so we need to use our rules only to determine the second dimension.

No dimensions or intrinsic ratio

If the image has no dimensions or intrinsic ratio, rule 4 applies, and we use the background area's dimension to determine the value for the `auto` dimension.

```
<div></div>
```

```
div {
  width: 300px;
  height: 200px;
  background-repeat: no-repeat;
  border: 2px solid black;
}
```

```
div {
  background-image: url("no-dimensions-or-ratio.svg");
  background-size: auto 140px;
}
```

Here, the width is determined using the background area's width per rule 4, while the height is the `140px` specified in the CSS.

One specified dimension with no intrinsic ratio

If the image has one specified dimension but no intrinsic ratio, that specified dimension is used per rule 3 if that dimension is set to `auto` in the CSS.

```
<div></div>
```

```
div {
  width: 300px;
  height: 200px;
  background-repeat: no-repeat;
  border: 2px solid black;
}
```

```
div {
  background-image: url("100px-wide-no-height-or-ratio.svg");
  background-size: 200px auto;
}
```

Here, the `200px` specified in the CSS overrides the `100px` width specified in the SVG, per rule 1. Since there's no intrinsic ratio or height provided, `auto` selects the height of the background area as the height for the rendered image.

```
<div></div>
```

```
div {
  width: 300px;
  height: 200px;
  background-repeat: no-repeat;
  border: 2px solid black;
}
```

```
div {
  background-image: url("100px-wide-no-height-or-ratio.svg");
  background-size: auto 125px;
}
```

In this case, the width is specified as `auto` in the CSS, so the `100px` width specified in the SVG is selected, per rule 3. The height is set at `125px` in the CSS, so that is selected per rule 1.

One specified dimension with intrinsic ratio

When a dimension is specified, rule 1 applies that dimension from the SVG to the rendered background unless specifically overridden by the CSS. When an intrinsic ratio is also specified, that's used to determine the other dimension.

```
<div></div>
```

```
div {
  width: 300px;
```

```
  height: 200px;
  background-repeat: no-repeat;
  border: 2px solid black;
}
```

```
div {
  background-image: url("100px-height-3x4-ratio.svg");
  background-size: 150px auto;
}
```

In this case, we use the width of the image specified in the CSS set at `150px`, so rule 1 is applied. The intrinsic 3:4 aspect ratio then determines the height for the `auto` case.

No specified dimensions with intrinsic ratio

If no dimensions are specified in the SVG, the specified dimension in the CSS is applied, then the intrinsic ratio is used to select the other dimension, per rule 2.

```
<div></div>
```

```
div {
  width: 300px;
  height: 200px;
  background-repeat: no-repeat;
  border: 2px solid black;
}
```

```
div {
  background-image: url("no-dimensions-1x1-ratio.svg");
  background-size: 150px auto;
}
```

The width is set by the CSS to `150px`. The `auto` value for the height is computed using that width and the 1:1 aspect ratio to be `150px` as well.

Using multiple backgrounds

You can apply **multiple backgrounds** to elements. These are layered atop one another with the first background you provide on top and the last background listed in the back. Only the last background can include a background color.

Multiple backgrounds are specified as a comma-separated list, such as `background: background1, background2, ...;`. This syntax is accepted by both the shorthand `background` property and the individual properties thereof except for `background-color`: `background-attachment`, `background-clip`, `background-image`, `background-origin`, `background-position`, `background-repeat`, `background-size`.

Example

In this example, three backgrounds are stacked: the Firefox logo, an image of bubbles, and a linear gradient:

HTML

```
<div class="multi-bg-example"></div>
```

CSS

```
.multi-bg-example {
  width: 100%;
  height: 400px;
  background-image:
    url("firefox.png"), url("bubbles.png"),
    linear-gradient(to right, rgb(30 75 115 / 100%), transparent);
  background-repeat: no-repeat, no-repeat, no-repeat;
  background-position:
    bottom right,
    left,
    right;
}
```

Result

As you can see here, the Firefox logo (listed first within `background-image`) is on top, directly above the bubbles graphic, followed by the gradient (listed last) sitting underneath all previous 'images'. Each subsequent sub-property (`background-repeat` and `background-position`) applies to the corresponding backgrounds. So the first listed value for `background-repeat` applies to the first (frontmost) background, and so forth.

Value repetition for multiple backgrounds

When using multiple backgrounds, if a background-related property is given fewer comma-separated values than the number of background layers, the user agent repeats the list of values until there are enough values for all layers.

For example:

```
.element {
  background-image: url("a.png"), url("b.png"), url("c.png");
  background-position: left top;
}
```

This is equivalent to:

```
.element {
  background-position:
    left top,
    left top,
    left top;
}
```

CSS basic user interface

The **CSS basic user interface** module allows you to define the rendering and functionality of features related to the user interface, including outline properties, visual feedback for pointing devices and keyboards, and modifying the default appearance of UI widgets.

Basic user interface properties can be used to improve user experience and accessibility by providing visual cues to elements that are being interacted with, including styling mouse cursors and keyboard directional focus navigation, and styling caret cursors when an editable element has focus. The module includes features for providing outlines to focused (or unfocused) elements without impacting an element's box model dimensions and styling. This UI module also enables the styling of user interface controls.

Basic user interface in action

To view how basic user interface properties can alter the appearance of UI features, interact with the elements in this sample. Note that some features in this sample improve usability while others harm user experience.

```
<div><span contenteditable>Edit this text </span></div>
<fieldset>
  <legend>Play with these fake form controls</legend>
  <input type="checkbox" id="check" />
  <input type="radio" name="a" />
  <input type="radio" name="a" />
  <input type="range" />
  <progress></progress>
</fieldset>
<fieldset>
  <legend>Be careful not to ruin usability: try resizing these.</legend>
  <textarea>
  cursor: wait;
  </textarea>
  <textarea>
  resize: none;
  </textarea>
  <textarea>
  pointer-events: none;
  </textarea>
</fieldset>
```

```
body {
  font-family: sans-serif;
  font-size: 1.25rem;
}
[contenteditable] {
  cursor: copy;
  caret-color: magenta;
  border: 1px solid #cccccc;
}
:focus {
  outline: dashed magenta 3px;
  outline-offset: 10px;
}
* {
  accent-color: magenta;
}
div,
fieldset {
  margin: 20px;
}
textarea:nth-of-type(1) {
  cursor: wait;
}
textarea:nth-of-type(2) {
  resize: none;
}
textarea:nth-of-type(3) {
  pointer-events: none;
}
```

The CSS `outline` and `outline-offset` properties were used to provide feedback to users on which element currently has focus. An `accent-color` provides a theme color to all the form controls. The caret that appears when the text is edited has the same color thanks to the `caret-color` property. These can all be considered UI improvements.

Some features harm usability. The `cursor` property was used to change cursors from the browser default, which is confusing. The `resize` property prevents the second `<textarea>` from being resizable while the `pointer-events` property prevents the third `<textarea>` from receiving click events. It is still focusable using the keyboard.

Click "Play" in the example above to see or edit the code for the animation in the MDN Playground.

Reference

Properties

- `accent-color`
- `appearance`
- `caret-animation`
- `caret-color`
- `caret-shape`
- `cursor`
- `interest-delay`, shorthand for:
  - `interest-delay-start`
  - `interest-delay-end`
- `outline`, shorthand for:
  - `outline-color`
  - `outline-style`
  - `outline-width`
- `outline-offset`

- `pointer-events`
- `resize`
- `user-select`

The CSS basic user interface module also defines the `caret`, `nav-down`, `nav-left`, `nav-right`, and `nav-up` properties. Currently, no browsers support these features.

CSS borders and box decorations

The **CSS borders and box decorations** module provides properties for adding borders, shaped corners, and box shadows to elements. This module extends borders and box decorations introduced in the CSS backgrounds and borders module, adding `corner-shape` and `border-shape` properties, logical `border-radius` properties, longhand properties for the `box-shadow` property, and properties to create partial borders.

Borders and box decorations in action

Select a `superellipse()` value from the dropdown menu to change the border shape. Use the slider to change the border radius size. Toggle the checkbox to hide and show the box shadow.

```
<p>
  <label for="corner-shape-choice"
    >Choose a <code>superellipse()</code> value:</label
  >
  <select id="corner-shape-choice">
    <option>superellipse(infinity)</option>
    <option>superellipse(5)</option>
    <option>superellipse(3)</option>
    <option>superellipse(2)</option>
    <option>superellipse(1.5)</option>
    <option>superellipse(1)</option>
    <option>superellipse(0.5)</option>
    <option>superellipse(0)</option>
    <option>superellipse(-0.5)</option>
    <option selected>superellipse(-1)</option>
    <option>superellipse(-1.5)</option>
    <option>superellipse(-2)</option>
    <option>superellipse(-3)</option>
    <option>superellipse(-5)</option>
    <option>superellipse(-infinity)</option>
  </select>
</p>
<p>
  <label for="radius">Choose a <code>border-radius</code> value:</label>
  <input
    type="range"
    step="5"
    min="0"
    max="100"
    value="30"
    id="radius"
    list="tens" />
  <datalist id="tens">
    <option value="0" label="0"></option>
    <option value="20" label="20px"></option>
    <option value="40" label="40px"></option>
    <option value="60" label="60px"></option>
    <option value="80" label="80px"></option>
    <option value="100" label="100px"></option>
  </datalist>
</p>

<p>
  <input type="checkbox" id="check" />
  <label for="check">Toggle the box-shadow</label>
</p>
<div></div>
```

```
div {
  width: 100%;
  height: 200px;
  background-color: plum;
  background-image:
    repeating-linear-gradient(transparent 0 19px, #00000022 19px 20px),
    repeating-linear-gradient(to left, transparent 0 19px, #00000022 19px 20px);
}

div {
  box-shadow: 3px 3px 5px rgb(0 0 0 / 0.5);
  border-radius: 30px;
}
body:has(input:checked) div {
  box-shadow: none;
}

@layer page-setup {
  html {
    font-family: "Helvetica", "Arial", sans-serif;
  }
```

```
  body {
    max-width: 600px;
    min-width: fit-content;
    margin: 20px auto;
  }
  div {
    display: flex;
    justify-content: center;
    align-items: center;
    margin-top: 20px;
  }
  select {
    padding: 3px 5px;
  }
  code {
    font-weight: bolder;
  }
}
```

```
const rectangle = document.querySelector("div");
const select = document.querySelector("select");
const range = document.getElementById("radius");

function setCornerShape() {
  rectangle.style.cornerShape = select.value;
  rectangle.style.borderRadius = `${range.value}px`;
  rectangle.innerHTML = `<pre>div {
  corner-shape: ${select.value};
  border-radius: ${range.value}px;
}</pre>`;
}

select.addEventListener("change", setCornerShape);
range.addEventListener("input", setCornerShape);
setCornerShape();
```

Creating an irregular nav menu with border-shape

The CSS `border-shape` property can be applied to elements to create precisely-shaped containers such as speech bubbles, abstract tooltip designs, and more, enabling many new creative ideas to be put into production without the need for workarounds or hacks. You can learn all about the property and see basic examples in action on the property reference page.

In this guide, we show you how to use `border-shape` to create an irregular animated navigation menu with each nav item shaped like a jigsaw piece.

Defining the nav menu markup

Our HTML is fairly typical for a navigation menu — a list of links.

```
<ul>
  <li><a href="#">One</a></li>
  <li><a href="#">Two</a></li>
  <li><a href="#">Three</a></li>
  <li><a href="#">Four</a></li>
</ul>
```

Setting the basic page styles

The basic page setup styles are as follows. We apply some rudimentary font styles, use `height` to cause the `<body>` to fill the viewport, and use flexbox to place the nav menu in the center of the screen.

```
* {
  box-sizing: border-box;
}

html {
  height: 100%;
  font-family: "Helvetica", "Arial";
  font-size: 1.2rem;
}

body {
  margin: 0;
  height: inherit;
  display: flex;
  justify-content: center;
  align-items: center;
}
```

Applying the general nav styles

First, we style the `<ul>` by removing the default `list-style-type` and `padding` and setting a `display` value of `flex` to lay out the contained `<li>` elements in a row. We then set a `gap` value of `0` and apply a `transition`, so that when the `<ul>` state changes, a change in the `gap` value animates smoothly.

```
ul {
  list-style-type: none;
  padding: 0;
  display: flex;
  gap: 0;
  transition: gap 0.6s;
}
```

Next, we style the `<li>` elements. We want each nav item to be square, so we set an equal `width` and `height`.

```
li {
  width: 160px;
  height: 160px;
}
```

Next, we style the `<a>` elements inside the list items. We start by removing the default `text-decoration` and setting the `color` to `black`. We then set a `width` and `height` of `100%` to make the `<a>` elements fill the full area of the `<li>` elements, then use flexbox to center their text horizontally and vertically.

We then set `box-shadow` and `text-shadow` properties on the links, plus a `transition` so that any property value changes are animated smoothly when the element's state changes.

```
a {
  text-decoration: none;
  color: black;
  width: 100%;
  height: 100%;
  display: flex;
  justify-content: center;
  align-items: center;

  box-shadow:
    2px 0px 2px rgb(0 0 0 / 0.5),
    inset 3px 3px 3px rgb(255 255 255 / 0.5);
  text-shadow: 1px 1px 1px rgb(0 0 0 / 0.5);
  transition: all 0.6s;
}
```

We then give each jigsaw piece a different color:

```
li:nth-child(1) a {
  background-color: #2de1fc;
}

li:nth-child(2) a {
  background-color: #2afc98;
}

li:nth-child(3) a {
  background-color: #09e85e;
}

li:nth-child(4) a {
  background-color: #16c172;
}
```

Handling the border shape

Now it's time to set the `border-shape` for each nav item to get the jigsaw piece look we are after. For variety, we've shaped each odd-numbered `<a>` element like a downwards-pointing jigsaw-piece, and each even-numbered `<a>` element like an upwards-pointing jigsaw-piece:

```
li:nth-child(even) a {
  border-shape: shape(
      from 0% 0%,
      hline to 33%,
      arc by 33% 0% of 16% 20% small cw,
      hline to 100%,
      line to 100% 33%,
      arc by 0% 33% of 20% 16% small cw,
      line to 100% 100%,
      hline to 66%,
      arc by -33% 0% of 16% 20% small ccw,
      hline to 0%,
      line to 0% 66%,
      arc by 0% -33% of 20% 16% small ccw,
      close
    )
    content-box;
}

li:nth-child(odd) a {
  border-shape: shape(
      from 0% 0%,
      hline to 33%,
      arc by 33% 0% of 16% 20% small ccw,
      hline to 100%,
      line to 100% 33%,
      arc by 0% 33% of 20% 16% small cw,
      line to 100% 100%,
      hline to 66%,
      arc by -33% 0% of 16% 20% small cw,
      hline to 0%,
      line to 0% 66%,
      arc by 0% -33% of 20% 16% small ccw,
      close
    )
    content-box;
}
```

This immediately creates an issue — the notches on the jigsaw pieces that extend out from the original `<a>` area aren't filled by the `<a>` elements' background colors.

There is a solution to this problem. We've deliberately included the `content-box` `<geometry-box>` value after each `shape()` function in the previous two rules. This means the shapes will be drawn relative to the elements' content boxes, and any applied `padding` won't be set inside the shape. Instead, the padding will be placed outside the shape, causing it to get smaller and forcing the background color to fill up the notches.

The required `padding` is set like so:

```
a {
  padding: 24px;
}
```

> **Note:** You can see what the background problem looks like by inspecting the live example in your browser's developer tools and disabling the `padding` applied to the `<a>` elements.

The `padding` causes the jigsaw pieces to get smaller, so there are gaps between them. We want them to touch initially, so we set a large negative `margin-right` value on each list item to bring them together:

```
li {
  margin-right: -47px;
}
```

A side-effect of this `margin-right` setting is that all of the `<li>` items are moved to the right, so the nav menu is no longer horizontally centered. To fix this, we use relative positioning to move the `<ul>` back to the left:

```
ul {
  position: relative;
  right: 23.5px;
}
```

Finally, we apply some style updates on `:hover` and `:focus` that, when combined with the `transition` properties we set earlier, produce some animated effects on interaction with the nav items. We increase the `gap` set on the `<ul>` flexbox layout when it is hovered over or focused. To handle the focus state, we use the `:has` pseudo-class to select the entire `<ul>` when any `<a>` inside it is focused.

```
ul:hover,
ul:has(a:focus) {
  gap: 30px;
}
```

We then set an increased `brightness` `filter`, `scale` factor, and outer `box-shadow` on the `<a>` elements themselves when they are hovered over or focused, making them appear brighter and raised up on interaction.

```
a:hover,
a:focus {
  filter: brightness(1.2);
  scale: 1.1;
  box-shadow:
    5px 0px 10px rgb(0 0 0 / 0.5),
    inset 3px 3px 3px rgb(255 255 255 / 0.5);
}
```

Result

Hover over or focus the nav items to see the animated effects. Note how naturally the different applied effects work with the `border-shape` values.

```
@supports not (border-shape: circle(50%)) {
  body::before {
    content: "Your browser does not support the 'border-shape' property.";
    font-family: sans-serif;
    background-color: wheat;
    padding: 1rem 0;
```

```
    text-align: center;

    z-index: 1;
    position: fixed;
    inset: 40% 0 auto;
  }
}
```

CSS box alignment

The **CSS box alignment** module specifies CSS features relating to the alignment of boxes within their containers. It defines the alignment of the various CSS box layout models including block layout, table layout, flexible box layout (flexbox), and grid layout, creating a consistent alignment method across all of CSS.

The module details alignment terminology, enabling alignment properties to be used in multiple layout modules, rather than limited to a particular layout method.

Alignment is linked to writing modes in that when we align an item we do not consider whether we are aligning it to the physical dimensions of top, right, bottom, and left. Instead, we describe alignment in terms of the start and end of the particular dimension we are working with. This ensures that alignment works in the same way whichever writing mode the document has.

The alignment of text and inline-level content is defined in CSS text module and CSS inline module, respectively.

Box alignment for block, absolutely positioned, and table layouts

The CSS box alignment module details how alignment works in various layout methods. In this guide, we explore how box alignment works in the context of block layout, including floated, positioned, and table elements. As this guide aims to detail things which are specific to block layout and box alignment, it should be read in conjunction with the box alignment guide, which details the common features of box alignment across layout methods.

align-content and justify-content

The `justify-content` property does not apply to block containers or table cells.

The `align-content` property applies to the block axis in order to align the contents of the box within its container. If a content distribution method such as `space-between`, `space-around` or `space-evenly` is requested then the fallback alignment will be used, as the content is treated as a single alignment subject.

justify-self

The `justify-self` property is used to align an item inside its containing block on the inline axis.

This property does not apply to floated elements or table cells.

align-self

The `align-self` property does not apply to block-level boxes (including floats), because there is more than one item in the block axis. It also does not apply to table cells.

Absolutely positioned elements

The alignment container is the positioned block, accounting for the offset values of top, left, bottom, and right. The normal keyword resolves to `stretch`, unless the positioned item is a replaced element, in which case it resolves to `start`.

Aligning in these layout methods today

As we do not currently have browser support for box alignment in block layout, your options for alignment are either to use one of the existing alignment methods or, to make even a single item inside a container a flex item in order to use the alignment properties as specified in flexbox.

Alignment of blocks horizontally prior to flexbox was typically achieved by way of setting auto margins on the block. A `margin` of `auto` will absorb all available space in that dimension, therefore setting a left and right margin of auto, you can push a block into the center:

```
.container {
  width: 20em;
  margin-left: auto;
  margin-right: auto;
}
```

In table layout, you have access to the `vertical-align` property to align the contents of a cell inside that cell.

For many use cases, turning the block container into a flex item will give you the alignment capability that you are looking for. In the example below, a container with a single item inside has been turned into a flex container for the purpose of being able to use the alignment properties.

```
<div class="box">
  <div></div>
</div>
```

```
.box {
  height: 300px;
  border: 2px dotted rgb(96 139 168);
}

.box > * {
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
  background-color: rgb(96 139 168 / 0.2);
}
.box {
  display: flex;
  align-items: center;
  justify-content: center;
}

.box div {
  width: 100px;
  height: 100px;
}
```

Box alignment in flexbox

The box alignment module details how alignment works in various layout methods. In this guide, we explore how box alignment works in the context of flexbox. As this guide aims to detail things which are specific to flexbox and box alignment, it should be read in conjunction with the box alignment overview guide, which details the common features of box alignment across layout methods.

Basic example

In this flexbox example, three flex items are aligned on the main axis using `justify-content` and on the cross axis using `align-items`. The first item overrides the `align-items` values set on the group by setting `align-self` to `center`.

```
body {
  font-family: sans-serif;
}
.box > * {
  padding: 20px;
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
  background-color: rgb(96 139 168 / 0.2);
}
```

```
<div class="box">
  <div>One</div>
  <div>Two</div>
  <div>Three <br />has <br />extra <br />text</div>
</div>
```

```
.box {
  display: flex;
  align-items: flex-start;
  justify-content: space-between;
  border: 2px dotted rgb(96 139 168);
}

.box :first-child {
  align-self: center;
}
```

The axes and flex-direction

Flexbox respects the writing mode of the document, therefore if you are working in English and set `justify-content` to `flex-end` this will align the items to the end of the flex container. If you are working with `flex-direction` set to `row`, this alignment will be in the inline direction.

However, in flexbox you can change the main axis by setting `flex-direction` to `column`. In this case, `justify-content` will align items in the block direction. Therefore it is easiest to think about the main and cross axis when working in flexbox like so:

- The main axis = direction set by `flex-direction` = alignment via `justify-content`
- The cross axis = runs across the main axis = alignment via `align-content`, `align-self`/`align-items`

Main Axis Alignment

- `justify-content`

Cross Axis Alignment

- `align-self`
- `align-items`
- `align-content`

There is no justify-self in flexbox

On the main axis, Flexbox deals with the flex items as a group. The amount of space required to lay out the items is calculated, and the leftover space is then available for distribution. The `justify-content` property controls how that leftover space is used. Set `justify-content: flex-end` and the extra space is placed before the items, `justify-content: space-around` and it is placed either side of the item in that dimension, etc.

This means that a `justify-self` property does not make sense in flexbox as we are always dealing with moving the entire group of items around.

On the cross axis `align-self` makes sense as we potentially have additional space in the flex container in that dimension, in which a single item can be moved to the start and end.

Alignment and auto margins

There is a specific use case in flexbox where we might think that a `justify-self` property is what we need, and this is when we want to split a set of flex items, perhaps to create a split navigation pattern. For this use case, we can use an `auto` margin. A margin set to `auto` will absorb all available space in its dimension. This is how centering a block with auto margins works. By setting the left and right margin to `auto`, both sides of our block try to take up all of the available space and so push the box into the center.

By setting a `margin` of `auto` on one item in a set of flex items all aligned to start, we can create a split navigation. This works well with flexbox and the alignment properties. As soon as there is no space available for the auto margin, the item behaves in the same way as all the other flex items and shrinks to try to fit into space.

```
<div class="box">
  <div>One</div>
  <div>Two</div>
  <div>Three</div>
  <div class="push">Four</div>
  <div>Five</div>
</div>
```

```
.box {
  display: flex;
  border: 2px dotted rgb(96 139 168);
}
.push {
  margin-left: auto;
}
```

The <code>gap</code> properties

- `row-gap`
- `column-gap`
- `gap`

Creating fixed size gaps between items

On the main axis, the `column-gap` property creates fixed size gaps between adjacent items.

On the cross axis the `row-gap` property creates spacing between adjacent flex lines, therefore `flex-wrap` must also be set to `wrap` for this to have any effect.

```
<div class="box">
  <div>One</div>
  <div>Two</div>
  <div>Three</div>
  <div>Four</div>
  <div>Five</div>
  <div>Six</div>
</div>
```

```
.box {
  width: 450px;
  display: flex;
  flex-wrap: wrap;
  row-gap: 10px;
  column-gap: 2em;
  border: 2px dotted rgb(96 139 168);
}

.box > * {
  flex: 1;
}
```

Box alignment in grid layout

The CSS box alignment module details how alignment works in various layout methods. On this page, we explore how box alignment works in the context of CSS grid layout.

As this guide aims to detail things which are specific to CSS grid layout and Box Alignment, it should be read in conjunction with the box alignment overview guide, which details the common features of box alignment across layout methods.

Basic example

In this example using grid layout, there is extra space in the grid container after laying out the fixed-width tracks on the inline main axis. This space is distributed using `justify-content`. On the block cross axis the alignment of the items inside their grid areas is controlled with `align-items`. The first item overrides the `align-items` value set on the group by setting `align-self` to `center`.

```
<div class="box">
  <div>One</div>
  <div>Two</div>
  <div>Three <br />has <br />extra <br />text</div>
  <div>Four</div>
  <div>Five</div>
  <div>Six</div>
</div>
```

```
body {
  font-family: sans-serif;
}
.box > * {
  padding: 20px;
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
  background-color: rgb(96 139 168 / 0.2);
}
```

```
.box {
  display: grid;
  grid-template-columns: 120px 120px 120px;
  align-items: start;
  justify-content: space-between;
  border: 2px dotted rgb(96 139 168);
}

.box :first-child {
  align-self: center;
}
```

Grid axes

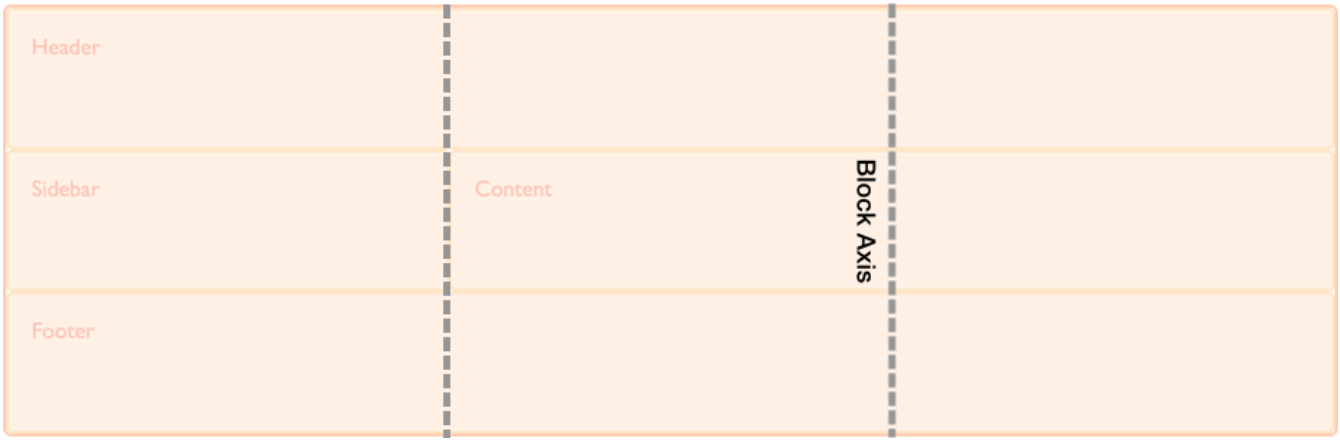
As a two-dimensional layout method, when working with grid layout we always have two axes on which to align our items. We have access to all of the box alignment properties to help us achieve this.

The inline axis is the axis that corresponds to the direction that words in a sentence would run in the writing mode used. Therefore, in a horizontal language such as English or Arabic, the inline direction runs horizontally. Should you be in a vertical writing mode, the inline axis will run vertically.

To align things on the inline axis you use the properties that start with `justify-`: `justify-content`, `justify-items` and `justify-self`.

The block axis crosses the inline axis in the direction that blocks are displayed down the page — for example, paragraphs in English are displayed one below the other vertically. This is the block dimension.

To align things on the block axis you use the properties that start with `align-`, `align-content`, `align-items` and `align-self`.



Self alignment

These properties deal with aligning the item inside the grid area it is placed into:

- `justify-self`
- `align-self`
- `place-self`
- `justify-items`
- `align-items`
- `place-items`

The `*-items` properties, `align-items` and `justify-items`, are applied to the grid container and set alignment for all grid items as a group. The `*-self` properties, `align-self` and `justify-self`, are instead set on grid items. This means that you can set alignment on all grid items, and then override any items that need a different alignment by applying the `align-self` or `justify-self` property to the rules for the individual grid items.

The initial value for `align-items` and `justify-items` is `stretch`, and the initial value for `align-self` and `justify-self` is `auto`, so the item will stretch over the entire grid area. The exception to this rule is where the item has an intrinsic aspect ratio, for example an image. In this case the item will be aligned to `start` in both dimensions in order that the image is not distorted.

Content alignment

These properties deal with aligning the tracks of the grid when there is extra space to distribute:

- `justify-content`
- `align-content`
- `place-content`

This scenario will occur if the tracks that you have defined total less than the total width of the grid container.

Gap and legacy grid-gap properties

These properties define the spacing between grid items within a grid container:

- `row-gap`
- `column-gap`
- `gap`

The grid specification originally contained the definition for the properties `grid-row-gap`, `grid-column-gap` and `grid-gap`. These have since been moved into the Box Alignment specification and aliased to `row-gap`, `column-gap`, and `gap`. This allows them to be used for other layout methods where a gap between items makes sense.

Box alignment in multi-column layout

The CSS box alignment module details how alignment works in various layout methods; in this guide, we explore how box alignment works in the context of multi-column layout. As this guide aims to detail things that are specific to both modules, it should be read in conjunction with the box alignment overview guide, which details the common features of box alignment across layout methods.

In multi-column layout, the alignment container is the content box of the multicol container. The alignment subject is the column box. The properties which apply to multi-column layouts are detailed below.

align-content and justify-content

The `align-content` property applies to the block axis and `justify-content` to the inline axis. Any spacing added to the columns due to use of space distribution will be added to the gap between the columns, therefore making the gap larger than might be specified by the `column-gap` (or `gap` shorthand) property.

Using a value of `justify-content` other than `normal` or `stretch` will cause column boxes to display at the `column-width` specified on the multicol container, and the remaining space distributed according to the value of `justify-content`.

column-gap

The `column-gap` property was originally specified in the multiple-column layout specification and then later unified with the gap properties for other layout methods in box alignment. While other layout methods treat the initial value of `column-gap` as `0`, multi-column layout treats it as `1em` — you generally want a gap between columns.

CSS box alignment overview

The CSS box alignment module specifies CSS features that relate to the alignment of boxes in the various CSS box layout models. The module aims to create a consistent method of alignment across all of CSS. The CSS box alignment properties provide full horizontal and vertical alignment capabilities.

This guide details the general concepts found in this module. Additional guides provide more information on box alignment in flexbox, grid layout, multiple-column layout, and block, absolutely positioned and table layout. Alignment of text is covered by the CSS text and CSS inline layout modules.

Key concepts and terminology

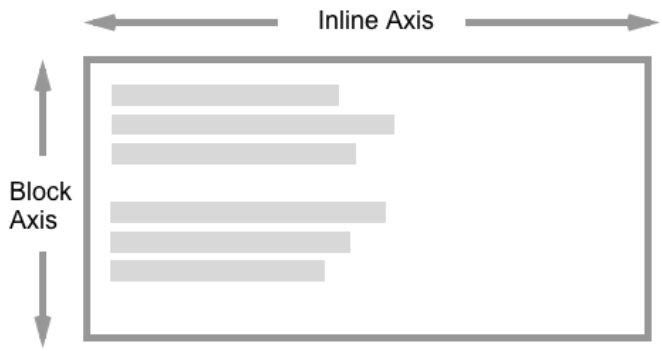
The specification details some alignment terminology to make it easier to discuss these alignment properties outside their implementation within a particular layout method. There are also some key concepts which are common to all layout methods.

Relationship to writing modes

Alignment is linked to writing modes in that when we align an item we do not consider whether we are aligning it to the physical dimensions of top, right, bottom and left. Instead we describe alignment in terms of the start and end of the particular dimension we are working with. This ensures that alignment works in the same way whichever writing mode the document has.

Two dimensions of alignment

When using the box alignment properties you will align content on one of two axes — the inline (or main) axis, and the block (or cross) axis. The inline axis is the axis along which words in a sentence flow in the writing mode being used. For English, for example, the inline axis is horizontal. The block axis is the axis along which blocks, such as paragraph elements, are laid out; it runs across the Inline axis.



When aligning items on the inline axis you will use the properties that begin with `justify-`:

- `justify-items`
- `justify-self`
- `justify-content`

When aligning items on the block axis you will use the properties that begin with `align-`:

- `align-items`
- `align-self`
- `align-content`

Flexbox adds an additional complication in that the above is true when `flex-direction` is set to `row`. The properties are swapped when flexbox is set to `column`. Therefore, when working with flexbox it is generally easier to think about the main and cross axis rather than inline and block. The `justify-` properties are always used to align on the main axis, the `align-` properties on the cross axis.

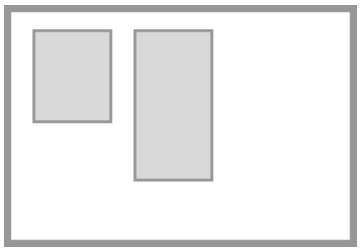
The alignment subject

The **alignment subject** is the thing that is being aligned. For `justify-self` or `align-self`, or when setting these values as a group with `justify-items` or `align-items`, this will be the margin box of the element that this property is being used on. The `justify-content` and `align-content` properties differ per layout method.

The alignment container

The **alignment container** is the box the subject is being aligned inside. This will typically be the alignment subject's containing block. An alignment container may contain one or many alignment subjects.

The below image shows an alignment container with two alignment subjects inside.



Types of alignment

There are three different types of alignment that the specification details; these use keyword values.

- Positional alignment
- Baseline alignment
- Distributed alignment

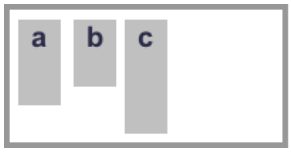
Positional alignment

Positional alignment is the position of an alignment subject with relation to its alignment container. The positional alignment keyword values are defined for positional alignment, and can be used as values for content alignment with `justify-content` and `align-content` and also for self alignment with `justify-self` and `align-self`.

- `center`
- `start`
- `end`
- `self-start`
- `self-end`
- `flex-start` for flexbox only
- `flex-end` for flexbox only
- `left`
- `right`

Other than the physical values of `left` and `right`, which relate to physical attributes of the screen, all of the other values, the `<self-position>` and `<content-position>` values, are logical values and relate to the writing mode of the content.

For example, when working in CSS grid layout, if you are working in English and set `justify-content` to `start` this will move the items in the inline dimension to the start, which will be the left as sentences in English start on the left-hand side of the page. If you were using Arabic, a right-to-left language, then the same value of `start` would result in the items moving to the right, as sentences in Arabic start on the right-hand side of the page.



Both have `justify-content: start`, but the location of the two starts is different because of the writing mode.

Baseline alignment

Baseline alignment is the relationship among the baselines of multiple alignment subjects within an alignment context. The Baseline alignment `<baseline-position>` keywords are used to align the baselines of boxes across a group of alignment subjects. They can be used as values for content alignment with `justify-content` and `align-content` and self-alignment with `justify-self` and `align-self`.

- `baseline`
- `first baseline`
- `last baseline`

Baseline content alignment — specifying a baseline alignment value for `justify-content` or `align-content` — works in layout methods that lay items out in rows. The alignment subjects are baseline aligned against each other by adding padding inside the boxes.

Baseline self-alignment shifts the boxes to align by baseline by adding a margin outside the boxes. Self-alignment is done for singular boxes using `justify-self` or `align-self`, or for groups of boxes using `justify-items` and `align-items`.

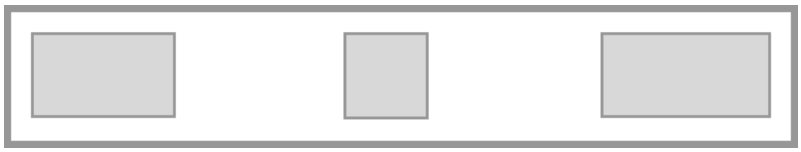
Distributed alignment

Distributed alignment defines alignment as a distribution of space among alignment subjects. The distributed alignment `<content-distribution>` keywords are used with the `align-content` and `justify-content` properties. These keywords define what happens to any additional space after alignment subjects have been displayed. The values are as follows:

- `stretch`
- `space-between`
- `space-around`
- `space-evenly`

For example, in Flex Layout items are aligned with `flex-start` initially. Working in a horizontal top-to-bottom writing mode (with a language such as English), with `flex-direction` set to `row`, the items start on the far left, and any available space after displaying the items is placed after them.

If you set `justify-content: space-between` on the flex container, the available space is now shared out and placed between the items.



For these keywords to take effect, space is required along the dimension in which you wish to align the items. With no space, there is nothing to distribute.

Basic examples

The following examples demonstrate how some of the box alignment properties are applied in Grid and Flexbox.

CSS grid layout alignment example

In this grid layout example, there is extra space in the grid container after laying out the fixed-width tracks on the inline (main) axis. This space is distributed using `justify-content`. On the block (cross) axis, the alignment of the items inside their grid areas is controlled with `align-items`. The first item overrides the `align-items` value set on the group by setting `align-self` to `center`.

```
<div class="box">
  <div>One</div>
  <div>Two</div>
  <div>Three <br />has <br />extra <br />text</div>
  <div>Four</div>
  <div>Five</div>
  <div>Six</div>
</div>
```

```
body {
  font: 1.2em sans-serif;
}

.box {
  border: 2px dotted rgb(96 139 168);
}

.box > * {
  padding: 20px;
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
  background-color: rgb(96 139 168 / 0.2);
}
```

```
.box {
  display: grid;
  grid-template-columns: 120px 120px 120px;
  align-items: start;
  justify-content: space-between;
}

.box :first-child {
  align-self: center;
}
```

Flexbox Alignment Example

In this example, three flex items are aligned on the main axis using `justify-content` and on the cross axis using `align-items`. The first item overrides the `align-items` set on the group by setting `align-self` to `center`.

```
<div class="box">
  <div>One</div>
  <div>Two</div>
  <div>Three <br />has <br />extra <br />text</div>
</div>
```

```
body {
  font: 1.2em sans-serif;
}

.box {
  border: 2px dotted rgb(96 139 168);
}

.box > * {
  padding: 20px;
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
  background-color: rgb(96 139 168 / 0.2);
}
```

```
.box {
  display: flex;
  align-items: flex-start;
  justify-content: space-between;
}

.box :first-child {
  align-self: center;
}
```

Overflow alignment

The `<overflow-position>` keywords `safe` and `unsafe` help define behavior when an alignment subject is larger than the alignment container. The `safe` keyword will align to `start` in the case of a specified alignment causing an overflow, the aim being to avoid "data loss" where part of the item is outside the boundaries of the alignment container and can't be scrolled to.

If you specify `unsafe` then the alignment will be honored even if it would cause such data loss.

Gaps between boxes

The box alignment specification also includes the `gap`, `row-gap`, and `column-gap` properties. These properties enable the setting of a consistent gap between items in a row or column, in any layout method which has items arranged in this way.

The `gap` property is a shorthand for `row-gap` and `column-gap`, which allows us to set these properties at once:

- `row-gap`
- `column-gap`
- `gap`

In the below example, a grid layout uses the `gap` shorthand to set a `10px` gap between row tracks, and a `2em` gap between column tracks.

```
<div class="box">
  <div>One</div>
  <div>Two</div>
  <div>Three</div>
  <div>Four</div>
  <div>Five</div>
  <div>Six</div>
</div>
```

```
body {
  font: 1.2em sans-serif;
}

.box {
  border: 2px dotted rgb(96 139 168);
}

.box > * {
  padding: 20px;
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
  background-color: rgb(96 139 168 / 0.2);
}
```

```
.box {
  display: grid;
  grid-template-columns: 1fr 1fr 1fr;
  gap: 10px 2em;
}

.box :first-child {
  align-self: center;
}
```

Early grid implementations included `gap` properties prefixed with `grid-`. All browsers support the unprefixed properties, though you may see the following properties in a code-base: `grid-row-gap`, `grid-column-gap`, and `grid-gap`. The prefixed versions are aliases of the unprefixed ones.

Be aware that other things may increase the visual gap displayed, for example using the space distribution keywords or adding margins to items.

Box-alignment by layout type

As the CSS box alignment properties are implemented differently depending on the specification they interact with, refer to the following guides for details of how to use the alignment properties with each layout type:

- Box alignment in flexbox
- Box alignment in CSS grid layout
- Box alignment in multiple-column layout
- Box alignment for block, absolutely positioned and table layout

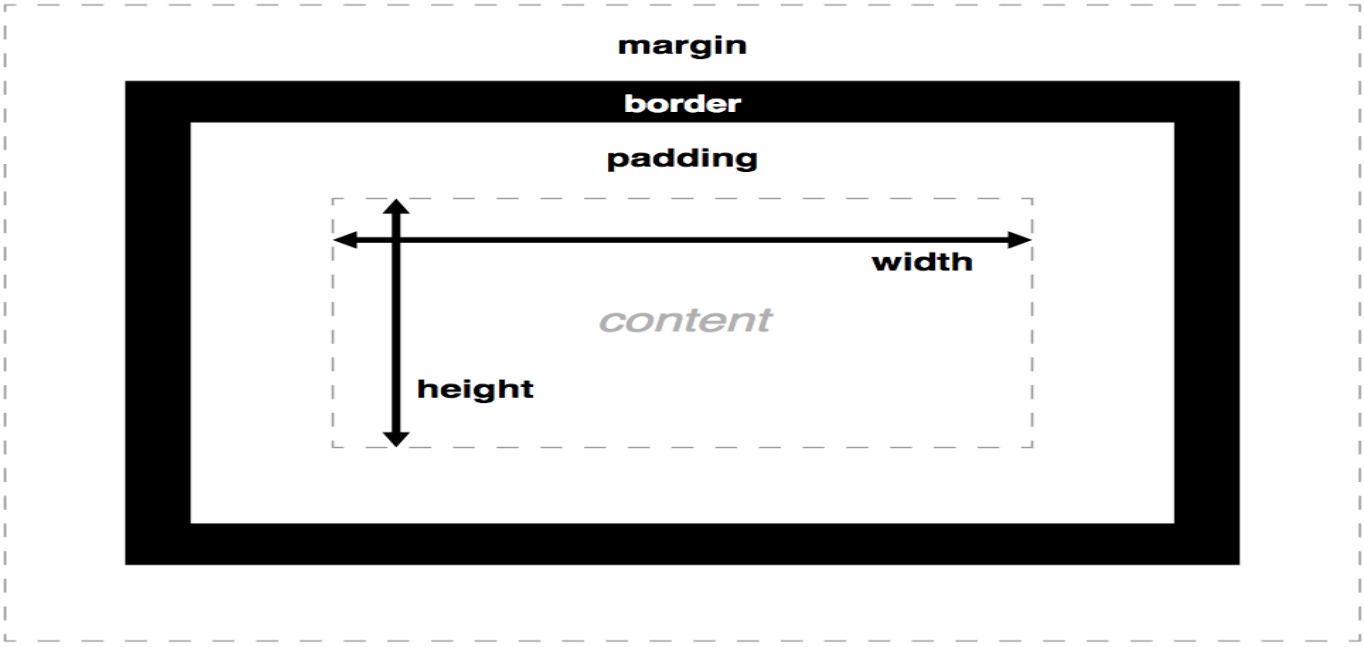
CSS box model

The **CSS box model** module defines the `margin` and `padding` properties, which along with the height, width and border properties, make up the CSS box model.

Every visible element on a webpage is a box laid out according to the visual formatting model. CSS properties define their size, position, and stacking level, with the box model properties (and others) defining the extrinsic size of each box, and the space around them.

Each box has a rectangular content area, inside which any text, images, and other content is displayed. The content may be surrounded by padding, a border, and a margin, on one or more sides. The padding is around the content, the border is around the padding, and the margin sits outside the border. The box model describes how these features — the content, padding, border, and margin — work together to create a box as displayed by CSS.



The CSS box model module defines physical (or "page relative") properties such as `margin-top` and `padding-top`. Flow-relative properties such as `margin-block-start` and `margin-inline-start` (which relate to text direction) are defined in Logical Properties and Values. The box model module is extended by the CSS box sizing module, which introduces the intrinsic size value and enables defining aspect ratio for elements that are auto-sized in at least one dimension.

Introduction to the CSS box model

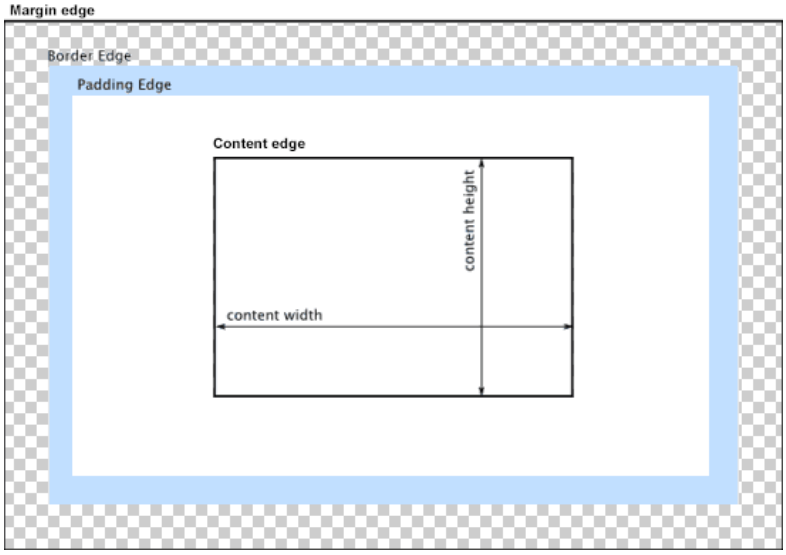
When laying out a document, the browser's rendering engine represents each element as a rectangular box according to the standard **CSS basic box model**. CSS determines the size, position, and properties (color, background, border size, etc.) of these boxes.

Every box is composed of four parts (or *areas*), defined by their respective edges: the *content edge*, *padding edge*, *border edge*, and *margin edge*.



Content area

The **content area**, bounded by the content edge, contains the "real" content of the element, such as text, an image, or a video player. Its dimensions are the *content width* (or *content-box width*) and the *content height* (or *content-box height*). It often has a background color or background image.

If the `box-sizing` property is set to `content-box` (default) and if the element is a block element, the content area's size can be explicitly defined with the `width`, `min-width`, `max-width`, `height`, `min-height`, and `max-height` properties.

Padding area

The **padding area**, bounded by the padding edge, extends the content area to include the element's padding. Its dimensions are the *padding-box width* and the *padding-box height*.

The thickness of the padding is determined by the `padding-top`, `padding-right`, `padding-bottom`, `padding-left`, and shorthand `padding` properties.

Border area

The **border area**, bounded by the border edge, extends the padding area to include the element's borders. Its dimensions are the *border-box width* and the *border-box height*.

The thickness of the borders is determined by the `border-width` and shorthand `border` properties. If the `box-sizing` property is set to `border-box`, the border area's size can be explicitly defined with the `width`, `min-width`, `max-width`, `height`, `min-height`, and `max-height` properties. When there is a background (`background-color` or `background-image`) set on a box, it extends to the outer edge of the border (i.e., extends underneath the border in z-ordering). This default behavior can be altered with the `background-clip` CSS property.

Margin area

The **margin area**, bounded by the margin edge, extends the border area to include an empty area used to separate the element from its neighbors. Its dimensions are the *margin box width* and the *margin box height*.

The size of the margin area is determined by the `margin-top`, `margin-right`, `margin-bottom`, `margin-left`, and shorthand `margin` properties. When margin collapsing occurs, the margin area is not clearly defined since margins are shared between boxes.

Finally, note that for non-replaced inline elements, the amount of space taken up (the contribution to the height of the line) is determined by the `line-height` property, even though the borders and padding are still displayed around the content.

Mastering margin collapsing

The top and bottom margins of blocks are sometimes combined (collapsed) into a single margin whose size is the largest of the individual margins (or just one of them, if they are equal), a behavior known as **margin collapsing**. Note that the margins of floating and absolutely positioned elements never collapse.

Margin collapsing occurs in three basic cases:

Adjacent siblings

> The margins of adjacent siblings are collapsed (except when the latter sibling needs to be cleared past floats).

No content separating parent and descendants

> The vertical margins between a parent block and its descendants can collapse. This happens when there is no separating content between them. Specifically, this occurs in two main cases:
>
> - The `margin-top` of a parent collapses with the `margin-top` of its first in-flow descendant unless the parent has a `border-top` , `padding-top` , contains any inline content (such as text), or has *clearance* applied.
> - The `margin-bottom` of a parent collapses with the `margin-bottom` of its last in-flow descendant unless the parent has a defined `height` or `min-height`, a `border-bottom`, or `padding-bottom`.
>
> In both cases, creating a new block formatting context on the parent will also prevent its margins from collapsing with its children.

Empty blocks

> If there is no border, padding, inline content, `height`, or `min-height` to separate a block's `margin-top` from its `margin-bottom`, then its top and bottom margins collapse.

Some things to note:

- More complex margin collapsing (of more than two margins) occurs when the above cases are combined.
- These rules apply even to margins that are zero, so the margin of a descendant ends up outside its parent (according to the rules above) whether or not the parent's margin is zero.
- When negative margins are involved, the size of the collapsed margin is the sum of the largest positive margin and the smallest (most negative) negative margin.
- When all margins are negative, the size of the collapsed margin is the smallest (most negative) margin. This applies to both adjacent elements and nested elements.
- Collapsing margins is only relevant in the vertical direction.
- Margins don't collapse in a container with `display` set to `flex` or `grid`.

Examples

HTML

```
<p>The bottom margin of this paragraph is collapsed …</p>
<p>
```

```
  … with the top margin of this paragraph, yielding a margin of
  <code>1.2rem</code> in between.
</p>

<div>
  This parent element contains two paragraphs!
  <p>
    This paragraph has a <code>.4rem</code> margin between it and the text
    above.
  </p>
  <p>
    My bottom margin collapses with my parent, yielding a bottom margin of
    <code>2rem</code>.
  </p>
</div>

<p>I am <code>2rem</code> below the element above.</p>
```

CSS

```
div {
  margin: 2rem 0;
  background: lavender;
}

p {
  margin: 0.4rem 0 1.2rem 0;
  background: yellow;
}
```

CSS box sizing

The **CSS box sizing** module enables you to specify how elements fit their content or fit into a particular layout context. It defines sizing, minimum sizing, and maximum sizing properties, and also extends the CSS sizing properties with keywords that represent content-based intrinsic size and context-based extrinsic size.

Elements can either be extrinsically or intrinsically sized. The CSS box model defines page-relative properties to explicitly, or "extrinsically" set an element's size, including `width`, `height`, `padding`, and `margin` properties (along with `border` properties defined in the CSS backgrounds and borders module). This CSS box sizing module extends the CSS box model module to enable an element to be sized intrinsically — setting element size based on the size of its content.

The sizing values introduced in this module allow elements with size containment to take explicit intrinsic sizes, as if their in-flow content's width and height match the specified explicit intrinsic size, rather than being sized as if they were empty.

This module also introduced the ability to define an aspect ratio for an element's box, meaning the browser can automatically adjust an element's dimensions to maintain a specified aspect ratio as long as one of the dimensions is automatically sized.

The logical properties and values module expanded the properties available in the box model and box sizing modules to include writing-mode-relative equivalents of the corresponding physical box model and intrinsic box sizing properties.

Understanding and setting aspect ratios

Every element rendered to the page has a height and a width, and, therefore, an aspect ratio, which is the ratio between the width and height. The natural dimensions of a media object, which are its size without any sizing, scaling, zooming, or borders applied, are known as its natural or intrinsic size. An element's intrinsic size is determined by the element itself, not by applying formatting such as box sizing or setting border, margin, or padding widths.

When developing sites, you often want to be able to set the width of an element to a percentage of the viewport or parent container size and have the height change size proportionally, thereby maintaining a specific aspect ratio depending on the size of the viewport. For replaced elements, like images and videos, maintaining a specific aspect ratio is not only necessary for creating responsive web design, but also a vital component of providing good user experience. Setting an asset's aspect ratio prevents loading jank—the layout shift that occurs when media loads after the page has already been painted, causing a reflow because the space for the asset has not been reserved.

Using CSS, you can adjust the size of replaced and non-replaced elements based on their aspect ratio. In this guide, we will learn about the `aspect-ratio` property, discuss aspect ratios for replaced and non-replaced elements, and then examine some common aspect ratio use cases.

How the <code>aspect-ratio</code> property works

The CSS `aspect-ratio` property value defines the preferred width-to-height ratio of an element's box. The value is either a `<ratio>`, the keyword `auto`, or a space-separated combination of both.

The `<ratio>` is the ratio of the width and height, in that order. It is represented by two positive `<number>` values separated by a forward slash (`/`) or a single `<number>`. When a single number is used, it is the same as writing the ratio as `<number> / 1`, which is also the width divided by the height.

The following values are all equivalent:

```
aspect-ratio: 3 / 6;
aspect-ratio: 1 / 2;
aspect-ratio: 0.5 / 1;
aspect-ratio: 0.5;
```

The following values are also all equivalent:

```
aspect-ratio: 9/6;
aspect-ratio: 3/2;
aspect-ratio: 1.5;
```

```
<div>0.5</div>
<div>1.5</div>
```

```
div {
  height: 121px;
  aspect-ratio: 0.5;
  background-color: pink;
  line-height: 100px;
  text-align: center;
  float: left;
  background-image:
    repeating-linear-gradient(to right, black 0px 1px, transparent 1px 20px),
    repeating-linear-gradient(black 0px 1px, transparent 1px 20px);
  background-size:
    181px 5px,
    5px 121px;
  background-repeat: no-repeat;
}

div + div {
  aspect-ratio: 1.5;
  background-color: lightgreen;
  margin-left: 10px;
}
```

The effect of the `auto` keyword depends on whether the element on which it is applied is a replaced element or not. For replaced elements with an intrinsic aspect ratio, `auto` means the intrinsic aspect ratio should be used. In all other instances, the `auto` value means the box has no preferred aspect ratio. In both cases, this is the default behavior as if no `aspect-ratio` property were applied.

When the value contains both the `auto` keyword and a `<ratio>` value, such as `aspect-ratio: auto 2 / 3;` or `aspect-ratio: 0.75 auto;`, the `auto` value is applied to replaced elements with a natural aspect ratio and the specified ratio of the `width / height` or `<number>` is used as the preferred aspect ratio.

You will have noticed the word "preferred" in the definitions above. The `aspect-ratio` value is not always applied when set. The `aspect-ratio` property sets a "preferred" aspect ratio, so only ever has an effect if at least one of the box's sizes is automatic.

When both the height and width or inline and block sizes are explicitly set, the `aspect-ratio` property value is ignored. In this case, no dimension is allowed to be automatically sized - the preferred sizes are explicitly set - so the `aspect-ratio` property has no effect. When you declare both the inline and block dimensions, those take precedence.

With replaced elements, if you don't explicitly set a value (other than `auto`) to either dimension, both will default to their intrinsic size (any `aspect-ratio` value isn't applied). The `aspect-ratio` will apply to non-replaced elements that don't have a dimension explicitly set, as non-replaced elements are either intrinsically or extrinsically sized, getting their size from their content, container, box model properties, etc.

When an element is rendered to the page, if no CSS is applied and no HTML sizing attributes are included, the user agent will render the object at its natural size.

Adjusting aspect ratios of replaced elements

Replaced elements like `<img>` and `<video>` are replaced with media that have set dimensions and, therefore, an intrinsic aspect ratio. Consider a raster image, such as a JPEG, PNG, or GIF. If you place an image on a page and do not set a height or width, either via `<img>` attributes or with CSS, it will be displayed at its intrinsic size.

```
<img
  src="https://mdn.github.io/shared-assets/images/examples/progress-pride-flag.jpg?image=good"
  alt="220 pixel square pride flag" />
```

This is a `220px` square image with no CSS applied; it is displayed at its intrinsic or default size.

If replaced content is auto-sized or you provide a size for only one dimension, such as setting a value for `width`, the browser will automatically resize the other dimension, in this case, the height, while maintaining the media's original aspect ratio.

In this example, only the `width` is set on the image, so the user agent preserves its aspect ratio. The same image is repeated three times, displayed at different widths: `55px`, `110px`, and at its natural size of `220px` via the `width: auto` value.

```
<img
  src="https://mdn.github.io/shared-assets/images/examples/progress-pride-flag.jpg"
  alt="Pride flag" />
<img
  src="https://mdn.github.io/shared-assets/images/examples/progress-pride-flag.jpg"
  alt="Pride flag" />
<img
  src="https://mdn.github.io/shared-assets/images/examples/progress-pride-flag.jpg"
  alt="Pride flag" />
```

```
img {
  width: 55px;
  margin-right: 5px;
}

img + img {
  width: 110px;
}

img + img + img {
  width: auto;
}
```

Only when you provide sizes for both dimensions is there a risk of distorting the replaced element. For example, setting `width: 100vw;` and `height: 100vh;` on an image creates a variable aspect ratio; the image will appear either stretched or squashed when the viewport's aspect ratio differs from the image's natural aspect ratio.

In this example, the same image is repeated three times, explicitly sized with the same `height` value (`110px`) but different `width` values (`55px`, `110px`, and `220px`).

```
<img
  src="https://mdn.github.io/shared-assets/images/examples/progress-pride-flag.jpg"
  alt="Pride flag" />
<img
  src="https://mdn.github.io/shared-assets/images/examples/progress-pride-flag.jpg"
  alt="Pride flag" />
<img
  src="https://mdn.github.io/shared-assets/images/examples/progress-pride-flag.jpg"
  alt="Pride flag" />
```

```
img {
  width: 55px;
  height: 110px;
}

img + img {
  width: 110px;
}

img + img + img {
  width: 220px;
}
```

We have distorted the images intentionally by setting both a `height` and `width`: we've squashed the first one and stretched the third.

We could have created this same distorted effect using the CSS `aspect-ratio` property, by setting a single dimension (not both or neither) and providing a value other than `1` (or `1 / 1`). You likely don't want to do this, but it's good to know that it's possible.

```
<img
  src="https://mdn.github.io/shared-assets/images/examples/progress-pride-flag.jpg"
  alt="Pride flag" />
```

```
img {
  height: 90vh;
  aspect-ratio: 3;
}
```

We have declared a single dimension; `100vh` is the full height of the example `<iframe>` viewport. For `aspect-ratio` to apply to replaced elements, only one dimension must be set. Setting both or neither doesn't work.

Fitting replaced elements within their containers

To fit a replaced element to the dimensions of its container while maintaining its intrinsic aspect ratio, set the `object-fit` property value to `cover` or `contain`. This will resize the replaced element and either clip it to "cover" the container or display it at a smaller size, fully "contained" within it.

In this example, the square image is placed into a grid of three items, each with an aspect ratio of `5 / 2`.

To begin with, we create a container with three items, each containing one image:

```
<div class="grid">
  <div>
    <img
      src="https://mdn.github.io/shared-assets/images/examples/progress-pride-flag.jpg"
      alt="Pride flag" />
  </div>
  <div>
    <img
      class="cover"
      src="https://mdn.github.io/shared-assets/images/examples/progress-pride-flag.jpg"
      alt="Pride flag" />
  </div>
  <div>
```

```
    <img
      class="contain"
      src="https://mdn.github.io/shared-assets/images/examples/progress-pride-flag.jpg"
      alt="Pride flag" />
  </div>
</div>
```

Next, we designate the container as a grid, where each item has an aspect ratio of `2.5` (`5/2`) with a minimum width of `150px`. Therefore, the minimum height will be `60px`. However, the final width and height are determined by the width of the example's iframe, which will be based on your viewport size:

```
.grid {
  display: grid;
  gap: 20px;
  grid-template-columns: repeat(auto-fill, minmax(150px, 1fr));
  font-size: 0; /* to minimize whitespace */
}

div div {
  aspect-ratio: 5 / 2;
  background-color: #cccccc;
}
```

We then size the images and set the `object-fit` property on the last two images:

```
img {
  height: 100%;
  width: 100%;
}

.cover {
  object-fit: cover;
}

.contain {
  object-fit: contain;
}
```

Only the first image is distorted (stretched). We could have used the `fill` value of `object-fit` to create the same effect. The `cover` image spans the full width of the container, centered vertically, and clipped to fit in the container. The `contain` value ensures the image is contained within the container, centered horizontally, and shrunk to fit.

Defining aspect ratios for non-replaced elements

While the aspect ratio of a replaced element is maintained by default, adjusting the intrinsic size of a non-replaced element usually changes its aspect ratio. For example, identical content may appear as three lines on a widescreen or in a wide parent container, but as eight lines on a narrow screen or container.

In this example, the same quote is displayed in `200px` and `600px` wide containers, and a square is set with a height matching its `200px` width:

```
<p>Narrow:</p>
<blockquote>
  <q
    >When you stop living your life based on what others think of you real life
    begins. At that moment, you will finally see the door of self acceptance
    opened.</q
  >
  - Shannon L. Alder
</blockquote>
<p>Wide:</p>
<blockquote>
  <q
    >When you stop living your life based on what others think of you real life
    begins. At that moment, you will finally see the door of self acceptance
    opened.</q
  >
  - Shannon L. Alder
</blockquote>
<p>Aspect ratio with overflow:</p>
<blockquote>
  <q
    >When you stop living your life based on what others think of you real life
    begins. At that moment, you will finally see the door of self acceptance
    opened.</q
  >
  - Shannon L. Alder
</blockquote>
<p>
  <label
    ><input type="checkbox" checked /> Toggle between
    <code>overflow</code> values <code>auto</code> and
    <code>visible</code></label
  >
</p>
```

To highlight the issue with setting a non-replaced element's aspect ratio via size dimensions, toggle the `overflow` property between `auto` and `visible`.

```
blockquote {
  border: 3px dotted #cccccc;
  padding: 0 3px;
  margin: 20px 0;
  font-size: 1.25rem;
  line-height: 1.5;
}

body:has(:checked) blockquote {
  overflow: auto;
}

:checked + code,
:not(:checked) + code + code {
  outline: 1px solid green;
}
```

```
p:nth-last-of-type(n + 2) {
  font-weight: bold;
}
```

```
blockquote {
  width: 200px;
}

blockquote:nth-of-type(2) {
  width: 600px;
}

blockquote:nth-of-type(3) {
  height: 200px;
}
```

While it's possible to define an aspect ratio on non-replaced elements by setting both the dimensions and hiding overflowing content, the CSS `aspect-ratio` property provides explicit aspect ratio support. This means a specific aspect ratio can be set even when you don't know the content or screen sizes.

In the next example, we render square boxes regardless of the width of the text by setting `aspect ratio: 1` on `<blockquote>`, a non-replaced element:

```
<p>Short text:</p>
<blockquote>Breath.</blockquote>
<p>Longer text:</p>
<blockquote>You're perfect just as you are.</blockquote>
```

```
blockquote {
  inline-size: max-content;
  aspect-ratio: 1;
}
```

```
blockquote {
  border: 1px solid #cccccc;
  padding: 1px;
  margin: 20px 0;
  background-color: #ededed;
}
```

Each box has one dimension defined: the `inline-size`, which is the width in horizontal languages, is set to `max-content`, which sets the size to be as wide as it needs to be to fit the content without wrapping. The second dimension, in this case, the `block-size` or `height`, is set to be the same length as the first dimension. This is accomplished with the `aspect-ratio` property. We defined the desired width-to-height ratio of the element's box to be `1`, which is the same as `1 / 1`, a square. This sets the block direction to match the width of the element, without using the `height` or `block-size` properties.

In these examples, a size was explicitly set on the element itself. When working with non-replaced elements, aspect ratio comes into play when no size dimension is explicitly set.

Creating a circle based on the container size

The inline-size of non-replaced block-level elements is the size of their container's content box. Because they have a size by default, they don't need to have an explicit size set for the `aspect-ratio` property to work.

In this example, we have a container `<div>` that is `200px` wide, which includes `5px` of padding on each side. Therefore, the inline-size of the content box is `190px`. Without setting a height or width on the nested `<p>` element, we know its inline-size is `190px`. With `aspect-ratio: 1` set, the paragraph will be `190px` tall, unless it has visible overflowing content causing it to be taller (which it doesn't).

The height of the `<div>` element is not explicitly set, but it contains the `190px` tall paragraph, the `5px` of padding on top and bottom, and the combined heights of the default top and bottom margins of `<p>`. As a result, it is taller than it is wide. Both elements have a `border-radius` of `50%`, so the container is an oval while the child, with an `aspect-ratio` of `1` but no inline or block sizing explicitly defined, is a circle.

```
<div><p>Hello world</p></div>
```

```
div,
p {
  border-radius: 50%;
}

div {
  width: 200px;
  padding: 5px;
  border: 1px solid black;
  background-color: #66ccff;
}

p {
  aspect-ratio: 1;
  text-align: center;
  border: 10px solid white;
  background-color: #f4aab9;
}
```

To make the `<div>` a circle, we can set the `height` and `width` to the same value, or set `aspect-ratio: 1` and set the `overflow` to `auto` or `hidden`. Alternatively, we can simply remove the margins on the paragraph with `margin-block: 0`. Both these options are shown below.

```
<div><p>Hello world</p></div>
<div><p>Hello world</p></div>
```

```
div {
  width: 200px;
  padding: 5px;
  margin: 1rem;
  border: 1px solid black;
  background-color: #66ccff;
}

p {
  text-align: center;
  border: 10px solid white;
  background-color: #f4aab9;
}
```

```
div,
p {
  aspect-ratio: 1;
  border-radius: 50%;
}

div:first-of-type {
  overflow: hidden;
}

div:last-of-type p {
  margin-block: 0;
}
```

Common <code>aspect-ratio</code> use cases

Let's look at a few situations where you can use `aspect-ratio` to address some common challenges while creating responsive designs.

Making external assets responsive

All content should be responsive, even when that content is third-party embeds, such as videos from TikTok, YouTube, or Instagram. The code snippet you include to embed these external videos generally creates an `<iframe>`.

While a `<video>` element typically adopts the aspect ratio of its media file, `iframe` elements lack this capability. This poses the challenge of ensuring that the `<iframe>` is responsive while always maintaining the aspect ratio of the video it contains. One of the techniques we can use is to set the iframe's width to `100%` of its container or `100vw` to match the viewport width regardless of the viewport's size. However, setting a fixed height might stretch or squash the video. Instead, we set the `aspect-ratio` on the video's container, aligning it to be the same aspect ratio as the video. Problem solved!

For context, the standard aspect ratio of YouTube videos is 16:9 when viewed on a desktop computer or laptop, while TikTok and Instagram videos have a 9:16 aspect ratio.

```
.youtube {
  aspect-ratio: 16/9;
}

.instagram,
.tiktok {
  aspect-ratio: 9/16;
}
```

We can use the `aspect-ratio` feature within the `@media` query alongside the `aspect-ratio` property to adjust the size of both the iframe and the video it contains. This ensures that the video content is always as large as possible - taking up either the full width or height of the viewport, regardless of the viewport size - while maintaining a specific aspect ratio.

We can set the landscape-oriented YouTube videos to be as wide as the viewport and the portrait-oriented TitTok and Instagram video iframes to be as tall as the viewport. If a viewport's aspect ratio is wider than 16:9, we set the YouTube video to be the height of the viewport. If the viewport is narrower than 9:16, we set both Instagram and TikTok videos to the width of the viewport.

```
iframe.youtube {
  aspect-ratio: 16/9;
  width: 100vw;
  height: auto;
}

iframe.instagram,
iframe.tiktok {
  aspect-ratio: 9/16;
  height: 100vh;
  width: auto;
}

/* If the viewport is very wide but not very tall */
@media (aspect-ratio > 16 / 9) {
  iframe.youtube {
    width: auto;
    height: 100vh;
  }
}

/* If the viewport is very tall but not very wide */
@media (aspect-ratio < 9 / 16) {
  iframe.instagram,
  iframe.tiktok {
    height: auto;
    width: 100vw;
  }
}
```

Making grid cells square

A grid of square cells can be created by defining fixed column track sizes, ensuring each row matches the size of the column track. However, when creating responsive grids using `auto-fill` to fit as many column tracks as possible within the container, the width of each item becomes uncertain. This makes it challenging to determine the appropriate height for creating square items.

By setting an aspect ratio on the items, we can ensure when the grid items are laid out, each grid item will be as tall as it is wide, creating square grid items regardless of the container's dimensions.

In this example of square grid items, the grid tracks are auto-sized, taking their size from the items. Each item will be at least `95px` wide but could be much wider. No matter the width, each item will be a square, with the height determined by the `aspect-ratio` to match its width.

```
.grid {
  display: grid;
  grid-template-columns: repeat(auto-fill, minmax(95px, 1fr));
}

.item {
  aspect-ratio: 1;
}
```

```
div {
  gap: 20px;
  font-size: 1.1rem;
}

div div {
```

```
  background-color: #cccccc;
  aspect-ratio: 1;
  counter-increment: items;
}

div div::after {
  content: counter(items);
}

.item::after {
  /*  hide the number if there's content  */
  position: absolute;
  color: transparent;
}
```

```
<div class="grid">
  <div></div>
  <div></div>
  <div class="item">
    This text would overflow the parent, but we've set properties to prevent it
    from doing so.
  </div>
  <div></div>
  <div></div>
  <div></div>
  <div class="item">
    <img
      src="https://mdn.github.io/shared-assets/images/examples/progress-pride-flag.jpg"
      alt="Pride flag" />
  </div>
  <div></div>
  <div></div>
  <div></div>
  <div></div>
  <div></div>
  <div></div>
  <div></div>
  <div></div>
</div>
```

For the content of a grid item to not grow beyond the preferred height set by the `aspect-ratio`, set the `min-height` to `0` and the `overflow` to a value other than `visible`. This will work for intrinsically sized content. If you have content that is intrinsically larger than the available space, set that content to not be larger than the grid item by setting the `max-height` (or `max-width`, depending on the content) to `100%`.

```
.item {
  min-height: 0;
  overflow: auto;
}

.item > * {
  max-height: 100%;
}
```

CSS cascading and inheritance

The **CSS cascading and inheritance** module defines the rules for assigning values to properties by way of cascading and inheritance. This module specifies the rules for finding the specified value for all properties on all elements.

One of the fundamental design principles of CSS is cascading of rules. It allows several style sheets to influence the presentation of a document. CSS property-value declarations define how a document is rendered. Multiple declarations may set different values for the same element and property combination, but only one value can be applied to any CSS property. The CSS cascade module defines how these conflicts are resolved.

The opposite also occurs. Sometimes there are no declarations defining the value of a property. The CSS cascade module defines how these missing values should be set via inheritance or from the property's initial value.

> **Note:** The rules for finding the specified values in the page context and its margin boxes are described in the CSS page module.

Inheritance

In CSS, **inheritance** controls what happens when no value is specified for a property on an element.

CSS properties can be categorized in two types:

- **inherited properties**, which by default are set to the computed value of the parent element
- **non-inherited properties**, which by default are set to initial value of the property

Refer to any CSS property definition to see whether a specific property inherits by default ("Inherited: yes") or not ("Inherited: no").

Inherited properties

When no value for an **inherited property** has been specified on an element, the element gets the computed value of that property on its parent element. Only the root element of the document gets the initial value given in the property's summary.

A typical example of an inherited property is the `color` property. Consider the following style rules and the markup:

```
p {
  color: green;
}
```

```
<p>This paragraph has <em>emphasized text</em> in it.</p>
```

The words "emphasized text" will appear green, since the `em` element has inherited the value of the `color` property from the `p` element. It does *not* get the initial value of the property (which is the color that is used for the root element when the page specifies no color).

Non-inherited properties

When no value for a **non-inherited property** has been specified on an element, the element gets the initial value of that property (as specified in the property's summary).

A typical example of a non-inherited property is the `border` property. Consider the following style rules and the markup:

```
p {
  border: medium solid;
}
```

```
<p>This paragraph has <em>emphasized text</em> in it.</p>
```

The words "emphasized text" will not have another border (since the initial value of `border-style` is `none`).

Notes

The `inherit` keyword allows authors to explicitly specify inheritance. It works on both inherited and non-inherited properties.

You can control inheritance for all properties at once using the `all` shorthand property, which applies its value to all properties. For example:

```
p {
  all: revert;
  font-size: 200%;
  font-weight: bold;
}
```

This reverts the style of the paragraphs' `font` property to the user agent's default unless a user stylesheet exists, in which case that is used instead. Then it doubles the font size and applies a `font-weight` of `"bold"`.

Overriding inheritance, an example

Using our previous example with `border`, if we explicitly set the inheritance with `inherit`, we get the following:

```
p {
  border: medium solid;
}

em {
  border: inherit;
}
```

```
<p>This paragraph has <em>emphasized text</em> in it.</p>
```

We can see here another border around the word "emphasized text".

Introduction to the CSS cascade

The **cascade** is an algorithm that defines how user agents combine property values originating from different sources. The cascade defines the origin and layer that takes precedence when declarations in more than one origin, cascade layer, or `@scope` block set a value for a property on an element.

The cascade lies at the core of CSS, as emphasized by the name: ***Cascading*** Style Sheets. When a selector matches an element, the property value from the origin with the highest precedence gets applied, even if the selector from a lower precedence origin or layer has greater specificity.

This article explains what the cascade is and the order in which CSS declarations cascade, covering cascade layers and origin type. Understanding origin precedence is key to understanding the cascade.

Origin types

The CSS cascade algorithm's job is to select CSS declarations in order to determine the correct values for CSS properties. CSS declarations come from different origin types: **User-agent stylesheets**, **Author stylesheets**, and **User stylesheets**.

Though stylesheets come from these different origins and can be within different layers in each of these origins, they overlap in terms of their default scope; to make this work, the cascade algorithm defines how they interact. Before addressing the interactions, we'll define some key terms in the next few sections.

User-agent stylesheets

User-agents, or browsers, have basic stylesheets that give default styles to any document. These stylesheets are named **user-agent stylesheets**. Most browsers use actual stylesheets for this purpose, while others simulate them in code. The end result is the same.

Some browsers let users modify the user-agent stylesheet, but this is rare and not something that can be controlled.

Although some constraints on user-agent stylesheets are set by the HTML specification, browsers have a lot of latitude: that means some differences exist between browsers. To simplify the development process, Web developers may use a CSS reset stylesheet, such as normalize.css, which sets common properties values to a known state for all browsers before beginning to make alterations to suit their specific needs.

Unless the user-agent stylesheet includes an `!important` next to a property, making it "important", styles declared by author styles, including a reset stylesheet, take precedence over the user-agent styles, regardless of the specificity of the associated selector.

Author stylesheets

Author stylesheets are the most common type of stylesheet; these are the styles written by web developers. These styles can reset user-agent styles, as noted above, and define the styles for the design of a given web page or application. The author, or web developer, defines the styles for the document using one or more linked or imported stylesheets, `<style>` blocks, and inline styles defined with the `style` attribute. These author styles define the look and feel of the website — its theme.

User stylesheets

In most browsers, the user (or reader) of the website can choose to override styles using a custom **user stylesheet** designed to tailor the experience to the user's wishes. Depending on the user agent, user styles can be configured directly or added via browser extensions.

Cascade layers

The cascade order is based on origin type. The cascade within each origin type is based on the declaration order of cascade layers within that type. For all origins - user-agent, author, or user - styles can be declared within or outside of named or anonymous layers. When declared using `layer`, `layer()` or `@layer`, styles are placed into the specified named layer, or into an anonymous layer if no name is provided. Styles declared outside of a layer are treated as being part of an anonymous last declared layer.

Let's take a look at cascading origin type before diving into cascade layers within each origin type.

Cascading order

The cascading algorithm determines how to find the value to apply for each property for each document element. The following steps apply to the cascading algorithm:

1. **Relevance**: It first filters all the rules from the different sources to keep only the rules that apply to a given element. That means rules whose selector matches the given element and which are part of an appropriate `media` at-rule.

2. **Origin and importance**: Then it sorts these rules according to their importance, that is, whether or not they are followed by `!important`, and by their origin. Ignoring layers for the moment, the cascade order is as follows:

Precedence Order (low to high)	Origin	Importance
1	user-agent (browser)	normal
2	user	normal
3	author (developer)	normal
4	CSS keyframe animations	
5	author (developer)	`!important`
6	user	`!important`
7	user-agent (browser)	`!important`
8	CSS transitions	

3. **Specificity**: In case of equality with an origin, the specificity of a rule is considered to choose one value or another. The specificity of the selectors are compared, and the declaration with the highest specificity wins.
4. **Scoping proximity**: When two selectors in the origin layer with precedence have the same specificity, the property value within scoped rules with the smallest number of hops up the DOM hierarchy to the scope root wins. See How `@scope` conflicts are resolved for more details and an example.
5. **Order of appearance**: In the origin with precedence, if there are competing values for a property that are in style block matching selectors of equal specificity and scoping proximity, the last declaration in the style order is applied.

The cascade is in ascending order, meaning:

- Animations take precedence over normal values, whether declared in user, author, or user-agent styles.
- Important values take precedence over animations, whether declared in user, author, or user-agent styles.
- Transitions take precedence over important values.

> **Note: Transitions and animations**
>
> Property values set by animation `@keyframes` are more important than all normal styles (those with no `!important` set).
>
> Property values being set in a `transition` take precedence over all other values set, even those marked with `!important`.

The cascade algorithm is applied *before* the specificity algorithm, meaning if `:root p { color: red;}` is declared in the user stylesheet (row 2) and a less specific `p {color: blue;}` is in the author stylesheet (row 3), the paragraphs will be blue.

Basic example

Before taking a deeper look at how cascade layers impact the cascade, let's look at an example involving multiple sources of CSS across the various origins, and work through the steps of the cascade algorithm:

Here we have a user agent stylesheet, two author stylesheets, and a user stylesheet, with no inline styles within the HTML:

User-agent CSS:

```
li {
  margin-left: 10px;
}
```

Author CSS 1:

```
li {
  margin-left: 0;
} /* This is a reset */
```

Author CSS 2:

```
@media screen {
  li {
    margin-left: 3px;
  }
}

@media print {
  li {
    margin-left: 1px;
  }
}

@layer namedLayer {
  li {
    margin-left: 5px;
  }
}
```

User CSS:

```
.specific {
  margin-left: 1em;
}
```

HTML:

```
<ul>
  <li class="specific">1<sup>st</sup></li>
  <li>2<sup>nd</sup></li>
</ul>
```

In this case, declarations inside `li` and `.specific` rules should apply.

Once again, there are five steps in the cascade algorithm, in order:

1. Relevance
2. Origin and importance
3. Specificity
4. Scoping proximity
5. Order of appearance

The `1px` is for print media. Due to lack of *relevance* based on its media type, it is removed from consideration.

No declaration is marked as `!important`, so the precedence order is author stylesheets over user stylesheets over user-agent stylesheet. Based on *origin and importance*, the `1em` from the user stylesheet and the `10px` from the user-agent stylesheet are removed from consideration.

Note that even though the user style on `.specific` of `1em` has a higher specificity, it's a normal declaration in a user stylesheet. As such, it has a lower precedence than any author styles, and gets removed by the origin and importance step of the algorithm before specificity even comes into play.

There are three declarations in author stylesheets:

```
li {
  margin-left: 0;
} /* from author css 1 */
```

```
@media screen {
  li {
    margin-left: 3px;
  }
}
```

```
@layer namedLayer {
  li {
    margin-left: 5px;
  }
}
```

The last one, the `5px` is part of a cascade layer. Normal declarations in layers have lower precedence than normal styles not in a layer within the same origin type. This is also removed by step 2 of the algorithm, *origin and importance*.

This leaves the `0` and the `3px`, which both have the same selector, hence the same *specificity*. Neither of them are inside a `@scope` block, so scoping proximity does not come into play in this example either.

We then look at *order of appearance*. The second one, the last of the two unlayered author styles, wins.

```
margin-left: 3px;
```

> **Note:** The declaration defined in the user CSS, while it may have greater specificity, is not chosen as the cascade algorithm's *origin and importance* is applied before the *specificity* algorithm. The declaration defined in a cascade layer, though it may come later in the code, will not take precedence either as normal styles in cascade layers have less precedence than normal unlayered styles. *Order of appearance* only matters when both origin, importance, and specificity are equal.

Author styles: inline styles, layers, and precedence

The table in Cascading order provided a precedence order overview. The table summarized the user-agent, user, and author origin type styles in two lines each with "origin type - normal" and "origin type - !important". The precedence within each origin type is more nuanced. Styles can be contained within layers within their origin type, and, with author styles, there is also the issue of where inline styles land in the cascade order.

The order in which layers are declared is important in determining precedence. Normal styles in a layer take precedence over styles declared in prior layers; with normal styles declared outside of any layer taking precedence over normal layered styles regardless of specificity.

In this example, the author used CSS's `@import` rule to import five external stylesheets within a `<style>` information element.

```
<style>
  @import "unlayeredStyles.css";
  @import "AStyles.css" layer(A);
  @import "moreUnlayeredStyles.css";
  @import "BStyles.css" layer(B);
  @import "CStyles.css" layer(C);
  p {
    color: red;
    padding: 1em !important;
  }
</style>
```

and then in the body of the document we have inline styles:

```
<p style="line-height: 1.6em; text-decoration: overline !important;">Hello</p>
```

In the CSS code block above, three cascade layers named "A", "B", and "C", were created, in that order. Three stylesheets were imported directly into layers and two were imported without creating or being assigned to a layer. The "All unlayered styles" in the list below (normal author style precedence - order 4) includes styles from these two stylesheets and the additional unlayered CSS style blocks. In addition, there are two inline styles, a normal `line-height` declaration and an important `text-decoration` declaration:

Precedence Order (low to high)	Author style	Importance
1	A - first layer	normal
2	B - second layer	normal
3	C - last layer	normal
4	All unlayered styles	normal
5	inline `style`	normal
6	animations	
7	All unlayered styles	`!important`
8	C - last layer	`!important`
9	B - second layer	`!important`
10	A - first layer	`!important`

Precedence Order (low to high)	Author style	Importance
11	inline `style`	`!important`
12	transitions	

In all origin types, normal styles contained in layers have the lowest precedence. In our example, the normal styles associated with the first declared layer (A) have lower precedence than normal styles in the second declared layer (B), which have lower precedence than normal styles in the third declared layer (C). These layered styles have lower precedence than all normal unlayered styles, which includes normal styles from `unlayeredStyles.css`, `moreUnlayeredStyles.css`, and the `color` of `p` in the `<style>` itself.

If any layered styles in A, B, or C have selectors with higher specificity matching an element, similar to `:root body p { color: black; }`, it doesn't matter. Those declarations are removed from consideration because of *origin*; normal layered styles have less precedence than normal unlayered styles. If, however, the more specific selector `:root body p { color: black; }` was found in `unlayeredStyles.css`, as both *origin and importance* have the same precedence, *specificity* would mean the more specific, black declaration would win.

The layer order of precedence is inverted for styles declared as `!important`. Important declarations found in a layer take precedence over important declarations found outside of a layer. Important declarations found in the first layer (A) take precedence over important declarations found in layer B, which take precedence over important declarations found in layer C, which take precedence over important declarations found outside of a layer.

Inline styles

Only relevant to author styles are inline styles, declared with the `style` attribute. Normal inline styles take precedence over any other normal author styles, no matter the specificity of the selector. If `line-height: 2;` were declared in a `:root body p` selector block in any of the five imported stylesheets, the line height would still be `1.6`. Normal inline styles do not take precedence over animated or transitioned properties.

Important inline styles take precedence over all other author styles, regardless of whether they are important, inline, or layered. Important inline styles also take precedence over animated properties, but not transitioned properties. Three things can override an important inline style:

- An important user style.
- An important user agent style.
- A transitioned property.

Importance and layers

The origin type precedence order is inverted for important styles. Important styles declared outside of any cascade layer have lower precedence than those declared as part of a layer. Important styles that come in early layers take precedence over important styles declared in subsequent cascade layers.

Take for example the following CSS:

```
p {
  color: red;
}

@layer B {
  :root p {
    color: blue;
  }
}
```

Even though the red is declared first and has a less specific selector, because unlayered CSS takes precedence over layered CSS, the paragraph will be red. Had we included an inline style on the paragraph setting it to a different color, such as `<p style="color: black">`, the paragraph would be black.

When we add `!important` to this bit of CSS, the precedence order is reversed with the stylesheet:

```
p {
  color: red !important;
}

@layer B {
  :root p {
    color: blue !important;
  }
}
```

Now the paragraph will be blue. The `!important` in the earliest declared layer takes precedence over subsequent layers and unlayered important declarations. If the inline style contained `!important`, such as `<p style="color: black !important">`, again the paragraph would be black. Inline importance does take precedence over all other author declared `!important` declarations, no matter the specificity.

> **Note:** The `!important` flag reverses the precedence of cascade layers. For this reason, try not to use `!important` to override external styles. Instead, use `@import` together with the `layer` keyword or `layer()` function to import external stylesheets (from frameworks, widget stylesheets, libraries, etc.) into layers. Importing stylesheets into a layer as the first declaration in your CSS demotes their precedence, and author-defined layers, defined later in your CSS, will have higher precedence. The `!important` flag should only be used sparingly, if ever, to guard required styles against later overrides, in the first declared layer.

Styles that are transitioning take precedence over all important styles, no matter who or how they are declared.

Complete cascade order

Now that we have a better understanding of origin type and cascade layer precedence, we realize the table in Cascading order could have more accurately been represented by the following table:

Precedence Order (low to high)	Style Origin	Importance
1	user-agent - first declared layer	normal
	user-agent - last declared layer	
	user-agent - unlayered styles	
2	user - first declared layer	normal
	user - last declared layer	
	user - unlayered styles	
3	author - first declared layer	normal
	author - last declared layer	
	author - unlayered styles	
	inline `style`	
4	animations	

Precedence Order (low to high)	Style Origin	Importance
5	author - unlayered styles	`!important`
	author - last declared layer	
	author - first declared layer	
	inline `style`	
6	user - unlayered styles	`!important`
	user - last declared layer	
	user - first declared layer	
7	user-agent - unlayered styles	`!important`
	user-agent - last declared layer	
	user-agent - first declared layer	
8	transitions	

Which CSS entities participate in the cascade

Only CSS property/value pair declarations participate in the cascade. CSS at-rule descriptors don't participate in the cascade and HTML presentational attributes are not part of the cascade.

At-rules

CSS at-rules containing entities other than declarations, such as a `@font-face` rule containing *descriptors*, don't participate in the cascade.

For the most part, the properties and descriptors defined in at-rules don't participate in the cascade. Only at-rules as a whole participate in the cascade. For example, within a `@font-face` rule, font names are identified by `font-family` descriptors. If several `@font-face` rules with the same descriptor are defined, only the most appropriate `@font-face`, as a whole, is considered. If more than one are identically appropriate, the entire `@font-face` declarations are compared using steps 1, 2, and 4 of the algorithm (there is no specificity when it comes to at-rules).

While the declarations contained in most at-rules — such as those in `@media`, `@document`, or `@supports` — participate in the cascade, the at-rule may make an entire selector not relevant, as we saw with the print style in the basic example.

Declarations in `@keyframes` don't participate in the cascade. As with `@font-face`, only the `@keyframes` as a whole is selected via the cascade algorithm. The precedence order of animation is described below.

When it comes to `@import`, the `@import` doesn't participate itself in the cascade, but all of the imported styles do participate. If the `@import` defines a named or anonymous layer, the contents of the imported stylesheet are placed into the specified layer. All other CSS imported with `@import` is treated as the last declared layer. This was discussed above.

Finally, `@charset` obeys specific algorithms and isn't affected by the cascade algorithm.

Presentational attributes

Presentational attributes are attributes in the source document that can affect styling. For example, when included, the deprecated `align` attribute sets the alignment on several HTML elements and the `fill` attribute defines the color used to paint SVG shapes and text and defines the final state for SVG animations. While they are author styles, presentational attributes do not participate in the cascade.

If the HTML presentation attribute is supported by the user agent, valid presentational attributes included in HTML and SVG, such as the `align` or `fill` attributes, are translated to the corresponding CSS rules (all SVG presentation attributes are supported as CSS properties) and inserted in the author stylesheet prior to any other styles with a specificity equal to `0`.

Presentational attributes cannot be declared `!important`.

CSS animations and the cascade

CSS animations, using `@keyframes` at-rules, define animations between states. `@keyframes` don't cascade, meaning that at any given time CSS takes values from only one single set of `@keyframes` and never mixes multiple ones. If multiple sets of `@keyframes` are defined with the same animation name, the last defined set in the origin and layer with the greatest precedence is used. Other `@keyframes` are ignored, even if they animate different properties.

```
p {
  animation: infinite 5s alternate repeatedName;
}

@keyframes repeatedName {
  from {
    font-size: 1rem;
  }
  to {
    font-size: 3rem;
  }
}

@layer A {
  @keyframes repeatedName {
    from {
      background-color: yellow;
    }
    to {
      background-color: orange;
    }
  }
}

@layer B {
  @keyframes repeatedName {
    from {
      color: white;
    }
    to {
      color: black;
    }
  }
}
```

In this example, there are three separate animation declaration named `repeatedName`. When `animation: infinite 5s alternate repeatedName` is applied to the paragraph, only one animation is applied: the keyframe animation defined in the unlayered CSS takes precedence over the layered keyframe animation declarations based on origin and layer precedence order. In this example, only the element's font size will be animated.

> **Note:** There are no important animations, as property declarations in a `@keyframes` block that contain `!important` as part of the value are ignored.

Resetting styles

After your content has finished altering styles, it may find itself in a situation where it needs to restore them to a known state. This may happen in cases of animations, theme changes, and so forth. The CSS property `all` lets you quickly set (almost) everything in CSS back to a known state.

`all` lets you opt to immediately restore all properties to any of their initial (default) state, the state inherited from the previous level of the cascade, a specific origin (the user-agent stylesheet, the author stylesheet, or the user stylesheet), or even to clear the values of the properties entirely.

CSS property value processing

For every element in a document tree, the browser assigns a value to every CSS property that applies to that element. The rendered value of each CSS property for a given element or box is the result of a calculation based on stylesheet definitions, inheritance, the cascade, dependencies, unit conversion, and the display environment. This guide provides an overview of the processing steps applied to define how each CSS value is ultimately rendered by exploring key concepts like specified, computed, used, and actual values.

Property values

Every style applied to an element or pseudo-element is based on a single CSS property declaration. Each CSS property has only one value. The value that is applied is determined by the cascaded values of all the declarations of that property that apply to that element or pseudo-element, with the single value applied coming from the property declaration that ranks highest in the cascade sorting order based on the cascade algorithm.

When there are multiple declared values, with multiple declarations, providing the same or different property values for the same element, each property value must still come from a single property name-value pair as only a single value is applied from each property, even if the value is a comma-separated list of values.

To determine which declared value is applied, the user agent gathers and processes all the styles from different sources, such as inline styles, and internal and external stylesheets.

The cascade determines which value should be applied when multiple conflicting styles target the same element. The cascade algorithm defines how user agents combine property values originating from different sources, scopes, and/or layers. When a selector matches an element, the property's declared value from the origin with the highest precedence gets applied, even if a selector from a lower precedence origin or layers has greater specificity.

Certain properties inherit values from their parent elements unless explicitly overridden. Inheritance may occur when no style information exists for a specific property on an element. If the property is inherited, the value is set to the computed value of the parent element. If the property is not inherited, its value is set to the initial value for that element.

After applying the cascading rules and defaulting values step by step, the browser ensures the visual presentation matches the processed CSS.

Processing overview

Before diving into the individual value stages, it's important to understand the three main phases that occur in value processing; filtering, cascading, and defaulting.

Filtering

Filtering is the process of identifying all declarations that apply to each element. A declaration applies to an element only if:

- The declaration belongs to a style sheet that currently applies to this document
- Any conditional rules (like `@media` or `@supports`) that contain the declaration are currently true.
- The declaration belongs to a style rule whose selector matches the element
- The declaration is syntactically valid: the property name is recognized by the browser and the value matches the expected syntax for that property

Only valid declarations become declared values. Declarations with invalid property names or invalid values get filtered out according to CSS error handling rules.

In this example, only the `font-size` and `font-weight` declarations are processed. The CSS parser filters out errors, ignoring or "filtering" out the declaration with the invalid property name:

```
p {
  font-size: 1.25em;
  colr: blue;
  font-weight: bold;
}
```

When filtering is complete, every element has zero or more declared values for every CSS property. These declared values are the starting point for the cascading processing stage.

Cascading

Cascade resolves conflicts when multiple declarations apply to the same property on the same element. Cascade sorts declarations using the cascade sorting order algorithm.

For example, both `font-size` declarations match `<p class="large">CSS is fun!</p>`, but the second declaration gets applied because it has higher specificity. Both declarations have author origin, but the second selector has specificity of `0-1-1` while the first has `0-0-1`:

```
p {
  font-size: 1em;
}

p.large {
  font-size: 1.5em;
}
```

After cascading, the browser determines the **cascaded value** for each property on each element. This is the value used in the next processing stage; defaulting.

Defaulting

Defaulting ensures every property on every element has a value. This involves applying default property values when no CSS declarations explicitly set that property value. This involves:

- Setting **inherited values** for inherited properties
- Setting **initial values** for non-inherited properties

As a result of defaulting, every property is guaranteed to have a specified value.

Note that explicit defaulting keywords (`initial`, `inherit`, `unset`, `revert`, `revert-layer`) are also resolved to their corresponding values to determine the specified value.

Processing stages

All elements that are part of the document's flattened element tree have declared, cascaded, specified, computed, used, and actual values. For a specific property, these values may or may not be the same. For example, if your large code base includes the CSS `p { font-size: 1.25em; }` and your HTML includes `<p class="large">CSS is fun!</p>`, what size will the paragraph be? The `font-size` value moves through a few stages to go from the `em` specified value to the rendered `px` value.

The value processing stages are Declared value, Cascaded value, Specified value, Computed value, Used value, and Actual value. These values are used to determine the final rendered value.

Declared value

A **declared value** is any syntactically valid value from a declaration that applies to an element. An element can have zero or more declared values for each property. These values come from style sheets (author, user, or user-agent) and are identified during the filtering stage.

Continuing our example, in which our stylesheet includes an occurrence of `p { font-size: 1.25em; }` and the document linking to that stylesheet includes `<p class="large">CSS is fun!</p>`, there may be other `font-size` declarations that could potentially apply to the same paragraph. The user-agent stylesheet might set `font-size: 1em` for all paragraphs, while another author declaration sets `font-size: 2em` for elements with class "large":

```
/* User agent styles */
p {
  font-size: 1em;
}

/* author styles */
p {
  font-size: 1.25em;
}

.large {
  font-size: 2em;
}
```

There may be many other `font-size` declarations in our stylesheets, but only declarations whose selectors match the element become declared values. In this example, as our `<p>` element has `class="large"`, all three declarations are declared values for this element.

Cascaded value

The **cascaded value** is the declared value that wins the cascade. There is at most one cascaded value per property per element.

From our declared values, author styles win over user agent styles. Within the same origin, higher specificity styles win over lower specificity styles. In this case, the cascaded value would be `font-size: 2em`, from the author origin with specificity `0-1-1`:

```
font-size: 2em;
```

If there are no declared values for a property, there is no cascaded value, which means the specified value for that property is determined by the defaulting process.

Specified value

The **specified value** is the result of the defaulting process. It is guaranteed to exist for every property on every element. The specified value is determined as follows:

1. If there is a cascaded value, the cascaded value is the specified value.
2. If there is *no* cascaded value and the property is inherited, the specified value is the computed value of the parent element.
3. If there is *no* cascaded value and the property is *not* inherited, the specified value is the property's initial value.

In our example, since we have a cascaded value of `2em`, this becomes the specified value:

```
font-size: 2em;
```

For properties without cascaded values, the defaulting process determines the value. For example, if `color` is not specified, the `color` is inherited from the parent's computed value since it's an inherited property. If `margin` is not specified, the `initial` value of `0` is used as `margin` is not an inherited property:

```
color: inherit;
margin: 0;
```

Initial value

A property's **initial value** is the default value as listed in its definition table in the specification. The initial value is used during defaulting when:

- For inherited properties, the initial value is used on the *root element only*, which has no parent element, when no cascaded value exists.
- For non-inherited properties, the initial value is used on *all elements* when no cascaded value exists.

You can explicitly set the initial value by using the `initial` keyword.

> **Note:** The initial value can be found in the formal syntax section of each CSS property reference page. For example, the initial value of `font-size` is `medium`. The initial value should not be confused with the value specified by the browser's style sheet.

Computed value

The **computed value** of a property is the value transferred from parent to child during inheritance. It is the result after resolving things like relative units and custom properties into absolute values, but before considering layout-specific information.

The computed value is calculated from the specified value by:

1. Handling the special values `inherit`, `initial`, `revert`, `revert-layer`, and `unset`.
2. Doing the computation needed to reach the value described in the "Computed value" line in the property's definition table.

The computation needed to reach a property's computed value typically involves converting relative values (such as those in `em` units or percentages) to absolute values. For example, if an element has specified values `font-size: 16px` and `padding-top: 2em`, then the computed value of `padding-top` is `32px` (double the font size).

However, for some properties (those where percentages are relative to something that may require layout to determine, such as `width`, `margin-right`, `text-indent`, and `top`), percentage-specified values turn into percentage-computed values. Additionally, unitless numbers specified on the `line-height` property become the computed value, as specified. The relative values that remain in the computed value become absolute when the used value is determined.

Used value

The **used value** is the property's value after all calculations have been performed on the computed value and it has been refined with layout-specific details (e.g., percentages resolved to actual pixel values).

Every CSS property has a used value. The used values of dimensions (e.g., `width` or `line-height`) are in pixels. The used values of shorthand properties (e.g., `background`) are consistent with those of their component properties (e.g., `background-color` or `background-size`) and with `position` and `float`.

The used value for the `width` or `inline-size` of an element is a pixel value even if the specified value of the property was set with percentages or keyword values.

If we have three container elements with their width set as `auto`, `50%`, and `inherit`:

```
<div id="no-width">
  <p>No explicit width.</p>
  <p class="show-used-width">..</p>

  <div id="width-50">
    <p>Explicit width: 50%.</p>
    <p class="show-used-width">..</p>

    <div id="width-inherit">
      <p>Explicit width: inherit.</p>
      <p class="show-used-width">..</p>
    </div>
  </div>
</div>
```

```
#no-width {
  width: auto;
}

#width-50 {
  width: 50%;
}

#width-inherit {
  width: inherit;
}

/* Make results easier to see */
div {
  border: 1px solid red;
  padding: 8px;
}
```

```
function updateUsedWidth(id) {
  const div = document.getElementById(id);
  const par = div.querySelector(".show-used-width");
  const wid = window.getComputedStyle(div)["width"];
  par.textContent = `Used width: ${wid}.`;
}

function updateAllUsedWidths() {
  updateUsedWidth("no-width");
  updateUsedWidth("width-50");
  updateUsedWidth("width-inherit");
}

updateAllUsedWidths();
window.addEventListener("resize", updateAllUsedWidths);
```

While the three specified values, `auto`, `50%`, and `inherit`, are keyword and `<percentage>` values, retrieving the `width` using `window.getComputedStyle(el)["width"];` returns an absolute length `px` value:

Change the window size or rotate your mobile device to change the size and the used values.

Rendered values

The rendered value is called the actual value, while the value retrieved via script is called the resolved value.

Actual value

The **actual value** of a property is the used value of that property after any necessary approximations have been applied. It is the final rendered value as implemented by the browser, including adjustments for rendering quirks or limitations. For example, a user agent that can only render borders with a whole-number pixel width may round the thickness of the border to the nearest integer.

The calculation includes these steps:

1. First, the specified value is determined based on the result of cascading, inheritance, or using the initial value.
2. Next, the computed value is calculated according to the specification (for example, a `span` with `position: absolute` will have its computed `display` changed to `block`).
3. Then, layout is calculated, resulting in the used value.
4. Finally, the used value is transformed according to the limitations of the local environment, resulting in the actual value.

Resolved value

The **resolved value** of a property is the value after applying active stylesheets and resolving any basic computation those values may contain. The `getComputedStyle()` method returns a live `CSSStyleDeclaration` object containing the resolved values of all CSS properties applied to a specified element. Each resolved value is either the computed value or the used value, depending on the property.

Historically, `getComputedStyle()` returned the computed value of an element or pseudo-element. As CSS evolved, so did the concept of "computed value", but the values returned by `getComputedStyle()` had to remain the same for backward compatibility with deployed scripts. These values are the "resolved values".

For most properties, the resolved value is the computed value, but for a few legacy properties (including `width` and `height`), it is the used value. The CSSOM specification provides per-property details.

CSS 2.0 defined *computed value* as the last step in a property's calculation. CSS 2.1 introduced the distinct definition of "used value". An element could then explicitly inherit the width/height of its parent, whose computed value is a percentage. For CSS properties that don't depend on layout (e.g., `display`, `font-size`, or `line-height`), the computed values and used values are the same. The following list contains the CSS 2.1 properties that *do* depend on layout, and therefore have a different computed value and used value (taken from CSS 2.1 Changes: Specified, computed, and actual values):

- `background-position`
- `bottom`, `left`, `right`, `top`
- `height`, `width`
- `margin-bottom`, `margin-left`, `margin-right`, `margin-top`
- `min-height`, `min-width`

- `padding-bottom`, `padding-left`, `padding-right`, `padding-top`
- `text-indent`

Shorthand properties

Shorthand properties are CSS properties that let you set the values of multiple other CSS properties in one declaration. Using a shorthand property, you can write more concise (and often more readable) style sheets, saving time and energy.

The CSS specification defines shorthand properties to group the definition of common properties acting on the same theme. For example, the CSS `background` property is a shorthand property that's able to define the values of `background-color`, `background-image`, `background-repeat`, and `background-position`.

Tricky edge cases

There are a few edge cases to keep in mind when using shorthand properties.

Omitting properties

A value which is not specified is set to a default value defined by the shorthand, which may differ from the property's initial value.

That means that it **overrides** previously set values. For example:

```
p {
  background-color: red;
  background: url("images/bg.gif") no-repeat left top;
}
```

This will not set the color of the background to `red` but to the default value for `background-color`, which is `transparent`.

Only the individual properties values can inherit. As missing values are replaced by their initial value, it is impossible to allow inheritance of individual properties by omitting them. The keyword `inherit` can be applied to a property, but only as a whole, not as a keyword for one value or another. That means that the only way to make some specific value to be inherited is to use the longhand property with the keyword `inherit`.

Ordering properties

Shorthand properties try not to force a specific order for the values of the properties they replace. This works well when these properties use values of different types, as the order has no importance, but this does not work as easily when several properties can have identical values.

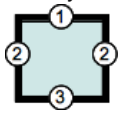
Two important cases here are:

- Properties related to the sides of the box, like `border-style`, `margin` or `padding`
- Properties related to the corners of the box, like `border-radius`

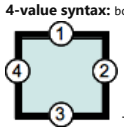
Sides of the box

Shorthands handling properties related to the sides of the box, like `border-style`, `margin` or `padding`, always use a consistent 1-to-4-value syntax representing those sides:

- **1-value syntax:** `border-width: 1em` — A single value represents all sides: 
- **2-value syntax:** `border-width: 1em 2em` — The first value represents the top and bottom sides, and the second value represents the left and right sides: 
- **3-value syntax:** `border-width: 1em 2em 3em` — The first value represents the top side, the second value represents the left and right sides, and the third value represents the bottom side:



- **4-value syntax:** `border-width: 1em 2em 3em 4em` — The four values represent the top, the right, the bottom, and the left sides, respectively, always in that order; that is, clock-wise starting at the top:



The initial letter of Top-Right-Bottom-Left matches the order of the consonant of the word *trouble*: TRBL. You can also remember it as the order that the hands would rotate on a clock: `1em` starts in the 12 o'clock position, then `2em` in the 3 o'clock position, then `3em` in the 6 o'clock position, and `4em` in the 9 o'clock position.

Corners of the box

Similarly, shorthands handling properties related to the corners of the box, like `border-radius`, always use a consistent 1-to-4-value syntax representing those corners:

- **1-value syntax:** `border-radius: 1em` — A single value represents all corners: 
- **2-value syntax:** `border-radius: 1em 2em` — The first value represents the top-left and bottom-right corners, and the second value represents the top-right and bottom-left corners: 
- **3-value syntax:** `border-radius: 1em 2em 3em` — The first value represents the top-left corner, the second value represents the top-right and bottom-left corners, and the third value represents the bottom-right corner: - **4-value syntax:** `border-radius: 1em 2em 3em 4em` — The four values represent the top-left, top-right, bottom-right, and bottom-left corners respectively, always in that order; that is, clock-wise starting at the top-left: 
Background properties

Consider a background with the following properties

```
background-color: black;
background-image: url("images/bg.gif");
background-repeat: no-repeat;
background-position: left top;
```

These four declarations can be shortened to just one:

```
background: black url("images/bg.gif") no-repeat left top;
```

(The shorthand form is actually the equivalent of the longhand properties above plus `background-attachment: scroll` and, in CSS3, some additional properties.)

See `background` for more detailed information, including CSS3 properties.

Font properties

Consider the following declarations:

```
font-style: italic;
font-weight: bold;
font-size: 0.8em;
line-height: 1.2;
font-family: "Arial", sans-serif;
```

These 5 statements can be shortened to the following:

```
font:
  italic bold 0.8em/1.2 "Arial",
  sans-serif;
```

This shorthand declaration is actually equivalent to the longhand declarations above plus `font-variant: normal`, `font-size-adjust: none`, and `font-stretch: normal`.

Border properties

With borders, the width, color, and style can be simplified into one declaration. For example, consider the following CSS:

```
border-width: 1px;
border-style: solid;
border-color: black;
```

It can be simplified as:

```
border: 1px solid black;
```

Margin and padding properties

Shorthand versions of margin and padding values work similarly; the margin property allows for shorthand values to be specified using one, two, three, or four values. Consider the following CSS declarations:

```
margin-top: 10px;
margin-right: 5px;
margin-bottom: 10px;
margin-left: 5px;
```

They are the same as the following declaration using the four value shorthand. Note that the values are in clockwise order, beginning at the top: top, right, bottom, then left (TRBL, the consonants in "trouble").

```
margin: 10px 5px 10px 5px;
```

Margin shorthand rules for one, two, three and four value declarations are:

- When **one** value is specified, it applies the same margin to **all four sides**.
- When **two** values are specified, the first margin applies to the **top and bottom**, the second to the **left and right**.
- When **three** values are specified, the first margin applies to the **top**, the second to the **left and right**, the third to the **bottom**.
- When **four** values are specified, the margins apply to the **top**, **right**, **bottom**, and **left** in that order (clockwise).

Position properties

With position, the shorthand versions of top, right, bottom and left can be simplified into one declaration. For example, consider the following CSS:

```
top: 0;
right: 20px;
bottom: 0;
left: 20px;
```

It can be simplified as:

```
inset: 0 20px 0 20px;
```

Just like margins and paddings, the inset values are ordered clockwise - top, right, bottom, then left (TRBL).

The universal shorthand property

CSS provides a universal shorthand property, `all`, which applies its value to every property in the document. Its purpose is to change the properties' inheritance model.

See Handling conflicts or Introducing the CSS Cascade for more information about how inheritance works in CSS.

Shorthand properties

Specificity

Specificity is the weight that browsers use in the cascade algorithm to determine the CSS declaration that is the most relevant to an element, which in turn, determines the property value to apply to the element. The specificity algorithm calculates this weight from a CSS selector, and compares the resulting values to decide which rule, from competing CSS declarations within the same origin and layer, gets applied to an element.

> **Note:** Browsers consider specificity **after** determining cascade origin and importance. In other words, for competing property declarations, specificity is relevant and compared only between selectors from the one cascade origin and layer that has precedence for the property. Scoping proximity and order of appearance become relevant when the selector specificities of the competing declarations in the cascade layer with precedence are equal.

How is specificity calculated?

Specificity is the weight that is applied to a given CSS declaration. The specificity algorithm calculates that weight based on the number of selectors of each weight category in the selector matching the element (or pseudo-element). If there are two or more declarations providing different property values for the same element, the declaration value in the style block having the matching selector with the greatest weight gets applied.

The specificity value is basically a three-column value of three categories or weights - ID, CLASS, and TYPE - corresponding to the three types of selectors. The value represents the count of selector components in each weight category and is written as *ID - CLASS - TYPE*. The three columns are created by counting the number of selector components for each selector weight category in the selectors that match the element.

Selector weight categories

The selector weight categories are listed here in the order of decreasing specificity:

ID column

> Includes only ID selectors, such as `#example`. For each ID in a matching selector, add 1-0-0 to the weight value.

CLASS column

> Includes class selectors, such as `.myClass`, attribute selectors like `[type="radio"]` and `[lang|="fr"]`, and pseudo-classes, such as `:hover`, `:nth-of-type(3n)`, and `:required`. For each class, attribute selector, or pseudo-class in a matching selector, add 0-1-0 to the weight value.

TYPE column

> Includes type selectors, such as `p`, `h1`, and `td`, and pseudo-elements like `::before`, `::placeholder`, and all other selectors with double-colon notation. For each type or pseudo-element in a matching selector, add 0-0-1 to the weight value.

No value

> The universal selector (`*`) and the pseudo-class `:where()` and its parameters aren't counted when calculating the weight so their value is 0-0-0, but they do match elements. These selectors do not impact the specificity weight value.

Combinators, such as `+`, `>`, `~`, `" "`, and `||`, may make a selector more specific in what is selected but they don't add any value to the specificity weight.

The `&` nesting combinator doesn't add specificity weight, but nested rules do. In terms of specificity, and functionality, nesting is very similar to the `:is()` pseudo-class.

Like nesting, the `:is()`, `:has()`, and negation (`:not()`) pseudo-classes themselves add no weight. The parameters in these selectors, however, do. The specificity weight of each comes from the selector parameter in the list of selectors with the highest specificity. Similarly, with nested selectors, the specificity weight added by the nested selector component is the selector in the comma-separated list of nested selectors with the highest specificity.

The `:not()`, `:is()`, `:has()` and CSS nesting exceptions are discussed below.

Matching selector

The specificity weight comes from the matching selector. Take this CSS selector with three comma-separated selectors as an example:

```
[type="password"],
input:focus,
:root #myApp input:required {
  color: blue;
}
```

The `[type="password"]` selector in the above selector list, with a specificity weight of `0-1-0`, applies the `color: blue` declaration to all password input types.

All inputs, no matter the type, when receiving focus, match the second selector in the list, `input:focus`, with a specificity weight of `0-1-1`; this weight is made up of the `:focus` pseudo-class (0-1-0) and the `input` type (0-0-1). If the password input has focus, it will match `input:focus`, and the specificity weight for the `color: blue` style declaration will be `0-1-1`. When that password doesn't have focus, the specificity weight remains at `0-1-0`.

The specificity for a required input nested in an element with attribute `id="myApp"` is `1-2-1`, based on one ID, two pseudo-classes, and one element type.

If the password input type with `required` is nested in an element with `id="myApp"` set, the specificity weight will be `1-2-1`, based on one ID, two pseudo-classes, and one element type, whether or not it has focus. Why is the specificity weight `1-2-1` rather than `0-1-1` or `0-1-0` in this case? Because the specificity weight comes from the matching selector with the greatest specificity weight. The weight is determined by comparing the values in the three columns, from left to right.

```
[type="password"] {
  /* 0-1-0 */
}
input:focus {
  /* 0-1-1 */
}
:root #myApp input:required {
  /* 1-2-1 */
}
```

Three-column comparison

Once the specificity values of the relevant selectors are determined, the number of selector components in each column is compared, from left to right.

```
#myElement {
  color: green; /* 1-0-0  - WINS!! */
}
.bodyClass .sectionClass .parentClass [id="myElement"] {
  color: yellow; /* 0-4-0 */
}
```

The first column is the value of the *ID* component, which is the number of IDs in each selector. The numbers in the *ID* columns of competing selectors are compared. The selector with the greater value in the *ID* column wins no matter what the values are in the other columns. In the above example, even though the yellow selector has more components in total, only the value of the first column matters.

If the number in the *ID* columns of competing selectors is the same, then the next column, *CLASS*, is compared, as shown below.

```
#myElement {
  color: yellow; /* 1-0-0 */
}
#myApp [id="myElement"] {
  color: green; /* 1-1-0  - WINS!! */
}
```

The *CLASS* column is the count of class names, attribute selectors, and pseudo-classes in the selector. When the *ID* column value is the same, the selector with the greater value in the *CLASS* column wins, no matter the value in the *TYPE* column. This is shown in the example below.

```
:root input {
  color: green; /* 0-1-1 - WINS because CLASS column is greater */
}
html body main input {
  color: yellow; /* 0-0-4 */
}
```

If the numbers in the *CLASS* and *ID* columns in competing selectors are the same, the *TYPE* column becomes relevant. The *TYPE* column is the number of element types and pseudo-elements in the selector. When the first two columns have the same value, the selector with the greater number in the *TYPE* column wins.

If the competing selectors have the same values in all the three columns, the proximity rule comes into play, wherein the last declared style gets precedence.

```
input.myClass {
  color: yellow; /* 0-1-1 */
}
:root input {
  color: green; /* 0-1-1 WINS because it comes later */
}
```

The <code>:is()</code>, <code>:not()</code>, <code>:has()</code> and CSS nesting exceptions

The matches-any pseudo-class `:is()`, the relational pseudo-class `:has()`, and the negation pseudo-class `:not()` are *not* considered as pseudo-classes in the specificity weight calculation. They themselves don't add any weight to the specificity equation. However, the selector parameters passed into the pseudo-class parenthesis are part of the specificity algorithm; the weight of the matches-any and negation pseudo-class in the specificity value calculation is the weight of the parameter's weight.

```
p {
  /* 0-0-1 */
}
:is(p) {
  /* 0-0-1 */
}

h2:nth-last-of-type(n + 2) {
  /* 0-1-1 */
}
h2:has(~ h2) {
  /* 0-0-2 */
}

div.outer p {
  /* 0-1-2 */
}
div:not(.inner) p {
  /* 0-1-2 */
}
```

Note that in the above CSS pairing, the specificity weight provided by the `:is()`, `:has()` and `:not()` pseudo-classes is the value of the selector parameter, not of the pseudo-class.

All three of these pseudo-classes accept complex selector lists, a list of comma-separated selectors, as a parameter. This feature can be used to increase a selector's specificity:

```
:is(p, #fakeId) {
  /* 1-0-0 */
}
h1:has(+ h2, > #fakeId) {
  /* 1-0-1 */
}
p:not(#fakeId) {
  /* 1-0-1 */
}
div:not(.inner, #fakeId) p {
  /* 1-0-2 */
}
```

In the above CSS code block, we have included `#fakeId` in the selectors. This `#fakeId` adds `1-0-0` to the specificity weight of each paragraph.

When creating complex selector lists with CSS nesting this behaves in exactly the same way as the `:is()` pseudo-class.

```
p,
#fakeId {
  span {
    /* 1-0-1 */
  }
}
```

In the above code block the complex selector `p, #fakeId` the specificity is taken from `#fakeId` and also the `span`, so this creates a specificity of `1-0-1` for both `p span` and `#fakeId span`. This is the equivalent specificity as the `:is(p, #fakeId) span` selector.

Generally, you want to keep specificity down to a minimum, but if you need to increase an element's specificity for a particular reason, these three pseudo-classes can help.

```
a:not(#fakeId#fakeId#fakeID) {
  color: blue; /* 3-0-1 */
}
```

In this example, all links will be blue, unless overridden by a link declaration with 3 or more IDs, a color value matching an `a` includes the `!important` flag, or if the link has an inline style color declaration. If you use such a technique, add a comment to explain why the hack was needed.

Inline styles

Inline styles added to an element (e.g., `style="font-weight: bold;"`) always overwrite any normal styles in author stylesheets, and therefore, can be thought of as having the highest specificity. Think of inline styles as having a specificity weight of `1-0-0-0`.

The only way to override inline styles is by using `!important`.

Many JavaScript frameworks and libraries add inline styles. Using `!important` with a very targeted selector, such as an attribute selector using the inline style, is one way to override these inline styles.

```
<p style="color: purple">…</p>
```

```
p[style*="purple"] {
  color: rebeccapurple !important;
}
```

Make sure to include a comment with every inclusion of the important flag so code maintainers understand why a CSS anti-pattern was used.

The <code>!important</code> exception

CSS declarations marked as important override any other declarations within the same cascade layer and origin. Although technically, `!important` has nothing to do with specificity, it interacts directly with specificity and the cascade. It reverses the cascade order of stylesheets.

If declarations from the same origin and cascade layer conflict and one property value has the `!important` flag set, the important declaration is applied no matter the specificity. When conflicting declarations from the same origin and cascade layer with the `!important` flag are applied to the same element, the declaration with a greater specificity is applied.

Using `!important` to override specificity is considered a **bad practice** and should be avoided for this purpose. Understanding and effectively using specificity and the cascade can remove any need for the `!important` flag.

Instead of using `!important` to override foreign CSS (from external libraries, like Bootstrap or normalize.css), import the third-party scripts directly into cascade layers. If you must use `!important` in your CSS, comment your usage so future code maintainers know why the declaration was marked important and know not to override it. But definitely, don't use `!important` when writing plugins or frameworks that other developers will need to incorporate without being able to control.

The <code>:where()</code> exception

The specificity-adjustment pseudo-class `:where()` always has its specificity replaced with zero, `0-0-0`. It enables making CSS selectors very specific in what element is targeted without any increase to specificity.

In creating third-party CSS to be used by developers who don't have access to edit your CSS, it's considered a good practice to create CSS with the lowest possible specificity. For example, if your theme includes the following CSS:

```
:where(#defaultTheme) a {
  /* 0-0-1 */
  color: red;
}
```

Then the developer implementing the widget can easily override the link color using only type selectors.

```
footer a {
  /* 0-0-2 */
  color: blue;
}
```

How <code>@scope</code> blocks affect specificity

Including a ruleset inside a `@scope` block does not affect the specificity of its selector, regardless of the selectors used inside the scope root and limit. However, if you decide to explicitly add the `:scope` pseudo-class, you'll need to factor it in when calculating their specificity. `:scope`, like all regular pseudo-classes, has a specificity of 0-1-0. For example:

```
@scope (.article-body) {
  /* :scope img has a specificity of 0-1-0 + 0-0-1 = 0-1-1 */
  :scope img {
  }
}
```

See Specificity in `@scope` for more information.

Tips for handling specificity headaches

Instead of using `!important`, consider using cascade layers and using low weight specificity throughout your CSS so that styles are easily overridden with slightly more specific rules. Using semantic HTML helps provide anchors from which to apply styling.

Making selectors specific with and without adding specificity

By indicating the section of the document you're styling before the element you're selecting, the rule becomes more specific. Depending on how you add it, you can add some, a lot, or no specificity, as shown below:

```
<main id="myContent">
  <h1>Text</h1>
</main>
```

```
#myContent h1 {
  color: green; /* 1-0-1 */
}
[id="myContent"] h1 {
  color: yellow; /* 0-1-1 */
}
```

```
:where(#myContent) h1 {
  color: blue; /* 0-0-1 */
}
```

No matter the order, the heading will be green because that rule is the most specific.

Reducing ID specificity

Specificity is based on the form of a selector. Including the `id` of an element as an attribute selector rather than an id selector is a good way to make an element more specific without adding an overabundance of specificity. In the previous example, the selector `[id="myContent"]` counts as an attribute selector for the purpose of determining the selector's specificity, even though it selects an ID.

You can also include the `id` or any part of a selector as a parameter in the `:where()` specificity-adjustment pseudo class if you need to make a selector more specific but don't want to add any specificity at all.

Increasing specificity by duplicating selector

As a special case for increasing specificity, you can duplicate weights from the *CLASS* or *ID* columns. Duplicating id, class, pseudo-class or attribute selectors within a compound selector will increase specificity when overriding very specific selectors over which you have no control.

```
#myId#myId#myId span {
  /* 3-0-1 */
}
.myClass.myClass.myClass span {
  /* 0-3-1 */
}
```

Use this sparingly, if at all. If using selector duplication, always comment your CSS.

By using `:is()` and `:not()` (and also `:has()`), you can increase specificity even if you can't add an `id` to a parent element:

```
:not(#fakeID#fakeId#fakeID) span {
  /* 3-0-1 */
}
:is(#fakeID#fakeId#fakeID, span) {
  /* 3-0-0 */
}
```

Precedence over third-party CSS

Leveraging cascade layers is the standard way of enabling one set of styles to take precedence over another set of styles; cascade layers enable this without using specificity! Normal (not important) author styles imported into cascade layers have lower precedence than unlayered author styles.

If styles are coming from a stylesheet you can't edit or don't understand and you need to override styles, a strategy is to import the styles you don't control into a cascade layer. Styles in subsequently declared layers take precedence, with unlayered styles having precedence over all layered styles from the same origin.

When two selectors from different layers match the same element, origin and importance take precedence; the specificity of the selector in the losing stylesheet is irrelevant.

```
@import "TW.css" layer();
p,
p * {
  font-size: 1rem;
}
```

In the above example, all paragraph text, including the nested content, will be `1rem` no matter how many class names the paragraphs have that match the TW stylesheet.

Avoiding and overriding <code>!important</code>

The best approach is to not use `!important`. The above explanations on specificity should be helpful in avoiding using the flag and removing it altogether when encountered.

To remove the perceived need for `!important`, you can do one of the following:

- Increase the specificity of the selector of the formerly `!important` declaration so that it is greater than other declarations
- Give it the same specificity and put it after the declaration it is meant to override
- Reduce the specificity of the selector you are trying to override.

All these methods are covered in preceding sections.

If you're unable to remove `!important` flags from an author's style sheet, the only solution to overriding the important styles is by using `!important`. Creating a cascade layer of important declaration overrides is an excellent solution. Two ways of doing this include:

Method 1

1. Create a separate, short style sheet containing only important declarations specifically overriding any important declarations you were unable to remove.
2. Import this stylesheet as the first import in your CSS using `layer()`, including the `@import` statement, before linking to other stylesheets. This is to ensure that the important overrides are imported as the first layer.

```
@import "importantOverrides.css" layer();
```

Method 2

1. At the beginning of your stylesheet declarations, create a named cascade layer, like so:

   ```
   @layer importantOverrides;
   ```

2. Each time you need to override an important declaration, declare it within the named layer. Only declare important rules within the layer.

   ```
   [id="myElement"] p {
     /* normal styles here */
   }
   @layer importantOverrides {
     [id="myElement"] p {
       /* important style here */
     }
   }
   ```

The specificity of the selector of the important style within the layer can be low, as long as it matches the element you are trying to override. Normal layers should be declared outside the layer because layered styles have lower precedence than unlayered styles.

Tree proximity ignorance

The proximity of an element to other elements that are referenced in a given selector has no impact on specificity.

```
body h1 {
  color: green;
}

html h1 {
  color: purple;
}
```

The `<h1>` elements will be purple because when declarations have the same specificity, the last declared selector has precedence.

Directly targeted elements vs. inherited styles

Styles for a directly targeted element will always take precedence over inherited styles, regardless of the specificity of the inherited rule. Given the following CSS and HTML:

```
#parent {
  color: green;
}

h1 {
  color: purple;
}
```

```
<html lang="en">
  <body id="parent">
    <h1>Here is a title!</h1>
  </body>
</html>
```

The `h1` will be purple because the `h1` selector targets the element specifically, while the green is inherited from the `#parent` declarations.

Examples

In the following CSS, we have three selectors targeting `<input>` elements to set a color. For a given input, the specificity weight of the color declaration having precedence is the matching selector with the greatest weight:

```
#myElement input.myClass {
  color: red;
} /* 1-1-1 */
input[type="password"]:required {
  color: blue;
} /* 0-2-1 */
html body main input {
  color: green;
} /* 0-0-4 */
```

If the above selectors all target the same input, the input will be red, as the first declaration has the highest value in the *ID* column.

The last selector has four *TYPE* components. While it has the highest integer value, no matter how many elements and pseudo-elements are included, even if there were 150, TYPE components never have precedence over *CLASS* components. The column values are compared starting from left to right when column values are equal.

Had we converted the id selector in the example code above to an attribute selector, the first two selectors would have the same specificity, as shown below:

```
[id="myElement"] input.myClass {
  color: red;
} /* 0-2-1 */
input[type="password"]:required {
  color: blue;
} /* 0-2-1 */
```

When multiple declarations have equal specificity, the last declaration found in the CSS is applied to the element. If both selectors match the same `<input>`, the color will be blue.

Additional notes

A few things to remember about specificity:

1. Specificity only applies when the same element is targeted by multiple declarations in the same cascade layer or origin. Specificity only matters for declarations of the same importance and same origin and cascade layer. If matching selectors are in different origins, the cascade determines which declaration takes precedence.
2. When two selectors in the same cascade layer and origin have the same specificity, scoping proximity is then calculated; the ruleset with the lowest scoping proximity wins. See How `@scope` conflicts are resolved for more details and an example.
3. If scope proximity is also the same for both selectors, source order then comes into play. When all else is equal, the last selector wins.
4. As per CSS rules, directly targeted elements will always take precedence over rules which an element inherits from its ancestor.
5. Proximity of elements in the document tree has no effect on the specificity.

CSS custom properties for cascading variables

The **CSS custom properties for cascading variables** module adds support for cascading variables in CSS properties and lets you create custom properties to define these variables along with the mechanisms to use custom properties as the values for other CSS properties.

When working with CSS, you often end up reusing common project-specific values such as widths that work well with your layout, or a set of colors for your color scheme. One way of managing repetition in stylesheets is to define a value once and use it many times in other places. Custom properties let you create and define custom variables that can be reused, simplifying complex or repetitive rules and making them easier to read and maintain. For example, `--dark-grey-text` and `--dark-background` are easier to understand than hexadecimal colors such as `#323831`, and the context of how you use them is more obvious, too.

Custom properties in action

To see how custom properties can be used, move the input slider left to right.

```
<div class="container">
  <div id="color-1">--hue</div>
  <div id="color-2">--hue + 10</div>
  <div id="color-3">--hue + 20</div>
  <div id="color-4">--hue + 30</div>
  <div id="color-5">--hue + 40</div>
  <div id="color-6">--hue + 50</div>
  <div id="color-7">--hue + 60</div>
  <div id="color-8">--hue + 70</div>
</div>
<input type="range" min="0" max="360" value="0" step="0.1" id="hue" />
```

```
const hue = document.querySelector("#hue");

const updateHue = () => {
  document.documentElement.style.setProperty("--hue", hue.value);
};

hue.addEventListener("input", updateHue);
```

```
.container {
  display: grid;
  font-family: sans-serif;
  color: white;
  gap: 0.5rem;
  grid-template-columns: repeat(4, 1fr);
  margin-bottom: 1rem;
}
.container div {
  border-radius: 0.5rem;
  padding: 1rem;
}

input {
  width: 100%;
  margin: 0;
}

:root {
  --hue: 0;
}

#color-1 {
  background-color: hsl(var(--hue) 50% 50%);
}
#color-2 {
  background-color: hsl(calc(var(--hue) + 10) 50% 50%);
}
#color-3 {
  background-color: hsl(calc(var(--hue) + 20) 50% 50%);
}
#color-4 {
  background-color: hsl(calc(var(--hue) + 30) 50% 50%);
}
#color-5 {
  background-color: hsl(calc(var(--hue) + 40) 50% 50%);
}
#color-6 {
  background-color: hsl(calc(var(--hue) + 50) 50% 50%);
}
#color-7 {
  background-color: hsl(calc(var(--hue) + 60) 50% 50%);
}
#color-8 {
  background-color: hsl(calc(var(--hue) + 70) 50% 50%);
}
```

In these color swatches, the `background-color` is set using the `hsl()` `<color>` function as `hsl(var(--hue) 50% 50%)`. Each color swatch increments the `<hue>` value by 10 degrees like `calc(var(--hue) + 10)`, `calc(var(--hue) + 20)` etc. As the slider's value changes from 0 up to 360, the value of the `--hue` custom property is updated using `calc()`, and the background color of each box inside the grid is updated, also.

Using CSS custom properties (variables)

Custom properties (sometimes referred to as **CSS variables** or **cascading variables**) are entities defined by CSS authors that represent specific values to be reused throughout a document. They are set using the `@property` at-rule or by custom property syntax (e.g., **`--primary-color: blue;`**). Custom properties are accessed using the CSS `var()` function (e.g., **`color: var(--primary-color);`**).

Complex websites have very large amounts of CSS, and this often results in a lot of repeated CSS values. For example, it's common to see the same color used in hundreds of different places in stylesheets. Changing a color that's been duplicated in many places requires a search and replace across all rules and CSS files. Custom properties allow a value to be defined in one place, then referenced in multiple other places so that it's easier to work with. Another benefit is readability and semantics. For example, `--main-text-color` is easier to understand than the hexadecimal color `#00ff00`, especially if the color is used in different contexts.

Custom properties defined using two dashes (`--`) are subject to the cascade and inherit their value from their parent. The `@property` at-rule allows more control over the custom property and lets you specify whether it inherits its value from a parent, what the initial value is, and the type constraints that should apply.

> **Note:** Variables do not work inside media queries and container queries. You can use the `var()` function in any part of a value in any property on an element. You cannot use `var()` for property names, selectors, or anything aside from property values, which means you can't use it in a media query or container query.

Declaring custom properties

In CSS, you can declare a custom property using two dashes as a prefix for the property name, or by using the `@property` at-rule. The following sections describe how to use these two methods.

Using a prefix of two dashes (<code>--</code>)

A custom property prefixed with two dashes begins with `--`, followed by the property name (e.g., `--my-property`), and a property value that can be any valid CSS value. Like any other property, this is written inside a ruleset. The following example shows how to create a custom property `--main-bg-color` and uses a `<named-color>` value of `brown`:

```
section {
  --main-bg-color: brown;
}
```

The selector given to the ruleset (`<section>` elements in the example above) defines the scope in which the custom property can be used. For this reason, a common practice is to define custom properties on the `:root` pseudo-class, so that it can be referenced globally:

```
:root {
  --main-bg-color: brown;
}
```

This doesn't always have to be the case: you maybe have a good reason for limiting the scope of your custom properties.

> **Note:** Custom property names are case sensitive — `--my-color` will be treated as a separate custom property to `--My-color`.

Using the <code>@property</code> at-rule

The `@property` at-rule allows you to be more expressive with the definition of a custom property with the ability to associate a type with the property, set default values, and control inheritance. The following example creates a custom property called `--logo-color` which expects a `<color>`:

```
@property --logo-color {
  syntax: "<color>";
  inherits: false;
  initial-value: #c0ffee;
}
```

If you want to define or work with custom properties in JavaScript instead of directly in CSS, there is a corresponding API for this purpose. You can read about how this works in the CSS Properties and Values API page.

Referencing custom properties with <code>var()</code>

Regardless of which method you choose to define a custom property, you use them by referencing the property in a `var()` function in place of a standard property value:

```
details {
  background-color: var(--main-bg-color);
}
```

First steps with custom properties

Let's start with some HTML that we would like to apply some styles to. There is a `<div>` that acts as a container that includes some child elements, some with nested elements:

```
<div class="container">
  <div class="one">
    <p>One</p>
  </div>
  <div class="two">
    <p>Two</p>
    <div class="three">
      <p>Three</p>
    </div>
  </div>
  <input class="four" placeholder="Four" />
```

```
  <textarea class="five">Five</textarea>
</div>
```

We will use the following CSS to style a few different elements based on their classes (some layout rules are not shown below so we can focus on colors). Depending on their classes, we're giving elements `teal` or `pink` background colors:

```
/* Set fonts, borders and padding */
body,
textarea,
::placeholder {
  font-family: sans-serif;
  color: white;
}

div,
input,
textarea {
  border: 2px black solid;
  padding: 4px;
  margin: 4px;
}

.container {
  display: grid;
  gap: 10px;
}
```

```
/* For each class, set some colors */
.one {
  background-color: teal;
}

.two {
  color: black;
  background-color: pink;
}

.three {
  color: white;
  background-color: teal;
}

.four {
  background-color: teal;
}

.five {
  background-color: teal;
}
```

This produces the following result:

There's an opportunity to use custom properties to replace repetitive values across these rules. After defining `--main-bg-color` in the `.container` scope and referencing its value in multiple places, the updated styles look like this:

```
/* Define --main-bg-color here */
.container {
  --main-bg-color: teal;
}

/* For each class, set some colors */
.one {
  background-color: var(--main-bg-color);
}

.two {
  color: black;
  background-color: pink;
}

.three {
  color: white;
  background-color: var(--main-bg-color);
}

.four {
  background-color: var(--main-bg-color);
}

.five {
  background-color: var(--main-bg-color);
}
```

Using the :root pseudo-class

For some CSS declarations, it is possible to declare this higher in the cascade and let CSS inheritance solve this problem. For non-trivial projects, this is not always possible. By declaring a custom property on the `:root` pseudo-class and using it where needed throughout the document, a CSS author can reduce the need for repetition:

```
/* Define --main-bg-color here */
:root {
  --main-bg-color: teal;
}

/* For each class, set some colors */
.one,
.three,
.four,
.five {
  background-color: var(--main-bg-color);
}
```

```
.two {
  color: black;
  background-color: pink;
}
```

This leads to the same result as the previous example, yet allows for one canonical declaration of the desired property value (`--main-bg-color: teal;`), which is very useful if you want to change the value across the entire project later.

Inheritance of custom properties

A custom property defined using two dashes `--` instead of `@property` always inherits the value of its parent. This is demonstrated in the following example:

```
<div class="one">
  <p>One</p>
  <div class="two">
    <p>Two</p>
    <div class="three"><p>Three</p></div>
    <div class="four"><p>Four</p></div>
  </div>
</div>
```

```
div {
  color: black;
  font-family: sans-serif;
  width: 75%;
  height: 80%;
  margin: 4px;
  border: 2px black solid;
  display: inline-block;
}

p {
  margin: 0;
}

.one {
  height: 250px;
}

.two {
  color: white;
  height: 80%;
}

.three {
  color: black;
  height: 40%;
}

.four {
  color: white;
  height: 40%;
}
```

```
div {
  background-color: var(--box-color);
}

.two {
  --box-color: teal;
}

.three {
  --box-color: pink;
}
```

The results of `var(--box-color)` depending on inheritance are as follows:

- `class="one"`: *invalid value*, which is the default value of a custom property defined in this way
- `class="two"`: `teal`
- `class="three"`: `pink`
- `class="four"`: `teal` (inherited from its parent)

One aspect of custom properties that the examples above demonstrate is that they don't behave exactly like variables in other programming languages. The value is computed where it is needed, not stored and reused in other places of a stylesheet. For instance, you cannot set a property's value and expect to retrieve the value in a sibling's descendant's rule. The property is only set for the matching selector and its descendants.

Using <code>@property</code> to control inheritance

The `@property` at-rule lets you explicitly state whether the property inherits or not. The following example creates a custom property using the `@property` at-rule. Inheritance is disabled, there's a `<color>` data type defined, and an initial value of `teal`.

The parent element sets `--box-color` to a value of `green` and uses `--box-color` as a value for its background color. The child element also uses `background-color: var(--box-color)`, and we would expect it to have the color `green` if inheritance was enabled (or if it was defined using the double dash syntax).

```
<div class="parent">
  <p>Parent element</p>
  <div class="child">
    <p>Child element with inheritance disabled for --box-color.</p>
  </div>
</div>
```

```
div {
  color: white;
  font-family: sans-serif;
  width: 200px;
  height: 200px;
  margin: 4px;
```

```
  padding: 8px;
  border: 2px black solid;
  display: inline-block;
}
```

```
@property --box-color {
  syntax: "<color>";
  inherits: false;
  initial-value: teal;
}

.parent {
  --box-color: green;
  background-color: var(--box-color);
}

.child {
  width: 80%;
  height: 40%;
  background-color: var(--box-color);
}
```

Because `inherits: false;` is set in the at-rule, and a value for the `--box-color` property is not declared within the `.child` scope, the initial value of `teal` is used instead of `green` that would have been inherited from the parent:

Custom property fallback values

You can define fallback values for custom properties using the `var()` function, and the `initial-value` of the `@property` at-rule.

> **Note:** Fallback values aren't used to fix compatibility issues for when CSS custom properties are not supported, as the fallback value won't help in this case. Fallbacks cover the case where the browser supports CSS custom properties and is able to use a different value if the desired variable isn't defined yet or has an invalid value.

Defining fallbacks in the <code>var()</code> function

Using the `var()` function, you can define multiple **fallback values** when the given variable is not yet defined; this can be useful when working with Custom Elements and Shadow DOM.

The first argument to the function is the name of the custom property. The second argument to the function is an optional fallback value, which is used as the substitution value when the referenced custom property is invalid. The function accepts two parameters, assigning everything following the first comma as the second parameter. If the second parameter is invalid, the fallback will fail. For example:

```
.one {
  /* Red if --my-var is not defined */
  color: var(--my-var, red);
}

.two {
  /* pink if --my-var and --my-background are not defined */
  color: var(--my-var, var(--my-background, pink));
}

.three {
  /* Invalid: "--my-background, pink" */
  color: var(--my-var, --my-background, pink);
}
```

Including a custom property as a fallback, as seen in the second example above (`var(--my-var, var(--my-background, pink))`), is the correct way to provide more than one fallback with `var()`. You should be aware of the performance impact of this method, however, as it takes more time to parse through the nested variables.

> **Note:** The syntax of the fallback, like that of custom properties, allows commas. For example, `var(--foo, red, blue)` defines a fallback of `red, blue` — anything between the first comma and the end of the function is considered a fallback value.

Fallbacks using the <code>@property</code> initial value

Aside from using `var()`, the `initial-value` defined in the `@property` at-rule can be used as a fallback mechanism. In fact, we've already seen this in the `@property` inheritance section.

The following example sets an initial value of `--box-color` to `teal` using the `@property` at-rule. In the ruleset following the at-rule, we want to set `--box-color` to `pink`, but there's a typo in the value name. The same is true for the third `<div>` where we've used `2rem` for the custom property that's expecting a valid `<color>` value. Both `2rem` and `peenk` are invalid color values, so the initial value of `teal` is applied:

```
@property --box-color {
  syntax: "<color>";
  initial-value: teal;
  inherits: false;
}

.one {
  --box-color: pink;
  background-color: var(--box-color);
}

.two {
  --box-color: peenk;
  background-color: var(--box-color);
}

.three {
  --box-color: 2rem;
  background-color: var(--box-color);
}
```

```
div {
  color: white;
  font-family: sans-serif;
  width: 100px;
  height: 100px;
  margin: 4px;
  padding: 8px;
  border: 2px black solid;
```

```
  display: inline-block;
}

.one {
  color: black;
}
```

```
<div class="one">
  <p>One</p>
</div>
<div class="two">
  <p>Two.</p>
</div>
<div class="three">
  <p>Three.</p>
</div>
```

Invalid custom properties

Each CSS property can be assigned a defined set of values. If you try to assign a value to a property that is outside its set of valid values, it's considered *invalid*.

When the browser encounters an invalid value for a regular CSS property (for example, a value of `16px` for the `color` property), it discards the declaration, and elements are assigned the values that they would have had if the declaration did not exist. In the following example, we see what happens when a regular CSS declaration is invalid; `color: 16px;` is discarded and the previous `color: blue` rule is applied instead:

```
<p>This paragraph is initially black.</p>
```

```
p {
  font-weight: bold;
  color: blue;
}

p {
  /* oops, not a valid color */
  color: 16px;
}
```

However, when the values of custom properties are parsed, the browser doesn't yet know where they will be used, so it must consider nearly all values as *valid*. Unfortunately, these valid values can be used, via the `var()` functional notation, in a context where they might not make sense. Properties and custom variables can lead to invalid CSS statements, leading to the concept of *valid at computed time*.

When the browser encounters an invalid `var()` substitution, then the initial or inherited value of the property is used. This example is just like the last one, except we use a custom property.

The browser substitutes the value of `--text-color` in place of `var(--text-color)`, but `16px` is not a valid property value for `color`. After substitution, the property doesn't make sense, so the browser handles this situation in two steps:

1. Check if the property `color` is inheritable. It is, but this `<p>` doesn't have any parent with the `color` property set. So we move on to the next step.
2. Set the value to its **default initial value**, which is black.

```
<p>This paragraph is initially black.</p>
```

```
:root {
  --text-color: 16px;
}

p {
  font-weight: bold;
  color: blue;
}

p {
  color: var(--text-color);
}
```

For such cases, the `@property` at-rule can prevent unexpected results by allowing you to define the initial value of the property:

```
<p>This paragraph is initially black.</p>
```

```
@property --text-color {
  syntax: "<color>";
  inherits: false;
  initial-value: teal;
}

:root {
  --text-color: 16px;
}

p {
  font-weight: bold;
  color: blue;
}

p {
  color: var(--text-color);
}
```

Values in JavaScript

To use the values of custom properties in JavaScript, it is just like standard properties.

```
// get variable from inline style
element.style.getPropertyValue("--my-var");

// get variable from wherever
getComputedStyle(element).getPropertyValue("--my-var");

// set variable on inline style
element.style.setProperty("--my-var", jsVar + 4);
```

CSS color adjustment

The **CSS color adjustment** module provides a model and controls automatic color adjustment by the user agent to handle user preferences, such as "Dark Mode", contrast adjustment, and other color scheme preferences.

Together with the `@media` features `prefers-color-scheme`, `prefers-contrast` and `forced-colors`, this module defines how and when colors are automatically adjusted by the browser.

CSS colors

The **CSS colors** module defines colors, color types, color blending, opacity, and how you can apply these colors and effects to HTML content.

While this module has only two CSS properties, `color` and `opacity`, over 20 CSS and SVG properties, CSS images, at-rules, and @media rules depend on these two properties.

Colors in action

The color syntax converter below shows the values of the currently selected color in red-green-blue (RGB), hexadecimal (HEX), hue, saturation, and lightness (HSL), and hue, whiteness, and blackness (HWB) CSS color formats. All the RGB, HEX, HSL, and HWB color values here, while written differently, represent the same color value.

Selecting a color via the color picker and an opacity via the slider updates the RGB, HEX, HSL, and HWB values. When you choose a new color or opacity value, the color of the background and the slider update via the CSS properties `background-color` and `accent-color`, respectively.

To see the code for this color syntax converter, view the source on GitHub.

Applying color to HTML elements using CSS

With CSS, there are lots of ways to add color to your HTML elements to create the look you want. This guide is a primer introducing how CSS can be used to apply colors to HTML elements. This guide includes lists of the CSS properties that set color in their values and how to use colors both in stylesheets and in other ways.

> **Note:** It is important to use colors wisely. Always select appropriate colors, ensuring the contrast between text and the background is sufficient to ensure legibility, and always keep the needs of people with differing visual capabilities in mind.

To learn more about CSS colors as a data type, see the CSS `<color>` data type reference and the CSS color values guide.

Properties that can have color

At the element level, everything in HTML can have color applied to it. Let's look at the different items rendered on the page — such as text, borders, etc. We'll provide lists of the CSS properties that apply color to each.

At a fundamental level, the `color` property defines the foreground color of an HTML element's content and the `background-color` property defines the element's background color. These can be used on just about any element.

Text

Whenever an element is rendered, these properties are used to determine the color of the text, its background, and any decorations on the text.

`color`

: The color to use when drawing the text and any text decorations (such as the addition of under- or overlines, strike-through lines, and so forth).

`background-color`

: The text's background color.

`text-shadow`

: Configures a shadow effect to apply to text. Among the options for the shadow is the shadow's base color (which is then blurred and blended with the background based on the other parameters). See Text drop shadows to learn more.

`text-decoration-color`

: The default text decorations (such as underlines, strikethroughs, etc.) color is `currentColor`. This keyword represents the current value of the `color` property. However, you can override that value and use a different color for them with the `text-decoration-color` property.

`text-emphasis-color`

: The color to use when rendering emphasis symbols adjacent to each character in the text. This is used primarily when drawing text for East Asian languages.

`caret-color`

: The color to use when drawing the caret (sometimes referred to as the text input cursor) within the element. This is only useful in elements that are editable, such as `<input>` and `<textarea>` or elements whose HTML `contenteditable` attribute is set to `true`.

Boxes

Every element is a box with some sort of content, and has a background and a border in addition to whatever contents the box may have.

Borders

: See the Borders section for a list of the CSS properties you can use to set the colors of a box's borders.

`background-color`

: The background color to use in areas of the element that have no foreground content.

`box-shadow`

: Configures inset shadow and drop shadow effects on the box. Among the options for each shadow is the shadow's base color (which is then blurred and blended with any background based on the other parameters).

`column-rule-color`

: The color to use when drawing the line separating columns of text when using CSS multi-column layout.

`outline-color`

: The color to use when drawing an outline around the outside of the element. This outline is different from the border in that it doesn't get space set aside for it in the document. Outlines do not participate in the box model, overlapping other content. Outlines are generally used as focus indicators, indicating which element currently has focus and will receive keyboard input events.

Borders

Any element can have a border drawn around it. A basic element border is a line drawn around the edges of the element's content. See The box model to learn about the relationship between elements and their borders, and the article Styling borders using CSS to learn more about applying styles to borders.

You can use the `border` shorthand property, which lets you configure everything about the border in one shot (including non-color features of borders, such as its width, style (solid, dashed, etc.), and so forth.

`border-color` shorthand

: Specifies a single color to use for every side of the element's border.

`border-left-color`, `border-right-color`, `border-top-color`, and `border-bottom-color`

Lets you set the color of the corresponding side of the element's border.

`border-block-start-color` and `border-block-end-color`

With these, you can set the color used to draw the borders which are closest to the start and end of the block the border surrounds. In a left-to-right writing mode (such as the way English is written), the block start border is the top edge and the block end is the bottom. This differs from the inline start and end, which are the left and right edges (corresponding to where each line of text in the box begins and ends).

`border-inline-start-color` and `border-inline-end-color`

These let you color the edges of the border closest to the beginning and the end of the start of lines of text within the box. Which side this is will vary depending on the `writing-mode`, `direction`, and `text-orientation` properties, which are typically (but not always) used to adjust text directionality based on the language being displayed. For example, if the box's text is being rendered right-to-left, then the `border-inline-start-color` is applied to the right side of the border.

Specifying colors as values in stylesheets

Now that you know which CSS properties let you apply color to elements, you can start adding colors to your websites. Let's look at some examples of using color within a style sheet. In this example, we use several previously mentioned properties, with the concept of applying colors in CSS being the same no matter the property.

Let's look at the result first, before going on to look at the code we need to create it:

HTML

The HTML responsible for creating the above example is shown here:

```
<div class="wrapper">
  <div class="boxLeft">
    <p>This is the first box.</p>
  </div>
  <div class="boxRight">
    <p>This is the second box.</p>
  </div>
</div>
```

Here we have a wrapper `<div>` containing two child `<div>`s, each with a single child paragraph (`<p>`). Each content `<div>` is given a different look and feel.

CSS

Let's look at the CSS that creates the above result a piece at a time.

> **Note:** We are using multiple different CSS color value types in this example to demonstrate their use. This is not recommended for production code. When writing CSS, use the most intuitive value type for you and your team.

```
.wrapper {
  height: 110px;
  padding: 10px;
  display: flex;
  gap: 10px;
  text-align: center;
  font:
    28px "Marker Felt",
    "Zapfino",
    cursive;
  border: 6px solid mediumturquoise;
}

div {
  flex: 1;
}
```

The `.wrapper` class is used to assign styles to the `<div>` that encloses all of our other content. This establishes the height of the container using `height`, allowing the width of this block-level element to default to 100% of its parent. Setting the `display` to `flex` and adding a `10px` `gap` creates a flex container to lay out the children side by side with a gap between all the container's children. We use `flex` to let the flex children grow to fill the container; it doesn't affect the flex container itself.

Of more interest to our discussion here is the use of the `border` property to establish a border around the outside edge of the element. This border is a solid line, 6 pixels wide, in the named color `mediumturquoise`.

Within our wrapper, we have a left box and a right box.

```
.boxLeft {
  background-color: rgb(245 130 130);
  outline: 2px solid darkred;
}
```

The `.boxLeft` class, used to style the box on the left, sets up the color of the background and the outline:

- The box's background color is set by changing the value of the CSS `background-color` property to `rgb(245 130 130)`, using the `rgb()` functional notation.
- An outline is defined for the box. Unlike the more commonly used `border`, `outline` doesn't affect layout at all; it draws over the top of whatever may happen to be outside the element's box instead of making room as `border` does. This outline is a solid, dark red line that's two pixels thick. Note the use of the `darkred` keyword when specifying the color.
- Notice that we're not explicitly setting the text color. That means the value of `color` will be inherited from the nearest containing element that defines it. By default, that's black.

```
.boxRight {
  background-color: hwb(270deg 63% 13%);
  outline: 4px dashed #6e1478;
  color: hsl(0deg 95% 95%);
  text-decoration-line: underline;
  text-decoration-style: wavy;
  text-decoration-color: #8f8;
  text-decoration: underline wavy #8f8;
  text-shadow: 2px 2px 3px black;
}
```

> **Note:** We included the `text-decoration-*` styles separately because Safari doesn't support `text-decoration` as a shorthand property.

Finally, the `.boxRight` class sets several styles on the box that's drawn to the right. Then the following colors are established (using five different ways of declaring color values):

- The `background-color` is set using `hwb()` functional notation — `hwb(270deg 63% 13%)`. This is a medium purple color.
- The box's `outline` is used to specify that the box should be enclosed in a four-pixel thick dashed line whose color is a somewhat deeper purple using the six-digit `<hex-color>` `#6e1478`.
- The foreground (text) color is specified by setting the `color` property using `hsl()` functional notation — `hsl(0deg 95% 95%)`. This is a very light pinkish color.
- We add a green wavy line under the text with the `text-decoration` shorthand, along with the longhand component for browser compatibility. We used the 3-digit `<hex-color>` `#8f8`, which is the equivalent of `#88ff88`.
- Finally, a bit of a shadow is added to the text using `text-shadow`. Its `color` parameter is set to `black`, a `<named-color>` value.

We used five different color syntaxes to demonstrate what is possible. In the real world, you and your team will preferably pick a preferred color notation, with everyone working on a code base using the same color syntax.

Other ways to use color

CSS isn't the only web technology that supports color. Other examples include:

The HTML Canvas API

> Lets you draw 2D bitmapped graphics in a `<canvas>` element. See our Canvas tutorial to learn more.

SVG (Scalable Vector Graphics)

> Lets you create images using commands that draw specific shapes, patterns, and lines. SVG commands are formatted as XML, and can be embedded directly into a web page or placed in the page using the `<img>` element, just like any other type of image.

WebGL

> The Web Graphics Library is an OpenGL ES-based API for drawing high-performance 2D and 3D graphics on the Web. See our WebGL tutorial to find out more. Also see WebGPU, a successor to WebGL for modern GPUs.

> **Note:** A few now obsolete HTML attributes accepted colors as values, such as `bgcolor` and `vlink`. These attributes only accepted `<named-color>` and three- or six-digit `<hex-color>` values.

Color format converter

This tool lets you enter or pick a color and copy its corresponding value in any CSS color format. You can use the generated color value anywhere the `<color>` data type is supported in CSS. This tool can also help you understand the syntax of the different color notations.

How to use the tool

Enter a color in any format or pick one in the sRGB color space. You can also adjust the opacity (alpha channel).

Click the **Copy** button next to the corresponding color format to quickly copy its value. You can also click a color format name to learn more about it.

```
<div class="container">
  <dialog open>
    <p>
      <label for="color-text">
        Enter a color value in any format or pick a color:
      </label>
      <span class="color-inputs">
        <input type="text" id="color-text" />
        <input type="color" id="color-input" />
      </span>
    </p>
    <p>
      <label for="opacity-input">Adjust the opacity: </label>
      <input
        type="range"
        id="opacity-input"
        value="1"
        min="0"
        max="1"
        step="0.01" />
    </p>
    <hr />
    <table id="output-colors">

Color mixer

This tool lets you mix two colors in any color space using the `color-mix()` function and copy the resulting color in any CSS color format.

The two input colors, `color-one` and `color-two`, are shown on the outside, and the mixed color returned by the function is shown in the middle. Click the outer swatches to select new colors to mix. Use the sliders to change the percentages of each input color included in the mix. Use the drop-down menu to change the color space of the function's output. The resulting color's values in different formats appear in a table following the widget and can be copied. You can also click a color format name to learn more about it.

```
<div id="color-mixer">
  <div>color-one</div>
  <div>mixed-color</div>
```

```

CSS color values

To represent a color in CSS, you have to find a way to translate the analog concept of "color" into a digital form that a computer can use. This is typically done by breaking the color down into components, such as amounts of different primary colors to mix together, or brightness and hue. Defined color models ensure that colors will appear the same no matter where they are rendered.

A color model is a mathematical model that represents colors using numeric values. Color models describe how to create the available colors within a color space. RGB was the first color model for the web. The `sRGB` color space of the RGB color model — the standard red, green, and blue color space — was created in 1996 for computer monitors and the web. A color space is a system for grouping colors so that describing any given color is consistent. If you transform a color between two different color spaces, it should look identical in both.

Originally, monitors were limited regarding how many colors they could render, and CSS colors were limited by those constraints, expanding as capabilities improved. With modern devices no longer limited to RGB, we now also have color models based on human perception instead, providing a much wider gamut of colors. We can now describe color in CSS in several ways, and the options keep expanding.

This guide introduces the different `<color>` value types. For a more detailed discussion, see the reference links provided below.

Keywords

The web defines a set of standard color names that lets you use keywords instead of numeric representations to describe colors. This is a simpler albeit more limited approach — there may not be a keyword representing the exact color you want to use.

Color keywords include standard primary and secondary colors (such as `red`, `blue`, or `orange`), shades of gray (from `black` to `white`, including colors like `darkgray` and `lightgrey`), and a variety of other blended colors, including `lightseagreen`, `cornflowerblue`, and `rebeccapurple`. Named colors use the RGB model and are associated with the sRGB (`srgb`) color space.

There are over 160 named colors. There are named colors of special interest: `transparent` sets a transparent color value, while `currentColor` sets the current value of the CSS `color` property. There are also named `<system-color>` colors, such as `accentcolortext` and `buttonface`, that reflect the default color choices made by the user, the browser, or the operating system.

All color keywords are case-insensitive. See the `<named-color>` data type for more information on color keywords.

RGB values

There are two primary ways of defining an RGB color by its red, green, and blue components in CSS — hexadecimal and `rgb()` values. Like named colors, these methods use the RGB model and are associated with the sRGB (`srgb`) color space. However, they allow a much wider range of colors to be specified.

Hexadecimal string notation

Hexadecimal (hex) string notation uses a hexadecimal value to represent each component (red, green, and blue) of an RGB color. It may also include a fourth component: the alpha channel (or opacity).

A color in hexadecimal string notation always begins with the character `"#"`. After that comes the hexadecimal digits of the color code. The string is case-insensitive.

`"#rrggbb"`

Specifies a fully opaque color whose red component is the hexadecimal number `0xrr`, green component is `0xgg`, and blue component is `0xbb`.

`"#rrggbbaa"`

Specifies a color whose red component is the hexadecimal number `0xrr`, green component is `0xgg`, and blue component is `0xbb`. The alpha channel is specified by `0xaa`; the lower this value is, the more translucent the color becomes.

`"#rgb"`

Specifies a color whose red component is the hexadecimal number `0xrr`, green component is `0xgg`, and blue component is `0xbb`.

`"#rgba"`

Specifies a color whose red component is the hexadecimal number `0xrr`, green component is `0xgg`, and blue component is `0xbb`. The alpha channel is specified by `0xaa`; the lower this value is, the more translucent the color becomes.

As shown above, the red, green, and blue color components can each be represented as a double-digit hex value representing a number between 0 (`00`) and 255 (`FF`) or a single-digit hex value (a number between 0 (`0`) and 15 (`F`)).

> **Note:** The leading `0x` in the values above indicates a hexadecimal integer literal. Hexadecimal integers can include digits (`0` - `9`) and the letters `a` – `f` and `A` – `F`. The case of a character does not change its value. Therefore: `0xa` = `0xA` = `10` and `0xf` = `0xF` = `15`.

These two hex colors are equivalent color values; they're both red:

```
color: #ff0000;
color: #f00;
```

All components *must* be specified using the same number of digits. If you use the single-digit notation, the final color is computed by using each component's digit twice; that is, `"#D"` becomes `"#DD"` when drawing.

To make the values 25% opaque, add in the alpha channel value as shown below:

```
color: #ff000044;
color: #f004;
```

See the `<hex-color>` data type for more information on hexadecimal string notation for colors.

HTML color input type

There are many situations in which your website may need to let the user select a color. Perhaps you have a customizable user interface, or you're implementing a drawing app. Maybe you have editable text and need to let the user choose the text color. Or perhaps your app lets the user assign colors to folders or items. For such use cases, the `<input>` element has a `"color"` `type`, which renders a color picker control.

This example allows you to choose a color. Once a choice is made, the `border-color` is set to that color, and the value is displayed.

```
<div id="box">
  <label for="colorPicker">Border color:</label>
  <input type="color" value="#8888ff" id="colorPicker" />
  <output></output>
</div>
```

The HTML creates a box containing a color picker control (with a label created using the `<label>` element) and an empty `<output>` element into which we'll output the color's value using JavaScript. The color input's value is always a hexadecimal string.

```
#box {
  width: 500px;
  height: 100px;
  border: 5px solid rgb(245 220 225);
  padding: 4px 6px;
  font:
    16px "Lucida Grande",
    "Helvetica",
    "Arial",
    sans-serif;
}
```

The following JavaScript updates the border's color to match the color picker's initial value, then adds two event handlers to the `<input type="color">` element to respond to changes made to its value.

```
const colorPicker = document.querySelector("#colorPicker");
const box = document.querySelector("#box");
const output = document.querySelector("output");

box.style.borderColor = colorPicker.value;

colorPicker.addEventListener("input", (event) => {
  box.style.borderColor = event.target.value;
});

colorPicker.addEventListener("change", (event) => {
  output.innerText = `${colorPicker.value}`;
});
```

The `input` event is sent every time the value of the element changes; that is, every time the user adjusts the color in the color picker. Each time this event arrives, we set the box's border color to match the color picker's current value.

The `change` event is received when the color picker's value is finalized. We respond by setting the contents of the `<output>` to the string value of the selected color.

RGB functional notation

RGB (Red/Green/Blue) functional notation, like hexadecimal string notation, represents colors using their red, green, and blue components (and, optionally, an alpha channel component for opacity). However, instead of using a string, the color is defined using the CSS function `rgb()`. This function accepts 3 or 4 input parameters — red, green, and blue component values and an optional alpha channel value.

Legal values for each of these parameters are:

`red`, `green`, and `blue`

Each must be an `<number>` value between 0 and 255 (inclusive), a `<percentage>` from 0% to 100%, or the keyword `none`, which is equal to `0` in this case.

`alpha`

The alpha channel is specified as a percentage between `0%` (fully transparent) and `100%` (fully opaque), or a number between `0.0` (equivalent to `0%`) and `1.0` (equivalent to `100%`).

For example, a bright red that's 50% opaque can be represented as `rgb(255 0 0 / 50%)` or `rgb(100% 0 0 / 0.5)`.

See the `rgb()` color function for more information on the RGB functional notation.

Color functions with a hue component

The color functions that have a `<hue>` component — an `<angle>` from that color model's color wheel — include the `srgb` color functions `hsl()` and `hwb()`, CIElab's `lch()` function, and OKLab's `oklch()` color function. These color functions are more intuitive as the hue allows us to tell the difference or similarity between colors like red, orange, yellow, green, blue, etc.

HSL functional notation

The `hsl()` CSS color function was the first hue-based color function to be supported in browsers. `hsl()` is more intuitive than `rgb()` — it is generally easier to determine the effect of varying hue (`h`), saturation (`s`), and lightness (`l`) values than it is to declare specific colors via red, green, and blue channel values. In addition, HSL is similar to the HSB (hue, saturation, and brightness) color picker in Photoshop, which made it immediately familiar to many people when first supported.

The `hsl()` and `hwb()` sRGB color functions are both cylindrical. Hue defines the color as an `<angle>` on a circular color wheel. The diagram below shows an HSL color cylinder. Saturation is a percentage that defines how far the color is along a scale between completely grayscale and having the maximum possible amount of the given hue. As the value of lightness increases, the color transitions from the darkest to the lightest possible color (from black to white).

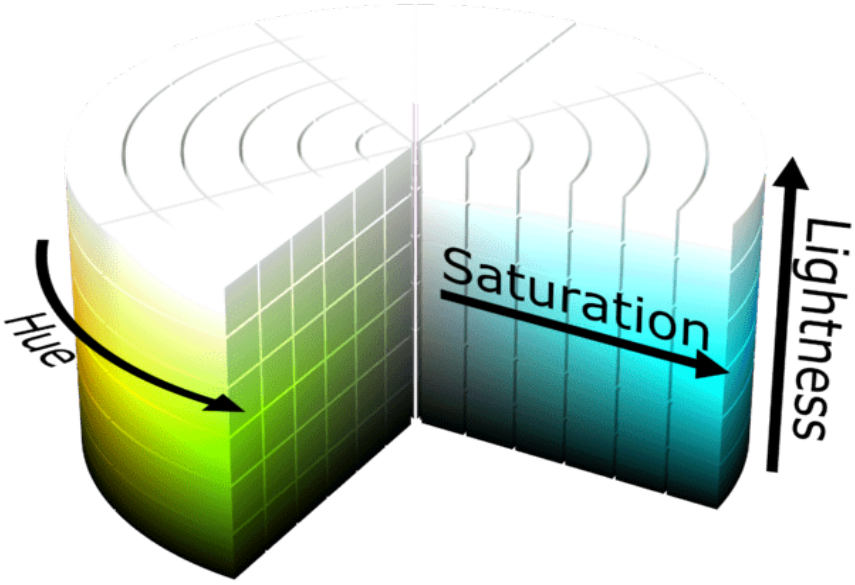

Image courtesy of user SharkD on Wikipedia, distributed under the CC BY-SA 3.0 license.

The value of the hue (`H`) component of an HSL (or HWB) color is an angle that starts at 0° as red, then moves through yellow, green, cyan, blue, and magenta, before ending up back at red again at 360°. The value can be specified in any `<angle>` unit supported by CSS, including degrees (`deg`), radians (`rad`), gradians (`grad`), or turns (`turn`). The hue value identifies what the base shade of the color is, but it doesn't control how vivid or dull, or how light or dark the color is.

The saturation (`S`) component of the color specifies the percentage of the final color comprised of the specified hue, with 100% being fully saturated and 0% being a complete lack of color (greyscale). The lightness (`L`) component specifies how light the color is along a sliding scale between completely black (`0%`) and completely white (`100%`). You can also optionally include an alpha channel, preceded by a slash (`/`) to make the color less than 100% opaque.

Here are some sample colors in HSL notation:

```
table {
  border: 1px solid black;
  font:
    16px "Open Sans",
    "Helvetica",
    "Arial",
    sans-serif;
  border-spacing: 0;
  border-collapse: collapse;
}

th,
td {
  border: 1px solid black;
  padding: 4px 6px;
  text-align: left;
}

th {
  background-color: hsl(0 0% 75%);
}
```

```
<table>
  <thead>
    <tr>
      <th scope="col">Color in HSL notation</th>
      <th scope="col">Example</th>
    </tr>
  </thead>
  <tbody></tbody>
</table>
```

```
const colors = [
  "hsl(90deg 0% 50%)",
  "hsl(90 100% 50%)",
  "hsl(0.15turn 50% 75%)",
  "hsl(0.15turn 90% 75%)",
  "hsl(0.15turn 90% 50%)",
  "hsl(270deg 90% 50% / 50%)",
];

const tbody = document.querySelector("tbody");
for (const color of colors) {
  const tr = document.createElement("tr");
  const td1 = document.createElement("td");
```

```
  td1.appendChild(document.createElement("code")).textContent = color;
  const td2 = document.createElement("td");
  td2.style.backgroundColor = color;
  tr.appendChild(td1);
  tr.appendChild(td2);
  tbody.appendChild(tr);
}
```

The last value is semi-opaque; it includes the optional alpha value, preceded by a forward slash.

> **Note:** When you omit the hue's unit, it's assumed to be in degrees (`deg`).

HWB functional notation

The `hwb()` color function uses the same hue coordinate system as `hsl()`, with `0deg` being red. However, instead of `hsl()`'s lightness and saturation, `hwb()` functions specify whiteness (`W`) and blackness (`B`). This function is also fairly intuitive — allowing you to pick a hue and then mix in amounts of white and or black to achieve the desired color.

`W` and `B` values range from `0%` to `100%` (or `0` to `1`). If the combined value of `W` and `B` is 100% (or `1`) or greater, the color will be gray, similar to setting the `s` to `0%` with `hsl()`. As with `hsl()`, an optional alpha value can be included, preceded by a forward slash `/`.

Here are some examples of using HWB notation:

```
/* These examples all specify varying shades of a lime green. */
hwb(90 10% 10%)
hwb(90 50% 10%)
hwb(90deg 10% 10%)
hwb(1.5708rad 60% 0%)
hwb(.25turn 0% 40%)

/* Same lime green but with an alpha value */
hwb(90 10% 10% / 0.5)
hwb(90 10% 10% / 50%)
```

In the below examples, we set the same hues as in the `hsl()` examples, but we are adding whiteness and blackness to each hue via `hwb()` instead of saturation and lightness:

```
table {
  border: 1px solid black;
  font:
    16px "Open Sans",
    "Helvetica",
    "Arial",
    sans-serif;
  border-spacing: 0;
  border-collapse: collapse;
}

th,
td {
  border: 1px solid black;
  padding: 4px 6px;
  text-align: left;
}

th {
  background-color: hwb(0 75% 25%);
}
```

```
<table>
  <thead>
    <tr>
      <th scope="col">Color in HWB notation</th>
      <th scope="col">Example</th>
    </tr>
  </thead>
  <tbody></tbody>
</table>
```

```
const colors = [
  "hwb(90deg 50% 50%)",
  "hwb(90 0% 0%)",
  "hwb(0.15turn 25% 0%)",
  "hwb(0.15turn 10% 25%)",
  "hwb(1turn 10% 65%)",
  "hwb(270deg 75% 10%)",
];

const tbody = document.querySelector("tbody");
for (const color of colors) {
  const tr = document.createElement("tr");
  const td1 = document.createElement("td");
  td1.appendChild(document.createElement("code")).textContent = color;
  const td2 = document.createElement("td");
  td2.style.backgroundColor = color;
  tr.appendChild(td1);
  tr.appendChild(td2);
  tbody.appendChild(tr);
}
```

LCH and OkLCh: CIELAB and Oklab color spaces

While `hsl()` and `hwb()` are intuitive, they have a major drawback. With these functions, every fully-saturated hue angle (`hsl(<angle> 100% 50%)` or `hwb(<angle> 0% 0%)`) has the same lightness, but that is not how human vision or monitors work. Putting white text on fully saturated blue (`hsl(240deg 100% 50%)`) is legible, but that same text on fully saturated yellow (`hsl(60deg 100% 50%)`) will not only be illegible, but may hurt your user's eyes. In these color functions, the lightness of a color is relative to other colors, not to human perception. In reality, not all hues have the same max saturation.

Wouldn't it be fantastic if you could simply change the hue channel of a color on a site without making text illegible? You can with color functions in the CIELAB and Oklab color spaces.

The CIELAB and Oklab color spaces represent the entire range of colors that humans can see. CIE Lab color functions include `lch()` and `lab()`. Oklab color functions include `oklch()` and `oklab()`. The primary purpose of these models is that they are uniform so that a given distance between any two points in the color space should appear equally different to a viewer. Oklab is a color space that uses the same model

type as CIELAB but is built using additional numerical optimization steps, so the values are considered more accurate than CIELAB. Because of this optimization, hues are more perceptually uniform.

The `lch()` and `oklch()` functions use lightness (`L`), chroma (`C`), and hue (`H`), and are discussed further in this section. The `lab()` and `oklab()` functions work differently, using lightness (`L`), red/green-ness (along the `a`-axis), and yellow/blue-ness (along the `b`-axis). These axes are referred to as rectangular coordinates. The main benefit of these color functions is that the "lightness" is perceived lightness; it is the brightness of a color as perceived by the human eye rather than the lightness as compared to other colors.

Similar to the sRGB hue color functions, the hue (`h`) value in `lch()` and `oklch()` is a number, an angle, or the keyword `none` (equivalent to `0deg`) representing the color's `<hue>` angle. However, the colors at each angle value are not the same. The angles corresponding to particular hues differ across the sRGB, CIELAB (used by `lch()`), and Oklab (used by `oklch()`) color spaces.

The following gradients demonstrate the hue colors at every angle form `0deg` to `360deg` in the sRGB, CIE Lab, and OKlab color spaces:

```
<p>sRGB (<code>hsl()</code> and <code>hwb()</code>)</p>
<div id="srgb"></div>
<p>CIE Lab (<code>lch()</code>)</p>
<div id="lch"></div>
<p>OKLab (<code>oklch()</code>)</p>
<div id="oklch"></div>
<p>
  <label><input type="checkbox" /> Toggle greyscale</label>
</p>
```

```
div:has(~ p input:checked) {
  filter: grayscale(100%);
}
p {
  margin: 0;
}
div {
  height: 50px;
  margin-bottom: 10px;
}
#srgb {
  background: linear-gradient(
    to right,
    hsl(0deg 100% 50%),
    hsl(90deg 100% 50%),
    hsl(180deg 100% 50%),
    hsl(270deg 100% 50%),
    hsl(360deg 100% 50%)
  );
}
#lch {
  background: linear-gradient(
    to right,
    lch(50% 100% 0deg),
    lch(50% 100% 90deg),
    lch(50% 100% 180deg),
    lch(50% 100% 270deg),
    lch(50% 100% 360deg)
  );
}
#oklch {
  background: linear-gradient(
    to right,
    oklch(50% 100% 0deg),
    oklch(50% 100% 90deg),
    oklch(50% 100% 180deg),
    oklch(50% 100% 270deg),
    oklch(50% 100% 360deg)
  );
}
```

You may notice how the brightness of the latter gradients is more even across the spectrum of hues than the sRGB gradient. Select the checkbox in the example above to convert the hue gradient to greyscale to make this more apparent.

Note also how the spread of blue values in CIE Lab is longer than in the other two. This is the difference between `lch()` and `oklch()`. The `lch()` blue spread is due to a bug that shifts the chroma and lightness of hue values between `270deg` and `330deg`. This was resolved in the oklab color space and therefore the `oklch()` color notation.

As discussed above, the hue (`H`) in the `lch()` and `oklch()` is an `<angle>`, `number` or the keyword `none`. The `lightness` is either a `<percentage>` or for `lch()` a number between `0` and `100` and for `oklch()` a number between `0` and `1`, with `0` or `0%` being the complete lack of lightness, which is black.

The `C` is a `<number>`, `<percentage>`, or the keyword `none` (equivalent to `0%`) is the color's chroma, or the "amount of color". This is similar to the `S` saturation value of the `hsl()` color function. The value `0` is the complete lack of chroma or saturation; resulting in a gray between white and black inclusive, depending on the lightness value. The number values are theoretically unbounded, with `100%` being equal to `150` for `lch()` and `0.4` with `oklch()`.

Like the other color functions, there is also an optional alpha transparency value, preceded by a slash (`/`).

The example below shows the effect of changing the lightness value in the `lch()` and `oklch()` functions.

```
/* Varying shades of pink */
.container {
  display: grid;
  font-family: sans-serif;
  font-size: 14px;
  color: white;
  grid-template-columns: repeat(6, 1fr);
  gap: 4px;
}

.dark-text {
  color: lch(1% 40 0deg);
}

.container div {
  border-radius: 8px;
  padding: 8px 4px;
}
```

```
<div class="container"></div>
```

```
const container = document.querySelector(".container");
for (let l = 0; l <= 100; l += 10) {
  const div = document.createElement("div");
  const usedL = l === 0 ? 1 : l === 100 ? 99 : l;
  div.textContent = div.style.backgroundColor = `lch(${usedL}% 40 0)`;
  if (usedL >= 80) div.classList.add("dark-text");
  container.appendChild(div);
}
container.appendChild(document.createElement("div"));
for (let l = 0; l <= 100; l += 10) {
  const div = document.createElement("div");
  const usedL = l === 0 ? 1 : l === 100 ? 99 : l;
  div.textContent = div.style.backgroundColor = `oklch(${usedL}% 0.12 0)`;
  if (usedL >= 80) div.classList.add("dark-text");
  container.appendChild(div);
}
```

Lab and OKLab

The `lab()` functional notation expresses a given color in the CIE L*a*b* color space. The `oklab()` function defines colors in the OKLab color space. These functions represent the entire range of colors that humans can see by specifying the color's lightness (`L`), a red/green axis value (`a`), a blue/yellow axis value (`b`), and an optional alpha transparency value.

Similar to `lch()` and `oklch()`, the `lightness` is either:

- A `<percentage>`, with `0%` being completely black and `100%` being completely white.
- A number between `0` and `100` for `lab()` and `0` and `1` for `oklab()`, where `0` is completely black and `1`/`100` is completely white.

The `a` value is `<number>` between `-125` and `125` for `lab()` or `-0.4` and `0.4` for `oklab()`, a `<percentage>` between `-100%` and `100%`, or the keyword `none` (equivalent to `0%` in this case). This value specifies the color's distance along the a-axis in the color space, which defines how green (moving towards -100%) or red (moving towards +100%) the color is.

Note that these values are signed (allowing both positive and negative values) and theoretically unbounded, meaning that you can set values outside the ±125 or ±0.4 (±100%) limits. In practice, values cannot exceed ±160 or ±0.5, respectively.

The `b` value has the same constraints. It specifies the color's distance along the b-axis in the color space, which defines how blue (moving towards -100%) or yellow (moving towards +100%) the color is.

The following example demonstrates the effects of varying the `a` axis via a `lab()` function and the `b` axis via an `oklab()` function.

```
<div class="container"></div>
```

```
/* Varying shades of pink */
.container {
  display: grid;
  font-family: sans-serif;
  font-size: 14px;
  color: white;
  grid-template-columns: repeat(5, 1fr);
  gap: 4px;
}
.container div {
  border-radius: 8px;
  padding: 8px 4px;
}
```

```
const container = document.querySelector(".container");

for (let a = -100; a <= 100; a += 25) {
  const div = document.createElement("div");
  div.textContent = div.style.backgroundColor = `lab(50% ${a}% 0)`;
  container.appendChild(div);
}
container.appendChild(document.createElement("div"));
for (let b = -4; b <= 4; b++) {
  const div = document.createElement("div");
  div.textContent = div.style.backgroundColor = `oklab(50% 0 ${b / 10})`;
  container.appendChild(div);
}
```

Additional color functional notations

The <code>color()</code> function

If you want explicit control over color spaces when defining colors, you can use the `color()` function.

This is useful to describe a color for high-definition devices with wider color gamuts. For example, if you wanted to show the `display-p3 0 0 1` color, which is outside of the sRGB gamut, you could use a `@media color-gamut` at-rule to detect if the client's hardware supports colors in this range before trying to use it:

```
.vibrant {
  background-color: color(srgb 0 0 1);
}

@media (color-gamut: p3) {
  .vibrant {
    background-color: color(display-p3 0 0 1);
    /* Equivalent to out-of-gamut color(srgb 0 0 1.042) */
  }
}
```

Understanding `color()` is important when it comes to relative colors, discussed next. The older sRGB color notations discussed above — `hsl()`, `hwb()`, and `rgb()`— do not express the full spectrum of visible colors, while the `color()` function supports a much wider color gamut. As a result, when using the older functions types to define relative colors, the output color returned by querying `HTMLElement.style` property or the `CSSStyleDeclaration.getPropertyValue()` method will be a `color(srgb ...)` value.

To see an example of converting the `rgb()`, `hsl()`, `hwb()`, and other color formats, check out our color format converter tool.

Relative colors

Every color function listed above can be used to define **relative colors**, which allows `<color>` values to be defined relative to other existing colors, rather than defining a color value from scratch each time. This powerful feature enables the creation of complements to existing colors — such as lighter, darker, saturated, semi-transparent, or inverted variants of an original color. Relative colors provide an effective mechanism to create palettes and define color adjustments. See each color function page to learn more about their relative syntaxes.

As noted above, when using `rgb()`, `hsl()`, or `hwb()` to output a relative color, the output color will be a `color()` function in the `srgb` color space.

color-mix() function

The `color-mix()` function takes two color values of any syntax mentioned above, optionally with proportional percent values for each color, and returns the result of mixing them in a given colorspace by a given amount.

light-dark() function

The `light-dark()` function lets you specify two color values for a property intended for use in light and dark color schemes, respectively. Which one is set depends on whether the developer has set or the user has requested a light or dark color scheme. This is a shortcut function, allowing you to achieve the same results as the `prefers-color-scheme` media feature query but with less code.

Using color wisely

Choosing the right colors for a website can be tricky, especially if you aren't well-grounded in art, design, or at least basic color theory. The wrong color choice can render your site unattractive, or worse, leave the content unreadable due to problems with contrast or conflicting colors. Using the wrong colors can result in your content being outright unusable by people with certain vision problems, particularly color blindness.

Finding the right colors

There are tools and processes available to help you pick a good color scheme. While they can't replace having a good designer helping you make these decisions, they can get you started.

Base color

The first step is to choose your **base color**. This color represents your website or its subject matter. Just as we associate green with the beverage Mountain Dew blue with the sky or the ocean, choosing an appropriate base color to represent your site is a good place to start. There are plenty of ways to select a base color; a few ideas include:

- A color that is naturally associated with the topic of your content, such as the existing color identified with a product or idea or a color representative of the emotion you wish to convey.
- A color that comes from imagery associated with your subject matter. If you're creating a website about a given item or product, choose a color that's physically present on that item.
- Browse websites that let you look at lots of existing color palettes and images to find inspiration.

Several useful browser extensions can help pick base colors. For example, the ColorZilla browser extension provides an eyedropper tool for picking colors from any webpage. It can also take averages of the colors of an area of a page.

An "average color" grab is useful because sometimes what may look like a solid block of color might actually be multiple related colors, such as grabbing the blue in a photograph of an ocean or the sky. A single pixel of blue selected from a photo may result in a color that looks out of place.

Fleshing out the palette

Once you have decided on your base color, the next step is to build a palette of appropriate colors to use alongside it. Several tools are available to apply color theory to your base color and output appropriate added colors. Online tools, like the free Adobe Color CC online color wheel can help you pick an accessible color palette.

Many of these tools can also apply filters to your palette so you can see what they look like to people with various forms of color blindness. See Color and accessibility for a brief explanation of why this matters.

When designing your palette, you'll probably also need to supplement it with some core neutral colors such as white (or nearly white), black (or nearly black), and one or more shades of gray.

> **Note:** Usually, you are better off using the smallest number of colors possible. Using color to highlight important content rather than adding color to everything will have more impact and your content will be more readable.

Color theory resources

A full review of color theory is beyond the scope of this article, however, there are plenty of articles about color theory available. We found the following resources particularly useful:

Color Science (Khan Academy in association with Pixar)

> An online course that introduces concepts such as what color is, how it's perceived, and how to use colors to express ideas. Presented by Pixar artists and designers.

Color theory on Wikipedia

> Wikipedia's entry on color theory has great information from a technical perspective. It likely won't help your color selection process, but is still full of useful information.

Color and accessibility

Make sure your content is accessible. There are several ways color can create an accessibility problem. Improper or careless use of color can result in a website or app that a percentage of your target audience may not be able to use adequately, resulting in lost traffic, lost business, and possibly even a public relations problem or a lawsuit. So it's important to consider your use of color carefully.

It's important to understand color and luminance and to always consider color blindness and vestibular disorders. There are several kinds; the most common is red-green color blindness, which causes people to be unable to differentiate between the colors red and green. There are others, too, ranging from an inability to tell the difference between certain colors to the total inability to see color at all. There are even color and animation combinations that can lead your photosensitive users to experience seizures.

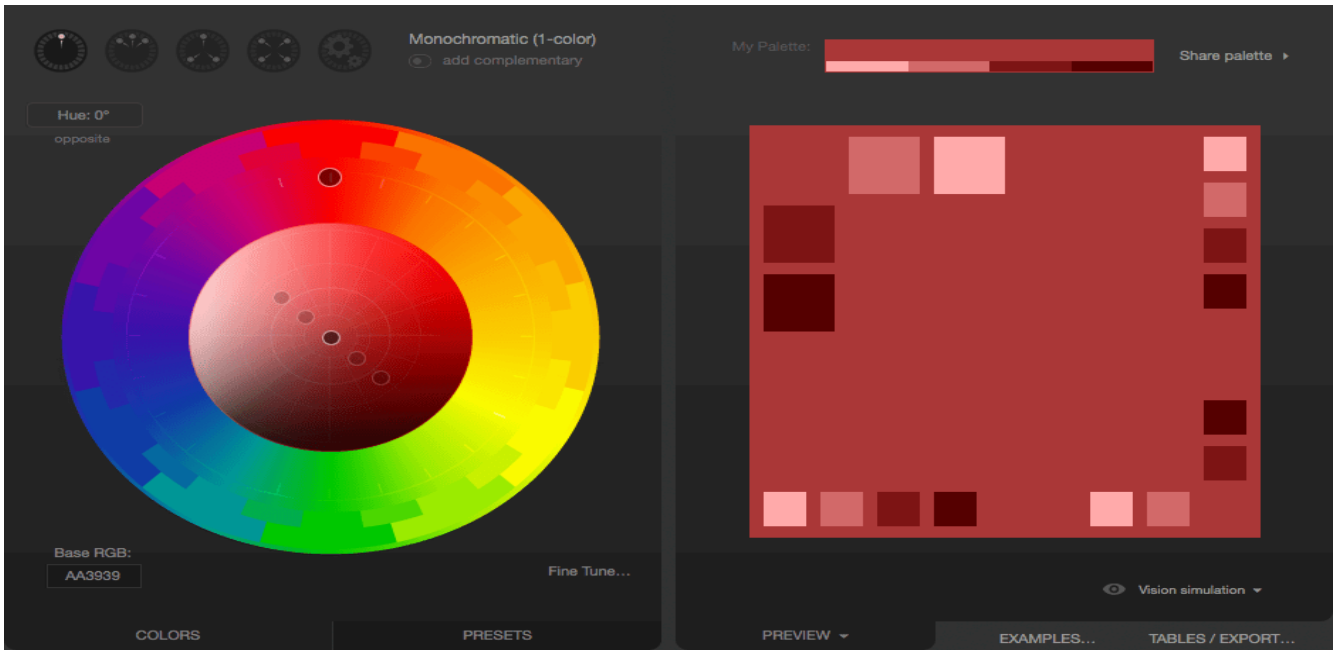
While higher color contrast is often a good thing when it comes to accessibility, when animating, especially rapidly, reducing color contrast on animating elements reduces seizure risk. If you include animations, use the `prefers-reduced-motion` `@media` query feature to reduce animations for users who have selected that preference.

That said, ensure you have enough color contrast between your background and foreground content to ensure legibility. Also, never use color as the only way to convey information. If, for example, you indicate the success of an operation with a green border around the associated UI element, and failure with a red border, users with red-green color blindness won't be able to use your site properly. Instead, use text and color indicators together to include those users. For example, a green check mark and a red cross mark would be better.

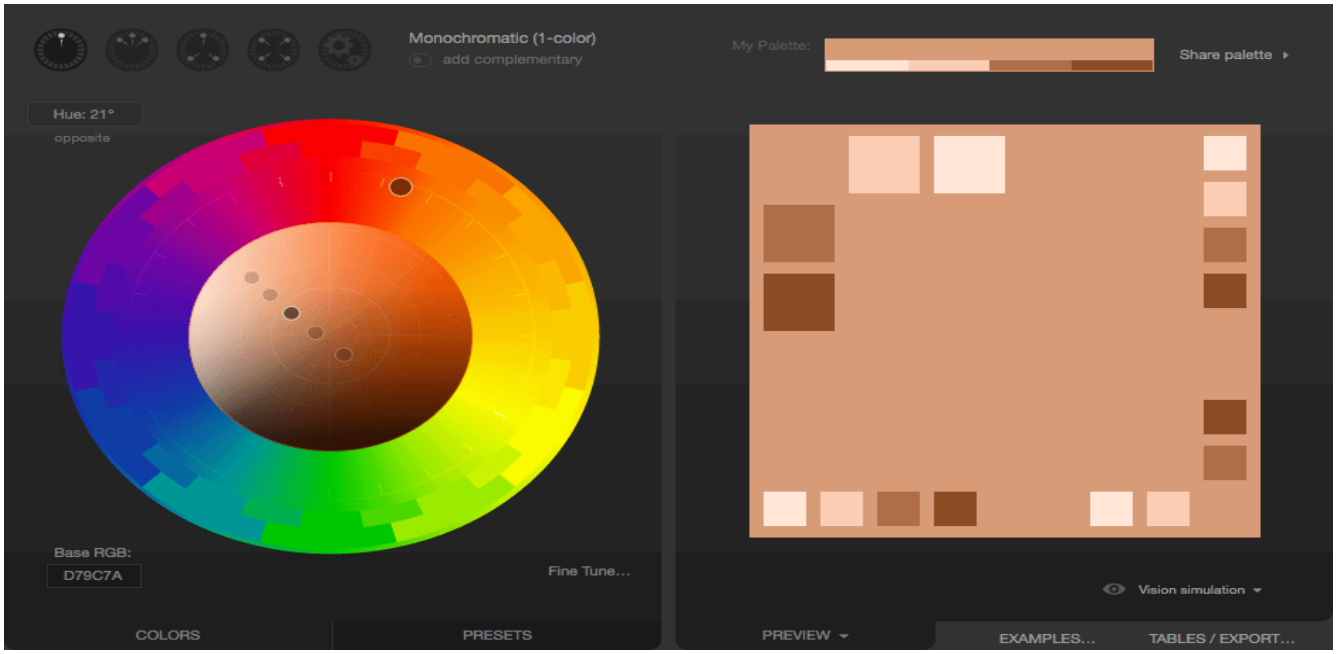
Palette design example

In this example, we will create an appropriate color palette for a website for a game that takes place on the planet Mars. A Google search for photos of Mars will output several color photos.

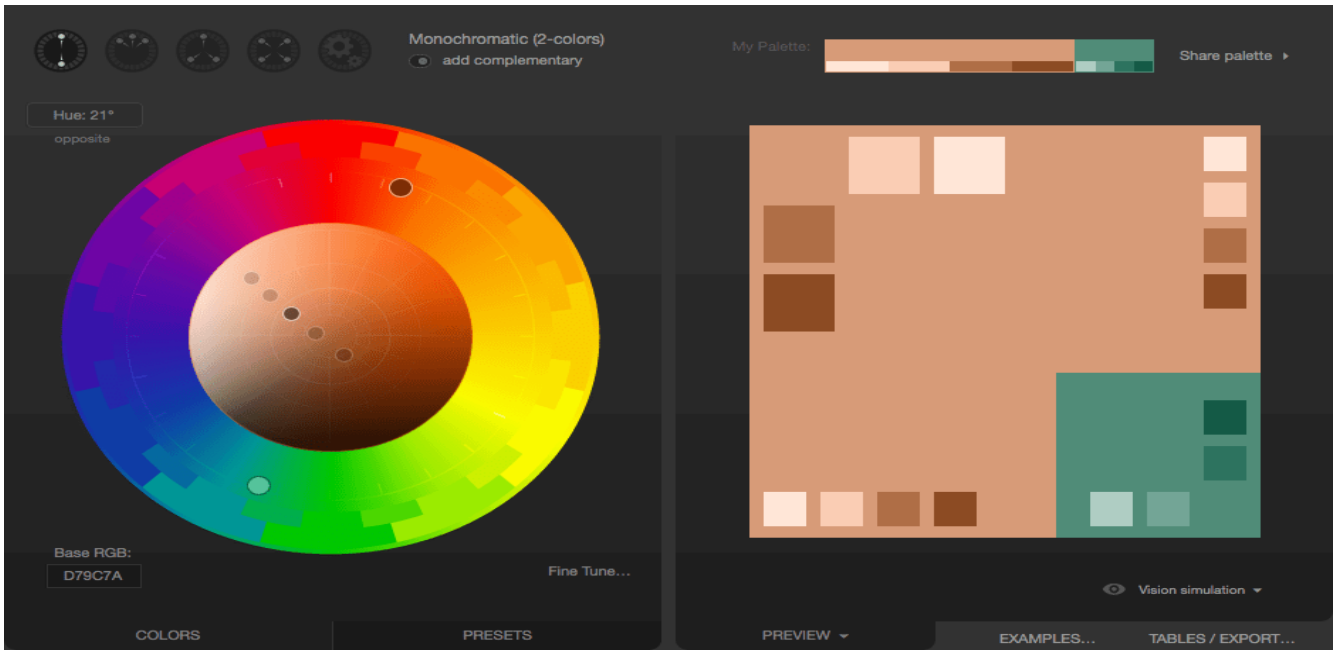
Use a color picker tool to select a color sample for the base color. For this example, we've selected `#D79C7A`, which is a rusty orange-red color. We can use Paletton to come up with the other colors for our palette. Upon opening Paletton, we see:



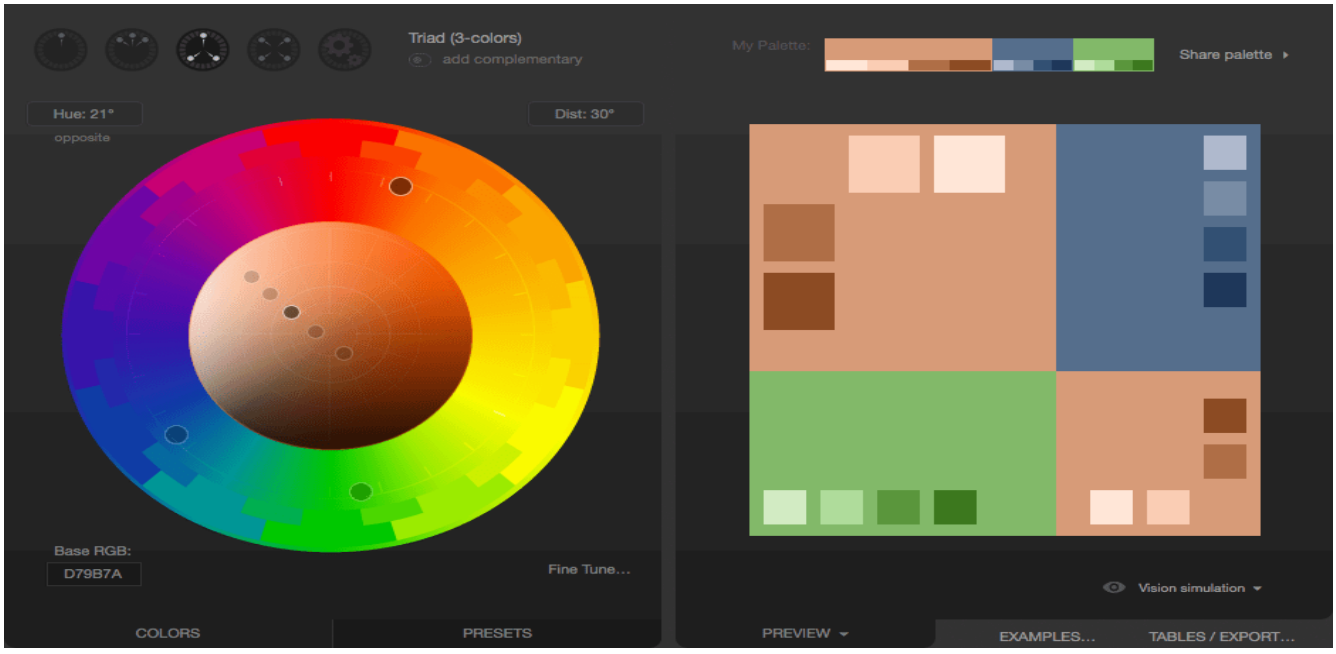
Next, we enter our color's hex code (`D79C7A`) into the "Base RGB" box at the bottom-left corner of the tool:



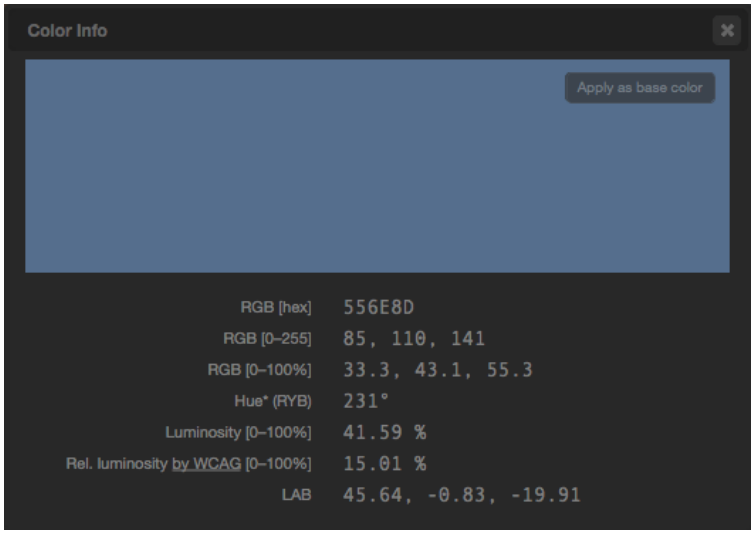
We now see a monochromatic palette based on the color we picked from the Mars photo. If you need related colors, these are likely good options. To find an accent color that pop alongside the base color, we click the "add complementary" toggle underneath the menu that lets you select the palette type. The default was "Monochromatic". Paletton computes an appropriate accent color; clicking on the accent color in the bottom-right corner tells us that this color is `#508D7C`.



If the proposed color doesn't work for your needs, you can change the color scheme. For example, if the proposed greenish-blue color doesn't work, select the Triad color scheme icon, which results in the following:



Click on the grayish blue in the top-right. The color is `#556E8D`. This can be used as an accent color to make things stand out, such as for headlines, tabs highlights, or other indicators on the site:



Now we have our base color and our accent. We also have a few complementary shades of both, which can be used to create gradients or as an accent color to indicate focus, such as for link hover states. The colors can be exported in several formats for you to use.

You should also select neutral colors. Find a color that provides enough contrast for your text to be crisp and readable while ensuring it isn't harsh for the eyes. If the contrast is too low, your text will be washed out by the background, leaving it unreadable, but if your contrast is too high, the user may find your site garish and unpleasant to look at.

Color, backgrounds, contrast, and printing

Your site may look very different when printed from what the user sees on their screen. When printing your page, the user may select to print in black and white only. Most browsers, by default, remove background colors and images when printing documents.

What matters most is usually the text itself, but if your background colors and images have been selected carefully and/or are crucial to the usefulness of the content, you can use the CSS `print-color-adjust` property to tell the browser that it should not make adjustments to the appearance of content.

The default value of `print-color-adjust: economy`, indicates that the browser is allowed to make appearance changes as it deems necessary to try to optimize the legibility and/or print economy of the content, given the type of output device the document is being drawn onto.

You can set `print-color-adjust: exact` to tell the browser that the element or elements on which you use it have been designed specifically to best work with the colors and images left as they are. With this set, the browser won't tamper with the appearance of the element on which this value is applied, and will draw it as indicated by your CSS.

> **Note:** There is no guarantee, though, that `print-color-adjust: exact` will result in your CSS being used exactly as given. If the browser provides user preferences to change the output (such as a "don't print backgrounds" checkbox in a print dialog box), that overrides the value of `print-color-adjust`.

Using relative colors

The CSS colors module defines **relative color syntax**, which allows a CSS `<color>` value to be defined relative to another color. This is a powerful feature that enables the programmatic creation of complements to existing colors — such as lighter, darker, saturated, semi-transparent, or inverted variants — enabling more effective color palette creation.

This article explains relative color syntax, shows what the different options are, and looks at some illustrative examples.

General syntax

A relative CSS color value has the following general syntax structure:

```
color-function(from origin-color channel1 channel2 channel3)
color-function(from origin-color channel1 channel2 channel3 / alpha)

/* color space included in the case of color() functions */
color(from origin-color colorspace channel1 channel2 channel3)
color(from origin-color colorspace channel1 channel2 channel3 / alpha)
```

Relative colors are created using the same color functions as absolute colors, but with different parameters:

1. Include a basic color function (represented by *`color-function()`* above) such as `rgb()`, `hsl()`, etc. Which one you pick depends on the color model you want to use for the relative color you are creating (the **output color**).
2. Pass in the **origin color** (represented above by *`origin-color`*) your relative color will be based on, preceded by the `from` keyword. This can be any valid `<color>` value using any available color model including a color value contained in a CSS custom property, system colors, `currentColor`, or even another relative color.
3. In the case of the `color()` function, include the *`colorspace`* of the output color.
4. Provide an output value for each individual channel. The output color is defined after the origin color — represented above by the *`channel1`*, *`channel2`*, and *`channel3`* placeholders. The channels defined here depend on the color function you are using for your relative color. For example, if you are using `hsl()`, you would need to define the values for hue, saturation, and lightness. Each channel value can be a new value, the same as the original value, or a value relative to the channel value of the origin color.
5. Optionally, an `alpha` channel value of type `<alpha-value>` for the output color can be defined, preceded by a slash (`/`). If the `alpha` channel value is not explicitly specified, it defaults to the alpha channel value of the *`origin-color`* (not 100%, which is the case for absolute color values).

The browser converts the origin color to a syntax compatible with the color function then destructures it into component color channels (plus the `alpha` channel if the origin color has one). These are made available as appropriately-named values inside the color function — `r`, `g`, `b`, and `alpha` in the case of the `rgb()` function, `l`, `a`, `b`, and `alpha` in the case of the `lab()` function, `h`, `w`, `b`, and `alpha` in the case of `hwb()`, etc. — that can be used to calculate new output channel values.

Let's look at relative color syntax in action. The below CSS is used to style two `<div>` elements, one with an absolute background color — `red` — and one with a relative background color created with the `rgb()` function, based on the same `red` color value:

```
<div id="container">
  <div class="item" id="one"></div>
  <div class="item" id="two"></div>
</div>
```

```
#container {
  display: flex;
  width: 100vw;
  height: 100vh;
  box-sizing: border-box;
}

.item {
  flex: 1;
  margin: 20px;
}
```

```
#one {
  background-color: red;
}

#two {
  background-color: rgb(from red 200 g b / alpha);
}
```

The output is as follows:

The relative color uses the `rgb()` function, which takes `red` as the origin color, converts it to an equivalent `rgb()` color (`rgb(255 0 0)`) and then defines the new color as having a red channel of value `200` and green, blue and alpha channels with a value the same as the origin color (it uses the `g` and `b` values made available inside the function by the browser, which are both equal to `0`, and the `alpha` is `100%`).

This results in an output of `rgb(200 0 0)` — a slightly darker red. If we had specified a red channel value of `255` (or just the `r` value), the resulting output color would be exactly the same as the input value. The browser's final output color (the computed value) is an sRGB `color()` value equivalent to `rgb(200 0 0)` — `color(srgb 0.784314 0 0)`.

> **Note:** As mentioned above, when calculating a relative color the first thing the browser does is to convert the provided origin color (`red` in the above example) into a value compatible with the color function being used (in this case, `rgb()`). This is done so that the browser is able to calculate the output color from the origin color. While the calculations are performed relative to the color function used, the actual output color value depends on the color's color space:
>
> - Older sRGB color functions cannot express the full spectrum of visible colors. The output colors of (`hsl()`, `hwb()`, and `rgb()`) are serialized to `color(srgb)` to avoid these limitations. That means that querying the output color value via the `HTMLElement.style` property or the `CSSStyleDeclaration.getPropertyValue()` method returns the output color as a `color(srgb ...)` value.
> - For more recent color functions (`lab()`, `oklab()`, `lch()`, and `oklch()`), relative color output values are expressed in the same syntax as the color function used. For example, if a `lab()` color function is being used, the output color will be a `lab()` value.

All the following lines produce an equivalent output color:

```
red
rgb(255 0 0)
rgb(from red 255 0 0)
rgb(from red 255 0 0 / 1)
rgb(from red 255 0 0 / 100%)

rgb(from red 255 g b)
rgb(from red r 0 0)
rgb(from red r g b / 1)
rgb(from red r g b / 100%)

rgb(from red r g b)
rgb(from red r g b / alpha)

/* With `red`, the g and b are the same, making them interchangeable */
rgb(from red r g g)
rgb(from red r b b)
rgb(from red 255 g g)
rgb(from red 255 b b)
```

Syntax flexibility

There is an important distinction to be made between the destructured origin color channel values made available in the function, and the channel values of the output color set by the developer.

To reiterate, when a relative color is defined, the channel values of the origin color are made available in the function to use when defining the output color channel values. The following example defines a relative color using an `rgb()` function and uses the origin color channel values (made available as `r`, `g`, and `b`) for the output channel values, meaning that the output color is the same as the origin color:

```
rgb(from red r g b)
```

However, when specifying the output values, you don't need to use the origin color channel values at all. You need to provide the output channel values in the right order (e.g., red, then green, then blue in the case of `rgb()`), but they can be any values you wish provided they are valid values for those channels. This gives relative CSS colors a high degree of flexibility.

For example, if you wanted to, you could specify absolute values like those shown below, transforming `red` into `blue`:

```
rgb(from red 0 0 255)
/* output color is equivalent to rgb(0 0 255), full blue */
```

> **Note:** If you are using relative color syntax but outputting the same color as the origin color or a color not based on the origin color at all, you are not really creating a relative color. You'd be unlikely to ever do this in a real codebase, and would probably just use an absolute color value instead. But, we felt it useful to explain that you *can* do this with relative color syntax, as a starting point for learning about it.

You can even mix up or repeat the provided values. The following takes a slightly darker red as an input and outputs a light gray color — the output color's `r`, `g`, and `b` channels are all set to the origin color's `r` channel value:

```
rgb(from rgb(200 0 0) r r r)
/* output color is equivalent to rgb(200 200 200), light gray */
```

The following uses the origin color's channel values for the output color's `r`, `g`, and `b` channel values, but in reverse order:

```
rgb(from rgb(200 170 0) b g r)
/* output color is equivalent to rgb(0 170 200) */
```

Color functions that support relative colors

In the section above we only saw relative colors defined via the `rgb()` function. However, relative colors can be defined using any modern CSS color function — `color()`, `hsl()`, `hwb()`, `lab()`, `lch()`, `oklab()`, `oklch()`, or `rgb()`. The general syntax structure is the same in each case, although the origin color values have different names appropriate for the function being used.

Below you can find relative color syntax examples for each color function. Each case is the simplest possible, with the output color channel values exactly matching the origin color channel values:

```
/* color() with and without alpha channel */
color(from red a98-rgb r g b)
color(from red a98-rgb r g b / alpha)

color(from red xyz-d50 x y z)
color(from red xyz-d50 x y z / alpha)

/* hsl() with and without alpha channel */
hsl(from red h s l)
hsl(from red h s l / alpha)

/* hwb() with and without alpha channel */
hwb(from red h w b)
hwb(from red h w b / alpha)

/* lab() with and without alpha channel */
lab(from red l a b)
```

```
lab(from red l a b / alpha)

/* lch() with and without alpha channel */
lch(from red l c h)
lch(from red l c h / alpha)

/* oklab() with and without alpha channel */
oklab(from red l a b)
oklab(from red l a b / alpha)

/* oklch() with and without alpha channel */
oklch(from red l c h)
oklch(from red l c h / alpha)

/* rgb() with and without alpha channel */
rgb(from red r g b)
rgb(from red r g b / alpha)
```

It is worth mentioning again that the color system of the origin color doesn't need to match the color system being used to create the output color. Again, this provides a lot of flexibility. Generally you won't be interested in and might not even know the system the origin color is defined in (you might just have a custom property value to manipulate). You'll just want to input a color and, for example, create a lighter variant of it by putting it into an `hsl()` function and varying the lightness value.

Using custom properties

When creating a relative color, you can use values defined in CSS custom properties both for the origin color and within the output color channel value definitions. Let's look at an example.

In the below CSS we define two custom properties:

- `--base-color` contains our base brand color — `purple`. Here we are using a named color keyword, but relative colors can accept any color syntax for the origin color.
- `--standard-opacity` contains the standard brand opacity value that we want to apply to semi-transparent boxes — `0.75`.

We then give two `<div>` elements a background color. One is given an absolute color — our `--base-color` brand purple. The other one is given a relative color equal to our brand purple, transformed to add an alpha channel equal to our standard opacity value.

```
<div id="container">
  <div class="item" id="one"></div>
  <div class="item" id="two"></div>
</div>
```

```
#container {
  display: flex;
  width: 100vw;
  height: 100vh;
  box-sizing: border-box;
  background-image: repeating-linear-gradient(
    45deg,
    white,
    white 24px,
    black 25px,
    black 50px
  );
}

.item {
  flex: 1;
  margin: 20px;
}
```

```
:root {
  --base-color: purple;
  --standard-opacity: 0.75;
}

#one {
  background-color: var(--base-color);
}

#two {
  background-color: hwb(from var(--base-color) h w b / var(--standard-opacity));
}
```

The output is as follows:

Using math functions

You can use CSS math functions such as `calc()` to calculate values for the output color channels. Let's look at an example.

The below CSS is used to style three `<div>` elements with different background colors. The middle one is given an unmodified `--base-color`, while the left and right ones are given lightened and darkened variants of that `--base-color`. These variants are defined using relative colors — the `--base-color` is passed into an `lch()` function, and the output color has its lightness channel modified to achieve the desired effect via a `calc()` function. The lightened color has 20% added to the lightness channel, and the darkened color has 20% subtracted from it.

```
<div id="container">
  <div class="item" id="one"></div>
  <div class="item" id="two"></div>
  <div class="item" id="three"></div>
</div>
```

```
#container {
  display: flex;
  width: 100vw;
  height: 100vh;
  box-sizing: border-box;
}

.item {
  flex: 1;
  margin: 20px;
}
```

```
:root {
  --base-color: orange;
}

#one {
  background-color: lch(from var(--base-color) calc(l + 20) c h);
}

#two {
  background-color: var(--base-color);
}

#three {
  background-color: lch(from var(--base-color) calc(l - 20) c h);
}
```

The output is as follows:

Manipulating the alpha channel

This example demonstrates changing the alpha channel of a named color. Here, we have an item wrapped in a container that both have a `teal` background. To distinguish between the backgrounds, we vary the alpha channel value using the relative color feature, the `calc()` function, and a custom property.

```
<div class="container">
  <div class="item"></div>
</div>
```

```
.container {
  padding: 60px;
}

.item {
  height: 60px;
}
```

```
div {
  background-color: rgb(
    from teal r g b / calc(alpha * var(--alpha-multiplier))
  );
}

.container {
  --alpha-multiplier: 0.3;
}

.item {
  --alpha-multiplier: 1;
}
```

The alpha channel is referenced using the `alpha` keyword. In this case, the `calc(alpha * var(--alpha-multiplier))` expression modifies the alpha channel value by multiplying `alpha` with the `--alpha-multiplier` custom property value. The container gets a semitransparent background because of the multiplier of `0.3` is less than `1.0`.

The output is as follows:

Channel values resolve to <code><number></code> values

To make channel value calculations work in relative colors, all origin color channel values resolve to appropriate `<number>` values. For example, in the `lch()` examples above, we are calculating new lightness values by adding or subtracting numbers from the origin color's `l` channel value. If we tried to do `calc(l + 20%)`, that would result in an invalid color — `l` is a `<number>` and cannot have a `<percentage>` added to it.

- Channel values originally specified as a `<percentage>` resolve to a `<number>` appropriate for the output color function.
- Channel values originally specified as a `<hue>` angle resolve to a number of degrees in a range of `0` to `360`, inclusive.

Check the different color function pages for the specifics of what their origin channel values resolve to.

Origin colors outside the sRGB gamut

Converting an origin color to the output color space does not clamp its channels to that space's usual range. In the following example, `color(display-p3 1 0.5 0.5)` is inside the Display P3 gamut but outside sRGB—its red channel, expressed on the `rgb()` scale, is approximately `273.88`, which is greater than `255`. The `background-color` calculation uses that out-of-range value, so the red value ends up as `272.88`. No clamping ever happens in this calculation. Whether the final background color can be rendered accurately depends on the display's capability.

```
.very-red {
  --origin: color(display-p3 1 0.5 0.5);
  background-color: rgb(from var(--origin) calc(r - 1) g b);
}
```

The absolute `rgb()` notation does clamp its arguments, so if you write `--origin: rgb(273.88 117.95 123.15)`, then the red channel would start at `255` and the background color's red channel would be `254`.

Checking for browser support

You can check that a browser supports relative color syntax by running it through a `@supports` at-rule.

For example:

```
@supports (color: hsl(from white h s l)) {
  /* safe to use hsl() relative color syntax */
}
```

Examples

> **Note:** You can find additional examples demonstrating the use of relative color syntax in the different functional notation types on their dedicated pages: `color()`, `hsl()`, `hwb()`, `lab()`, `lch()`, `oklab()`, `oklch()`, `rgb()`.

Color palette generator

This example allows you to choose a base color and a color palette type. The browser will then show an appropriate palette of colors based on the chosen base color. The color palette choices are as follows:

- **Complementary**: Includes two colors that are at opposite sides of a color wheel, or to put it another way, *opposite hues* (see the `<hue>` data type for more information on hues and color wheels). The two colors are defined as a base color, and the base color with hue channel +180 degrees.
- **Triadic**: Includes three colors equal distances apart around the color wheel. The three colors are defined as a base color, base color with hue channel -120 degrees, and base color with hue channel +120 degrees.
- **Tetradic**: Includes four colors equal distances apart around the color wheel. The four colors are defined as a base color, and base color with hue channel +90, +180, and +270 degrees.
- **Monochrome**: Includes multiple colors with the same hue but varying lightness values. In our example we've defined five colors in a monochrome palette — base color, and base color with lightness channel -20, -10, +10, and +20.

HTML

The full HTML is included below for reference. The most interesting parts are as follows:

- The `--base-color` custom property is stored as an inline `style` on the `<div>` element with the ID of `container`. We've placed it there so we can update the value using JavaScript. We've provided an initial value of `#ff0000` (`red`) to show a color palette based on that value when the example loads. Note that normally we'd probably set this on the `<html>` element, but the MDN live sample was removing it when rendering.
- The base color picker is created using an `<input type="color">` control. When a new value is set in this control, the `--base-color` custom property is set to this value using JavaScript, which in turn generates a new color palette. All the displayed colors are relative colors based on `--base-color`.
- The set of `<input type="radio">` controls enables choosing a color palette type to generate. When a new value is chosen here, JavaScript is used to set a new class on the `container` `<div>` to represent the chosen palette. In the CSS, descendant selectors are used to target the child `<div>`s (e.g., `.comp :nth-child(1)`) so they can have the correct colors applied to them and hide the unused `<div>` nodes.
- The `container` `<div>` containing the child `<div>`s that display the colors of the generated palette. Note that an initial class of `comp` is set on it, so that the page will display a complementary color scheme when first loaded.

```
<div>
  <h1>Color palette generator</h1>
  <form>
    <div id="color-picker">
      <label for="color">Select a base color:</label>
      <input type="color" id="color" name="color" value="#ff0000" />
    </div>
    <div>
      <fieldset>
        <legend>Select a color palette type:</legend>

        <div>
          <input
            type="radio"
            id="comp"
            name="palette-type"
            value="comp"
            checked />
          <label for="comp">Complementary</label>
        </div>

        <div>
          <input
            type="radio"
            id="triadic"
            name="palette-type"
            value="triadic" />
          <label for="triadic">Triadic</label>
        </div>

        <div>
          <input
            type="radio"
            id="tetradic"
            name="palette-type"
            value="tetradic" />
          <label for="tetradic">Tetradic</label>
        </div>

        <div>
          <input
            type="radio"
            id="monochrome"
            name="palette-type"
            value="monochrome" />
          <label for="monochrome">Monochrome</label>
        </div>
      </fieldset>
    </div>
  </form>
  <div id="container" class="comp">
    <div></div>
    <div></div>
    <div></div>
    <div></div>
    <div></div>
  </div>
</div>
```

CSS

Below we are only showing the CSS that sets the palette colors. Note how, in each case, descendant selectors are used to apply the correct `background-color` to each child `<div>` for the chosen palette. We care more about the position of the `<div>`s in the source order than the type of element, so we have used `:nth-child` to target them.

In the last rule we've used the general sibling selector (`~`) to target the unused `<div>` elements in each palette type, setting `display: none` to stop them being rendered.

The colors themselves include the `--base-color`, plus relative colors derived from that `--base-color`. The relative colors use the `lch()` function — passing in the origin `--base-color` and defining an output color with an adjusted lightness or hue channel as appropriate.

```
html {
  font-family: sans-serif;
}

body {
  margin: 0;
}
```

```
h1 {
  margin-left: 16px;
}

/* Basic form styling */

#color-picker {
  margin-left: 16px;
  margin-bottom: 20px;
}

#color-picker label,
legend {
  display: block;
  font-size: 0.8rem;
  margin-bottom: 10px;
}

input[type="color"] {
  width: 200px;
  display: block;
}

fieldset {
  display: flex;
  gap: 20px;
  border: 0;
}

/* Palette container styling */

#container {
  /* Default value */
  --base-color: red;

  display: flex;
  width: 100vw;
  height: 250px;
  box-sizing: border-box;
}

#container div {
  flex: 1;
}
```

```
/* Complementary colors */
/* Base color, and base color with hue channel +180 degrees */

.comp :nth-child(1) {
  background-color: var(--base-color);
}

.comp :nth-child(2) {
  background-color: lch(from var(--base-color) l c calc(h + 180));
}

/* Use @supports to add in support old syntax that requires deg units
   to be specified in hue calculations. This is required for Safari 16.4+. */
@supports (color: lch(from red l c calc(h + 180deg))) {
  .comp :nth-child(2) {
    background-color: lch(from var(--base-color) l c calc(h + 180deg));
  }
}

/* Triadic colors */
/* Base color, base color with hue channel -120 degrees, and base color */
/* with hue channel +120 degrees */

.triadic :nth-child(1) {
  background-color: var(--base-color);
}

.triadic :nth-child(2) {
  background-color: lch(from var(--base-color) l c calc(h - 120));
}

.triadic :nth-child(3) {
  background-color: lch(from var(--base-color) l c calc(h + 120));
}

/* Use @supports to add in support old syntax that requires deg units
   to be specified in hue calculations. This is required for Safari 16.4+. */
@supports (color: lch(from red l c calc(h + 120deg))) {
  .triadic :nth-child(2) {
    background-color: lch(from var(--base-color) l c calc(h - 120deg));
  }

  .triadic :nth-child(3) {
    background-color: lch(from var(--base-color) l c calc(h + 120deg));
  }
}

/* Tetradic colors */
/* Base color, and base color with hue channel +90, +180, and +270 degrees */

.tetradic :nth-child(1) {
  background-color: var(--base-color);
}

.tetradic :nth-child(2) {
  background-color: lch(from var(--base-color) l c calc(h + 90));
}
```

```
.tetradic :nth-child(3) {
  background-color: lch(from var(--base-color) l c calc(h + 180));
}

.tetradic :nth-child(4) {
  background-color: lch(from var(--base-color) l c calc(h + 270));
}

/* Use @supports to add in support old syntax that requires deg units
   to be specified in hue calculations. This is required for Safari 16.4+. */
@supports (color: lch(from red l c calc(h + 90deg))) {
  .tetradic :nth-child(2) {
    background-color: lch(from var(--base-color) l c calc(h + 90deg));
  }

  .tetradic :nth-child(3) {
    background-color: lch(from var(--base-color) l c calc(h + 180deg));
  }

  .tetradic :nth-child(4) {
    background-color: lch(from var(--base-color) l c calc(h + 270deg));
  }
}

/* Monochrome colors */
/* Base color, and base color with lightness channel -20, -10, +10, and +20 */

.monochrome :nth-child(1) {
  background-color: lch(from var(--base-color) calc(l - 20) c h);
}

.monochrome :nth-child(2) {
  background-color: lch(from var(--base-color) calc(l - 10) c h);
}

.monochrome :nth-child(3) {
  background-color: var(--base-color);
}

.monochrome :nth-child(4) {
  background-color: lch(from var(--base-color) calc(l + 10) c h);
}

.monochrome :nth-child(5) {
  background-color: lch(from var(--base-color) calc(l + 20) c h);
}

/* Hide unused swatches for each palette type */
.comp :nth-child(2) ~ div,
.triadic :nth-child(3) ~ div,
.tetradic :nth-child(4) ~ div {
  display: none;
}
```

An aside on `@supports` testing

In the example CSS you'll notice `@supports` blocks being used to provide different `background-color` values to browsers that support a previous draft specification of the relative color syntax. These are required because Safari's initial implementation was based on an older version of the spec in which origin color channel values resolved to `<number>`s or other unit types depending on the context. This meant that values sometimes required units when performing additions and subtractions, which created confusion. In newer implementations, origin color channel values always resolve to an equivalent `<number>` value, which means calculations are always done with unitless values.

Note how the support test in each case is done using any color declaration — `color: lch(from red l c calc(h + 90deg))` for example — not necessarily the actual value that we need to vary for other browsers. When testing complex values like these, you should use the simplest possible declaration that still contains the syntactic difference you want to test for.

Including a custom property in the `@supports` test doesn't work — the test always comes back as positive regardless of what value the custom property is given. This is because a custom property value only becomes invalid when assigned to be an invalid value (or part of an invalid value) of a regular CSS property. To work around this, in each test we have replaced `var(--base-color)` with the `red` keyword.

JavaScript

In the JavaScript, we:

- Add a `change` event listener to the radio buttons so that when one is selected, the `setContainer()` function runs. This function updates the `class` value of the `<div>` with `id="container"` with the value of the selected radio button so that the correct background colors will be applied to the child `<div>`s for the chosen palette type.
- Add an `input` event listener to the color picker control so that when a new color is selected, the `setBaseColor()` function runs. This function sets the `--base-color` custom property's value to the new color.

```
const form = document.forms[0];
const radios = form.elements["palette-type"];
const colorPicker = form.elements["color"];
const containerElem = document.getElementById("container");

for (const radio of radios) {
  radio.addEventListener("change", setContainer);
}

colorPicker.addEventListener("input", setBaseColor);

function setContainer(e) {
  const palType = e.target.value;
  console.log("radio changed");
  containerElem.setAttribute("class", palType);
}

function setBaseColor(e) {
  console.log("color changed");
  containerElem.style.setProperty("--base-color", e.target.value);
}
```

Results

The output is as follows. This starts to show the power of relative CSS colors — we are defining multiple colors and generating palettes that are updated live by adjusting a single custom property.

Live UI color scheme updater

This example shows a card containing a heading and text, but with a twist — below the card is a slider (`<input type="range">`) control. When its value is changed, JavaScript is used to set a `--hue` custom property value to the new slider value.

This in turn adjusts the color scheme for the entire UI:

- The `--base-color` value is a relative color with its hue channel set to the value of `--hue`.
- The other colors used in the design are relative colors based on `--base-color`. As a result, they change when the `--base-color` changes.

HTML

The HTML for the example is shown below.

- The `<main>` element acts as an outer wrapper to contain the rest of the content, allowing the card and form to be centered vertically and horizontally inside `<main>` as one unit.
- The `<section>` element contains the `<h1>` and `<p>` elements that define the card's content.
- The `<form>` element contains the (`<input type="range">`) control and its `<label>`.

```
<main>
  <section>
    <h1>A love of colors</h1>
    <p>
      Colors, the vibrant essence of our surroundings, are truly awe-inspiring.
      From the fiery warmth of reds to the calming coolness of blues, they bring
      unparalleled richness to our world. Colors stir emotions, ignite
      creativity, and shape perceptions, acting as a universal language of
      expression. In their brilliance, colors create a visually enchanting
      tapestry that invites admiration and sparks joy.
    </p>
  </section>
  <form>
    <label for="hue-adjust">Adjust the hue:</label>
    <input
      type="range"
      name="hue-adjust"
      id="hue-adjust"
      value="240"
      min="0"
      max="360" />
  </form>
</main>
```

CSS

In the CSS the `:root` has a default `--hue` value set on it, relative `lch()` colors to define the color scheme, plus a radial gradient that fills the whole body.

The relative colors are as follows:

- `--base-color`: The base color takes an origin color of `red` (although any full color would do) and adjusts its hue value to the value set in the `--hue` custom property.
- `--bg-color`: A much lighter variant of `--base-color`, intended to be used as a background. This is created by taking an origin color of `--base-color` and adding 40 to its lightness value.
- `--complementary-color`: A complementary color 180 degrees around the color wheel from `--base-color`. This is created by taking an origin color of `--base-color` and adding 180 to its hue value.

Now have a look at the rest of the CSS and take note of all the places where these colors are used. This includes backgrounds, borders, `text-shadow`, and even the `accent-color` of the slider.

> **Note:** For brevity, only the parts of the CSS relevant to relative color usage are shown.

```
html {
  font-family: sans-serif;
}

main {
  width: 80vw;
  margin: 2rem auto;
}

h1 {
  text-align: center;
  margin: 0;
  color: black;
  border-radius: 16px 16px 0 0;
  font-size: 3rem;
  letter-spacing: -1px;
}

p {
  line-height: 1.5;
  margin: 0;
  padding: 1.2rem;
}

form {
  width: fit-content;
  display: flex;
  margin: 2rem auto;
  padding: 0.4rem;
}
```

```
:root {
  /* Default hue value */
  --hue: 240;

  /* Relative color definitions */
  --base-color: lch(from red l c var(--hue));
  --bg-color: lch(from var(--base-color) calc(l + 40) c h);
  --complementary-color: lch(from var(--base-color) l c calc(h + 180));

  background: radial-gradient(ellipse at center, white 20%, var(--base-color));
}
```

```
/* Use @supports to add in support for --complementary-color with old
   syntax that requires deg units to be specified in hue calculations.
   This is required for in Safari 16.4+. */
@supports (color: lch(from red l c calc(h + 180deg))) {
  body {
    --complementary-color: lch(from var(--base-color) l c calc(h + 180deg));
  }
}

/* Box styling */

section {
  background-color: var(--bg-color);
  border: 3px solid var(--base-color);
  border-radius: 20px;
  box-shadow: 10px 10px 30px rgb(0 0 0 / 0.5);
}

h1 {
  background-color: var(--base-color);
  text-shadow:
    1px 1px 1px var(--complementary-color),
    -1px -1px 1px var(--complementary-color),
    0 0 3px var(--complementary-color);
}

/* Range slider styling */

form {
  background-color: var(--bg-color);
  border: 3px solid var(--base-color);
}

input {
  accent-color: var(--complementary-color);
}
```

JavaScript

The JavaScript adds an `input` event listener to the slider control so that when a new value is set, the `setHue()` function runs. This function sets a new inline `--hue` custom property value on the `:root` (the `<html>` element) that overrides the original default value we set in our CSS.

```
const rootElem = document.querySelector(":root");
const slider = document.getElementById("hue-adjust");

slider.addEventListener("input", setHue);

function setHue(e) {
  rootElem.style.setProperty("--hue", e.target.value);
}
```

Results

The output is shown below. Relative CSS colors are being used here to control the color scheme of an entire UI, which can be adjusted live as a single value is modified.

CSS compositing and blending

The **CSS compositing and blending** module defines how an element's background layers can be blended together, how an element can be blended with its container, and whether the element must create a new stacking context.

The properties in this CSS module can be used to define the blending mode that should be used, if any, to blend an element's background images and colors into a single background image. This module provides 16 blending modes. You can also define how an element's borders, background, and content, including text, emojis, and images, should be blended with the background of its container.

Compositing and blending in action

In this example, each box has a border, two striped background images, and a solid color background. The common background for all the boxes contains a pattern of circles. The three boxes in the second row are set to blend with the background of the container.

```
<section>
  <div><span>Normal, with no blending</span></div>
  <div><span>Multiplies colors</span></div>
  <div><span>Multiplies based on background color</span></div>
  <div>Normal, with no blending</div>
  <div>Multiplies colors</div>
  <div>Multiplies based on background color</div>
</section>
```

```
/* Creates a div with two offset striped background images and a background color. */
div {
  width: 200px;
  height: 200px;
  background-image:
    repeating-linear-gradient(45deg, red 0 15px, pink 15px 30px),
    repeating-linear-gradient(-45deg, blue 0 15px, lightblue 15px 30px);
  background-size: 150px 150px;
  background-repeat: no-repeat;
  background-position:
    top left,
    bottom right;
  background-color: palegoldenrod;
  text-align: center;
  padding-top: 150px;
```

```
  font-family: sans-serif;
  box-sizing: border-box;
  border: 5px solid black;
}
div:nth-of-type(3n + 1) {
  background-blend-mode: normal;
}
div:nth-of-type(3n + 2) {
  background-blend-mode: multiply;
}
div:nth-of-type(3n + 3) {
  background-blend-mode: overlay;
}
div:nth-of-type(n + 4) {
  mix-blend-mode: difference;
}
/* Put a pink background with transparent round holes that covers the
  entire element, and lay the examples in two rows with three columns each */
section {
  padding: 0.75em;
  background: radial-gradient(
    circle,
    transparent 0 20px,
    rgb(255 200 200) 20px
  );
  background-size: 60px 60px;
  background-position: center;
  display: inline-grid;
  grid-template-columns: 1fr 1fr 1fr;
  gap: 1em;
}
/* Make some of the text more legible */
span {
  background-color: #ffffff99;
}
```

Notice how the background, border, and the content are all impacted as a result of the blending. Click "Play" in the example above to see or edit the code for the animation in the MDN Playground.

CSS conditional rules

The **CSS conditional rules** module defines CSS media and support queries, enabling you to define styles that are only applied if specific conditions are met. The conditional rules defined in this module are based on device, user-agent, and viewport capabilities. With conditional rules, you can target CSS styles based on query values or browser and device features, independent of the document being rendered.

The first CSS conditional rules were media types specifying the intended destination medium for the linked styles, for example `screen` or `print`. These were set as the value of the HTML `<link>` and `<style>` elements' `media` attributes or as a comma-separated list of media types within an `@import` statement or at-rule. The ability to conditionally apply CSS rules has been greatly expanded since the CSS 2.1 and HTML 4.01 implementations that limited conditional queries to a few media types.

CSS conditional rules now include feature queries; the `@supports` at-rule enables targeting CSS styles based on a user-agent's CSS capabilities. Additional conditions include which selector, font-formats, and font-techs are supported.

The CSS conditional rules module also expands `@media` to enable nesting at-rules, with the related CSS media queries module removing unused media types and adding many media features and conditions that can be targeted.

The CSS container queries module defines similar conditional rules, but based on an element's parent rather than the viewport.

There are plans to further extend possible queries by adding the generalized conditional rule `@when` and the chained conditional rule `@else`. These two at-rules are not yet supported.

Reference

Properties

- `container`
- `container-name`
- `container-type`

At-rules and descriptors

- `@container`
  - `aspect-ratio`
  - `block-size`
  - `fallback`

        - `height`
        - `inline-size`
        - `orientation`
        - `scrollable`
        - `snapped`
        - `stuck`
        - `width`
- `@media`
- `@supports`

The CSS conditional rules module also introduces the `@else` and `@when` at-rules. Currently, no browsers support these features.

Functions

- `anchored()`
- `style()`
- `font-tech()`
- `font-format()`
- `scroll-state()`
- `selector()`
- `supports()`

The CSS conditional rules module also introduces a `media()` CSS function. Currently, no browsers support this feature.

data types

- `<container-name>`
- `<style-feature>`
- Container relative `<length>` units
- `<media-query>`
- `<supports-condition>`
- `<supports-feature>` (see `supports()`)

Interfaces

- `CSSConditionRule`
- `CSSMediaRule`
- `CSSSupportsRule`
- `supports()` method

Terms and glossary definitions

- Media
- Supports query (See feature query)

Using container scroll-state queries

Container scroll-state queries are a type of container query. Rather than selectively applying styles to descendant elements based on the container's size, scroll-state queries allow you to selectively apply styles to descendant elements based on the container's scroll state. This can include whether the container is partially scrolled, snapped to a scroll snap container ancestor, or positioned via `position: sticky` and stuck to a boundary of a scroll container ancestor.

This article explains how to use container scroll-state queries, walking through an example of each type. It assumes that you know the basics of container queries. If you are new to container queries, read CSS container queries before continuing.

Types of container scroll-state query

There are three `@container` descriptors you can use in a `scroll-state()` query:

- `scrollable`: Queries whether a container can be scrolled in the given direction via user-initiated scrolling (for example by dragging the scrollbar or using a trackpad gesture). In other words, is there any overflowing content in the given direction that can be scrolled to? This is useful for applying styling related to the scroll position of a scroll container. For example, you could display a hint that encourages people to scroll down and see more content when the scrollbar is up at the top, and hide it when the user has actually started scrolling.
- `scrolled`: Queries whether a container was most recently scrolled in the given direction. This allows you to selectively apply styles based on the user's scroll direction, for example a top menu bar that only displays when the user is scrolling upwards.
- `snapped`: Queries whether a container is going to be snapped to a scroll snap container ancestor along a given axis. This is useful for applying styles when an element is snapped to a scroll snap container. For example, you might want to highlight a snapped element in some way, or reveal some of its content that was previously hidden.
- `stuck`: Queries whether a container with a `position` value of `sticky` is stuck to an edge of its scroll container ancestor. This is useful for styling `position: sticky` elements differently when stuck — for example, you could give them a different color scheme or layout.

Syntax overview

To establish a container element as a scroll-state query container, set the `container-type` property on it with a value of `scroll-state`. You can optionally also give it a `container-name`, so that you can target it with a specific container query:

```
.container {
  container-type: scroll-state;
  container-name: my-container;
}
```

You can then create a `@container` block that specifies the query, the rules that are applied to children of the container if the test passes, and optionally, the `container-name` of the container(s) you want to query. If you don't specify a `container-name`, the container query will be applied to all scroll-state query containers on the page.

Here, we query only containers named `my-container` to determine whether the container can be scrolled towards its top edge:

```
@container my-container scroll-state(scrollable: top) {
  /* CSS rules go here */
}
```

> **Note:** To separate scroll-state queries from other container queries, the scroll-state descriptors and value are placed inside parentheses, preceded by `scroll-state` (`scroll-state( ... )`). These constructs look like functions, but they're not.

Using <code>scrollable</code> queries

Scroll-state `scrollable` queries, written as `scroll-state(scrollable: <keyword>)`, test whether a container's scrolling ancestor can be scrolled in the given direction via user-initiated scrolling. If not, the query returns false.

The keyword value indicates the direction you are testing for scrolling availability in, for example:

- `top`: Tests whether the container can be scrolled towards its top edge.
- `inline-end`: Tests whether the container can be scrolled towards its inline-end edge.
- `y`: Tests whether the container can be scrolled in either or both directions along its y axis.

If the test passes, the rules inside the `@container` block are applied to descendants of the matching scroll container.

Let's look at an example in which we have a scrolling container full of content, and a handy little link to scroll back to the top if wished. We will use a `scrollable` query to only show the link when the user has started to scroll down through the content.

HTML

In the HTML we have an `<article>` element containing enough content to cause the document to scroll, preceded by a back-to-top link:

```
<a class="back-to-top" href="#" aria-label="Top of page">↑</a>
<article>
  <h1>Reader with container query-controlled "back-to-top" link</h1>
  <section>
    <header>
      <h2>This first section is interesting</h2>

      <p>Lorem ipsum dolor sit amet, consectetur adipiscing elit.</p>
    </header>

    ...
  </section>

  ...
</article>
```

We have hidden most of the HTML for brevity.

```
<a class="back-to-top" href="#" aria-label="Scroll back to top">↑</a>
<article>
  <h1>Reader with container query-controlled "back-to-top" link</h1>
  <section>
    <header>
      <h2>This first section is interesting</h2>

      <p>Lorem ipsum dolor sit amet, consectetur adipiscing elit.</p>

CSS

The `.back-to-top` link is given a `position` value of `fixed`, placed at the bottom-right corner of the viewport, and moved off the viewport using a `translate` value of `80px 0`. A `transition` value will animate the `translate` and `background-color` when either value changes.

```
/* General styling */

* {
  box-sizing: border-box;
}

html {
  font-family: "Helvetica", "Arial", sans-serif;
  height: 100%;
}

body {
  height: inherit;
  width: 100%;
  max-width: 540px;
  padding: 20px;
  margin: 0 auto;
}

p {
  line-height: 1.5;
}

img {
  display: block;
  width: 90%;
  margin: 30px auto;
  padding: 20px;
  border: 2px solid gray;
  aspect-ratio: 3/2;
}
```

```
.back-to-top {
  width: 64px;
  height: 64px;
  color: white;
  text-align: center;
  position: fixed;
  bottom: 10px;
  right: 10px;
  translate: 80px 0;
  transition:
    0.4s translate,
    0.2s background-color;
}
```

```
.back-to-top {
  text-decoration: none;
  border-radius: 50%;
  border: 1px solid #00000077;
  background-color: #00000077;
  color: white;
```

```
  font-size: 3rem;
  text-shadow: 0 0 2px black;
  padding-bottom: 10px;
}

.back-to-top:hover,
.back-to-top:focus {
  background: #00000099;
}
```

The scroll container in this example is the `<html>` element itself, denoted as a scroll-state query container with a `container-type` value of `scroll-state`. The `container-name` isn't strictly necessary but is useful in cases where the code is added to a codebase with multiple scroll-state query containers targeted with different queries.

```
html {
  container-type: scroll-state;
  container-name: scroller;
}
```

Next, we define a `@container` block that sets the container name targeted by this query, and the query itself — `scrollable: top`. This query applies the rules contained inside the block only if the `<html>` element can be scrolled toward its top edge — in other words, if the container has previously been scrolled downwards. If that is the case, `translate: 0 0` is applied to the `.back-to-top` link, which transitions it back on-screen.

```
@container scroller scroll-state(scrollable: top) {
  .back-to-top {
    translate: 0 0;
  }
}
```

We've hidden the rest of the example CSS for brevity.

Result

Try scrolling the document down, and note how the "back-to-top" link appears as a result, animating smoothly from the right side of the viewport due to the `transition`. If you scroll back to the top by activating the link or manually scrolling, the "back-to-top" link transitions off-screen.

Using <code>scrolled</code> queries

Scroll-state `scrolled` queries, written as `scroll-state(scrolled: <keyword>)`, test whether a container's scrolling ancestor was most recently scrolled in the given direction. If not, the query returns false.

The keyword value indicates the direction you are testing. For example:

- `block-start`: Tests whether the container was most recently scrolled towards its block-start edge.
- `right`: Tests whether the container was most recently scrolled towards its right-hand edge.
- `y`: Tests whether the container was most recently scrolled up or down along the y axis.
- `none`: Tests whether the container is not a scroll container or has not been scrolled in any direction since rendering.

If the test returns true, the rules inside the `@container` block are applied to the descendants of the matching scroll container.

Let's look at an example of a scroll container with a `scrolled` query that displays top and bottom content "bars" only when the user is scrolling up or down, respectively.

HTML

In our HTML, we have an `<article>` element containing enough content to cause the document to scroll, preceded by two `<div>` elements that represent our top and bottom "bars":

```
<div class="bar" id="top-bar">You're currently scrolling towards the top.</div>
<div class="bar" id="bottom-bar">
  You're currently scrolling towards the bottom.
</div>
<article>
  <h1>Document with scrolled container query</h1>
  <section>
    <header>
      <h2>This first section is interesting</h2>

      <p>Lorem ipsum dolor sit amet, consectetur adipiscing elit.</p>
    </header>

    ...
  </section>

  ...
</article>
```

We have hidden most of the HTML for brevity.

```
<div class="bar" id="top-bar">You're currently scrolling towards the top.</div>
<div class="bar" id="bottom-bar">
  You're currently scrolling towards the bottom.
</div>
<article>
  <h1>Document with scrolled container query</h1>
  <section>
    <header>
      <h2>This first section is interesting</h2>

      <p>Lorem ipsum dolor sit amet, consectetur adipiscing elit.</p>
    </header>

    <p>
      Mauris non malesuada est, sed vestibulum nibh. Duis vestibulum iaculis
      lectus, eu sagittis dolor dignissim iaculis. Nunc et orci sed sapien
      eleifend placerat. Curabitur dapibus risus eget odio sollicitudin, sit
      amet luctus justo pellentesque.
    </p>

    <p>
      <strong>Morbi non pharetra quam.</strong> Fusce vestibulum sem diam, ac
      consequat augue consectetur ut. Donec at augue viverra, tempus urna sit
      amet, porta augue.
```

```
    <em>Phasellus fringilla tincidunt sem ullamcorper varius.</em> Aenean
    gravida feugiat sem nec ultricies.
  </p>

  <img src="#" alt="Placeholder" />

  <p>
    Sed pellentesque placerat mi sed maximus. Sed vitae dui vitae mi pulvinar
    gravida sed et libero.
    <a href="#">Duis nec venenatis dolor, sed tristique felis.</a>
    Integer dapibus facilisis leo elementum vulputate. Curabitur a urna quis
    nulla vulputate tincidunt quis ac enim.
  </p>

  <p>
    Cras non elit vel leo dignissim convallis. Duis eros urna, varius sit amet

  </section>
</article>
```

CSS

The "bars" are given some rudimentary styling. Most significantly, they are given a `position` value of `fixed`, which we offset from either side using `left` and `right` values.

```
/* General styling */

* {
  box-sizing: border-box;
}

html {
  font-family: "Arial", sans-serif;
  height: 100%;
}

body {
  height: inherit;
  width: 90%;
  margin: 0 auto;
}

p {
  line-height: 1.5;
}

img {
  display: block;
  width: 90%;
  margin: 30px auto;
  padding: 20px;
  border: 2px solid gray;
  aspect-ratio: 3/2;
}
```

```
.bar {
  border-radius: 10px;
  border: 1px solid black;
  background-color: #00000099;
  padding: 10px;
  color: white;
  text-shadow: 1px 1px 1px black;
  display: flex;
  justify-content: center;
  align-items: center;

  position: fixed;
  left: 5px;
  right: 5px;
}
```

Next, we set negative `top` and `bottom` length values on the top and bottom bars so they are hidden above and below the viewport by default. We add a `transition` to smoothly animate them into view when their `translate` values change.

```
#top-bar {
  top: -50px;
  transition: 0.6s translate;
}

#bottom-bar {
  bottom: -50px;
  transition: 0.6s translate;
}
```

The scroll container in this example is the `<html>` element itself, denoted as a scroll-state query container with a `container-type` value of `scroll-state`. The `container-name` isn't strictly necessary, but it is useful when a codebase has multiple scroll-state query containers targeted with different queries.

```
html {
  container-type: scroll-state;
  container-name: scroller;
}
```

Next, we define two `@container` blocks, both of which target the `scroller` container name. The first block defines a query `scrolled: block-end` and the second defines a query `scrolled: block-start`. Respectively, these queries apply the rules contained within their block only if the `<html>` element was most recently scrolled toward its block-end edge or block-start edge. In other words, when the container is scrolled down or up. When either condition becomes true, the bar referenced inside the block has a `translate` value set to cause it to transition on-screen. The bar referenced in the `@condition` that is no longer true transitions off-screen.

```
@container scroller scroll-state(scrolled: block-start) {
  #top-bar {
```

```
    translate: 0 55px;
  }
}

@container scroller scroll-state(scrolled: block-end) {
  #bottom-bar {
    translate: 0 -55px;
  }
}
```

We've hidden the rest of the example CSS for brevity.

Result

Try scrolling the document up and down, and note how the different bars appear as a result, animating smoothly on- and off-screen.

Using <code>snapped</code> queries

Relevant only when scroll snapping is implemented, scroll-state `snapped` queries, written as `scroll-state(snapped: <keyword>)`, test whether a container is going to be snapped to a scroll snap container ancestor along the given axis. If not, the query returns false.

The keyword value in this case indicates the direction you are testing the element's ability to snap in, for example:

- `x`: Tests whether the container is snapping horizontally to its scroll-snap container ancestor.
- `inline`: Tests whether the container is snapping to its scroll-snap container ancestor in the inline direction.
- `y`: Tests whether the container is snapping to its scroll-snap container ancestor in both directions.

To evaluate a container with a non-`none` `snapped` scroll-state query, it must be a container with a scroll-snap container ancestor, that is, the ancestor has a `scroll-snap-type` value other than `none`. The container query `scroll-state(snapped: none)` matches scroll-state containers that do not have a scroll container ancestor.

Evaluation will occur when the `scrollsnapchanging` event fires on the scroll snap container.

If the test passes, the rules inside the `@container` block are applied to descendants of the matching scroll snap target container.

In this example, we'll look at a scroll snap container with children that snap to it vertically and use a `snapped` query to style the children only when they are snapped or about to be snapped.

HTML

The HTML consists of a `<main>` element that will be a scroll snap container. Inside are several `<section>` elements that will be snap targets. Each `<section>` contains a wrapper `<div>` and an `<h2>` heading. The wrappers are included to create a style target as container queries enable styling a container's descendants, not the container itself.

```
<main>
  <section>
    <div class="wrapper">
      <h2>Section 1</h2>
    </div>
  </section>

  ...
</main>
```

We have hidden most of the HTML for brevity.

```
<main>
  <section>
    <div class="wrapper">
      <h2>Section 1</h2>
    </div>
  </section>
  <section>
    <div class="wrapper">
      <h2>Section 2</h2>
    </div>
  </section>
  <section>
    <div class="wrapper">
      <h2>Section 3</h2>
    </div>
  </section>
  <section>
    <div class="wrapper">
      <h2>Section 4</h2>
    </div>
  </section>
  <section>
    <div class="wrapper">
      <h2>Section 5</h2>
    </div>
  </section>
  <section>
    <div class="wrapper">
      <h2>Section 6</h2>
    </div>
  </section>
  <section>
    <div class="wrapper">
      <h2>Section 7</h2>
    </div>
  </section>
  <section>
    <div class="wrapper">
      <h2>Section 8</h2>
    </div>
  </section>
  <section>
    <div class="wrapper">
      <h2>Section 9</h2>
    </div>
  </section>
  <section>
    <div class="wrapper">
```

```
      <h2>Section 10</h2>
    </div>
  </section>
  <section>
    <div class="wrapper">
      <h2>Section 11</h2>
    </div>
  </section>
  <section>
    <div class="wrapper">
      <h2>Section 12</h2>
    </div>
  </section>
  <section>
    <div class="wrapper">
      <h2>Section 13</h2>
    </div>
  </section>
  <section>
    <div class="wrapper">
      <h2>Section 14</h2>
    </div>
  </section>
  <section>
    <div class="wrapper">
      <h2>Section 15</h2>
    </div>
  </section>
  <section>
    <div class="wrapper">
      <h2>Section 16</h2>
    </div>
  </section>
</main>
```

CSS

```
* {
  box-sizing: border-box;
}

html {
  height: 100%;
}

/* body and main sizing */

body {
  display: flex;
  align-items: center;
  justify-content: center;
  height: inherit;
}

main {
  gap: 50px;
}
```

We set an `overflow` value of `scroll` and a fixed `height` on the `<main>` element to turn it into a vertical scroll container. We also set a `scroll-snap-type` value of `y mandatory` to turn `<main>` into a scroll snap container that snap targets will snap to along the y axis; `mandatory` means that a snap target will *always* be snapped to.

```
main {
  overflow: scroll;
  scroll-snap-type: y mandatory;
  height: 450px;
  width: 250px;
  border: 3px solid black;
}
```

The `<section>` elements are designated as snap targets by setting a non-`none` `scroll-snap-align` value. The `center` value means that they will snap to the container at their center points.

```
section {
  font-family: "Helvetica", "Arial", sans-serif;
  width: 150px;
  height: 150px;
  margin: 50px auto;

  scroll-snap-align: center;
}
```

```
.wrapper {
  width: 100%;
  height: 100%;
  border-radius: 5px;
  background: #eeeeee;
  box-shadow:
    inset 1px 1px 4px rgb(255 255 255 / 0.5),
    inset -1px -1px 4px rgb(0 0 0 / 0.5);

  display: flex;
  align-items: center;
  justify-content: center;

  transition:
    0.6s background,
    0.6s color;
}

h2 {
  font-size: 1rem;
```

```
  letter-spacing: 1px;
}
```

We want to enable the `<section>` elements to be queried. Specifically, we want to test whether the `<section>` elements are in the process of snapping to their container, so we denote them as scroll-state query containers by setting a `container-type` value of `scroll-state` on them. We also give them a `container-name`, which isn't strictly necessary, but will be useful if our code gets more complex later and we have multiple scroll-state query containers that we want to target with different queries.

```
section {
  container-type: scroll-state;
  container-name: snap-container;
}
```

Next, we define a `@container` block that sets the container name we are targeting with this query, and the query itself — `snapped: y`. This query applies the rules contained inside the block only if a `<section>` element is being snapped vertically to its container. If that is the case, we apply a new `background` and `color` to the `<section>` element's child `.wrapper` `<div>` to highlight it.

```
@container snap-container scroll-state(snapped: y) {
  .wrapper {
    background: purple;
    color: white;
  }
}
```

Result

The rendered result is shown below. Try scrolling the container up and down, and note how the `<section>` style changes when it becomes snapped to its container.

Using <code>stuck</code> queries

Scroll-state `stuck` queries, written as `scroll-state(stuck: <keyword>)`, test whether a container with a `position` value of `sticky` is stuck to an edge of its scroll container ancestor. If not, the query returns false.

The keyword value in this case indicates the scroll container edge you are testing, for example:

- `top`: Tests whether the container is stuck to the top edge of its scroll container ancestor.
- `block-end`: Tests whether the container is stuck to the block-end edge of its scroll container ancestor.
- `none`: Tests whether the container is not stuck to any edges of its scroll container ancestor. Note that `none` queries will match even if the container does not have `position: sticky` set on it.

If the query returns true, the rules inside the `@container` block are applied to descendants of the matching `position: sticky` container.

Let's look at an example where we have a scrolling container with overflowing content, in which the headings are set to `position: sticky` and stick to the top edge of the container when they scroll to that position. We will use a `stuck` scroll-state query to style the headings differently when they are stuck to the top edge.

HTML

In the HTML, we have an `<article>` element containing enough content to cause the document to scroll. It is structured using several `<section>` elements, each containing a `<header>` with nested content:

```
<article>
  <h1>Sticky reader with scroll-state container query</h1>
  <section>
    <header>
      <h2>This first section is interesting</h2>

      <p>Lorem ipsum dolor sit amet, consectetur adipiscing elit.</p>
    </header>

    ...
  </section>

  <section>
    <header>
      <h2>This one, not so much</h2>

      <p>Confecta res esset.</p>
    </header>

    ...
  </section>

  ...
</article>
```

We have hidden most of the HTML for brevity.

```

  </section>
</article>
```

CSS

Each `<header>` has a `position` value of `sticky` and a `top` value of `0`, which sticks them to the top edge of the scroll container. To test whether the `<header>` elements are stuck to the container top edge, they are denoted as scroll-state query containers with a `container-type` value of `scroll-state`. The `container-name` isn't strictly necessary but will be useful if this code gets added to a code base with multiple scroll-state query containers targeted with different queries.

```
/* General styling */

* {
  box-sizing: border-box;
}

html {
  font-family: "Helvetica", "Arial", sans-serif;
  height: 100%;
}

body {
  height: inherit;
  width: 100%;
  max-width: 540px;
  padding: 20px;
  margin: 0 auto;
}

p {
  line-height: 1.5;
}

img {
  display: block;
  width: 90%;
  margin: 30px auto;
  padding: 20px;
  border: 2px solid gray;
  aspect-ratio: 3/2;
}
```

```
header {
  background: white;
  position: sticky;
  top: 0;
  container-type: scroll-state;
  container-name: sticky-heading;
}
```

We also give the `<h2>` and `<p>` elements inside the `<header>` elements some basic styling, and a `transition` value so they will smoothly animate when their `background` values change.

```
h2,
header p {
  margin: 0;
  transition: 0.4s background;
}

h2 {
  padding: 20px 5px;
  margin-bottom: 10px;
}

header p {
  font-style: italic;
  padding: 10px 5px;
}
```

Next, we define a `@container` block that sets the container name we are targeting with this query, and the query itself — `stuck: top`. This query applies the rules contained inside the block only if a `<header>` element is stuck to the top of its scroll container. When that is the case, a different `background` and a `box-shadow` are applied to the contained `<h2>` and `<p>`.

```
@container sticky-heading scroll-state(stuck: top) {
  h2,
  p {
    background: #cccccc;
    box-shadow: 0 5px 2px #00000077;
  }
}
```

```
@supports not (container-type: scroll-state) {
  body::before {
    content: "Your browser does not support `scroll-state` container queries.";
    color: black;
```

```
    background-color: wheat;
    position: fixed;
    left: 0;
    right: 0;
    top: 40%;
    text-align: center;
    padding: 1rem 0;
    z-index: 1;
  }
}
```

We have hidden the rest of the CSS for brevity.

Result

Try scrolling the document down and up, and note how the `<h2>` and `<p>` elements transition to a new color scheme when they become stuck to the top of their container's top edge.

Using feature queries

Feature queries are conditional group rules that test whether the user agent supports or doesn't support one or more CSS features, such as CSS properties and property values. Feature queries give web developers a way to test to see if a browser has support for a certain feature, and then provide CSS that will only run based on the result of that test. In this guide, you will learn how to implement progressive enhancement using feature queries.

Feature queries are created using the CSS at-rule `@supports` (or the `supports()` function within `@import` at-rules).

Syntax

CSS feature queries are part of the CSS conditional rules module, which also defines the media query `@media` at-rule. Feature queries behave similarly to media queries. The difference is that with a media query, you are testing something about the environment in which the web page is running, whereas with feature queries you are testing browser support for CSS features.

A feature query consists of the `@supports` at-rule followed by the support condition or a `supports()` function and declaration parameter within an `@import` at-rule declaration:

```
/* `@supports` at-rule */
@supports <support-condition> {
  /* CSS rules to apply */
}

/* `supports()` function */
@import url_to_import supports(<declaration>);
```

For example, we can apply a set of styles or import an entire stylesheet if the user-agent supports `red` as a valid value for the CSS `color` property:

```
/* `@supports` at-rule */
@supports (color: red) {
  /* CSS rules to apply */
}

/* `supports()` function */
@import "/css/styles.css" supports(color: red);
```

As another example, if you want to check if a browser supports the `row-gap` property you would write the following feature query. It doesn't matter which value you use in a lot of cases: if all you want is to check that the browser supports this property, then any valid value will do.

```
<div class="box">
  If your browser supports the row-gap property, the border will be dashed and
  text will be red.
</div>
```

```
body {
  font: 1.2em / 1.5 sans-serif;
}
.box {
  border: 4px solid blue;
  color: blue;
  padding: 1em;
}
@supports (row-gap: 10px) {
  .box {
    border: 4px dashed darkgreen;
    color: red;
  }
}
```

The value part of the property-value pair matters more if you are testing for new values of a particular property. All browsers support `color: red`: this dates back to CSS1. However, there are often additional values added to properties in CSS, like relative colors, which may not be supported. Feature queries enable testing property and value pairs, meaning we can detect support for values.

Expanding on the `color` property example above, here we check if the browser supports the `color: AccentColor` declaration:

```
/* `@supports` at-rule */
@supports (color: AccentColor) {
  /* CSS rules to apply */
}

/* `supports()` function */
@import "/css/styles.css" supports(color: AccentColor);
```

In these examples, we've used feature queries to check if the user-agent supports a specific value of a CSS property, listing the single declaration within parenthesis. You can test for multiple property values or the lack of support.

Testing for lack of support

In addition to asking the browser if it supports a feature, you can test for the opposite by adding in the `not` keyword:

```
/* `@supports` at-rule with `not` */
@supports not (property: value) {
  /* CSS rules to apply */
}
```

The CSS inside the following example feature query will run if the browser does not support `row-gap`.

```
<div class="box">
  If your browser does not support row-gap, the content will be darkgreen with a
  dashed border.
</div>
```

```
body {
  font: 1.2em / 1.5 sans-serif;
}
.box {
  border: 4px solid blue;
  color: blue;
  padding: 1em;
}
@supports not (row-gap: 10px) {
  .box {
    border: 4px dashed darkgreen;
    color: darkgreen;
  }
}
```

Testing for more than one feature

You may need to test support for more than one property in your feature query. To do so, you can include a list of features to test for, separated by `and` keywords:

```
/* multiple feature `@supports` at-rule */
@supports (property1: value) and (property2: value) {
  /* CSS rules to apply */
}
```

For example, if the CSS you want to run requires that the browser supports CSS Shapes and CSS grid, you could create a rule that tests browser support for both of these features. The following rule will only return true if `shape-outside: circle()` and `display: grid` are both supported by the browser.

```
<div class="box">
  If your browser supports <code>display: grid</code> and
  <code>shape-outside: circle()</code>, the content will be darkgreen with a
  dashed border.
</div>
```

```
body {
  font: 1.2em / 1.5 sans-serif;
}
.box {
  border: 4px solid blue;
  color: blue;
  padding: 1em;
}
@supports (display: grid) and (shape-outside: circle()) {
  .box {
    border: 4px dashed darkgreen;
    color: darkgreen;
  }
}
```

Testing for at least one of multiple features

You can also use `or` to apply CSS only if one or more declarations are supported:

```
/* any feature `@supports` at-rule */
@supports (property1: value) or (property2: value) {
  /* CSS rules to apply */
}
```

This can be particularly useful if a feature is vendor prefixed, as you can test for the standard property plus any vendor prefixes.

```
<div class="box">
  The text and border will be green if your browser supports font smoothing.
</div>
```

```
body {
  font: 1.2em / 1.5 sans-serif;
}
.box {
  border: 4px solid blue;
  color: blue;
  padding: 1em;
}
@supports (font-smooth: always) or (-webkit-font-smoothing: antialiased) {
  .box {
    border: 4px dashed darkgreen;
    color: darkgreen;
  }
}
```

Additional feature query options

Feature queries are not limited to property-value pairs. You can include `font-tech()`, `font-format()`, and `selector()` functions in your feature queries to selectively apply CSS based on whether the user-agent supports a specified font technology, font format, or selector syntax, respectively.

For example, the `selector()` function can be used to import a stylesheet for browsers that support a vendor-prefixed pseudo-element:

```
/* A `selector()` query within a `supports()` function */
@import "/css/webkitShadowStyles.css"
  supports(selector(::-webkit-inner-spin-button));
```

Examples

Browser support test

In this example, we check if the browser supports the `AccentColor` `<system-color>` and use `display: none` to change the default "not supported" message to a "supported" message if the color type is supported.

HTML

```
<p class="accentcolor">
  Your browser does <span>not</span> support <code>AccentColor</code> as a color
  value.
</p>
```

CSS

```
body {
  font: 1.2em / 1.5 sans-serif;
}
p {
  padding: 1em;
}
@supports (color: AccentColor) {
  p {
    color: green;
    border: 2px solid;
  }
  span {
    display: none;
  }
}
@supports not (color: AccentColor) {
  p {
    color: red;
  }
}
```

Result

Limitations of feature queries

The `@supports` rule tests to see if browsers can parse one or more property/value pairs, and therefore if they claim to support the associated feature(s). If the property/value pairs are understood by a browser it returns a positive response. Feature queries check that declarations are considered valid by a browser, but can't be used to check if it supports a feature properly without bugs or spec violations. Feature queries cannot test for *partial implementations*.

Summary

Feature queries are a useful tool for progressively enhancing a site. They enable you to provide a good solution for all browsers, and an enhanced solution for browsers that support newer properties and values.

You don't need to use feature queries to start using new CSS features; CSS error handling means the browser simply ignores CSS it does not yet recognize. However, feature queries are a useful alternative to fallback declarations, and enable writing code once that can eventually be supported everywhere.

CSS containment

The **CSS containment** module defines containment and container queries.

Containment enables the isolation of page subtrees from the rest of the DOM. The browser can then improve performance by optimizing the rendering of these independent parts.

Container queries are similar to dimension media queries, except that the queries are based on the dimensions of a specific container element defined as a containment context, rather than on the dimensions of the viewport. Container queries enable querying a container's size, properties, property values, or even just its assigned `container-name` to conditionally apply CSS styles. When applying these conditional styles, you can use container query length units, which specify lengths relative to the dimensions of the query container. Additional properties are defined to enable establishing a specific element as a query container and giving it a specific name.

CSS container queries

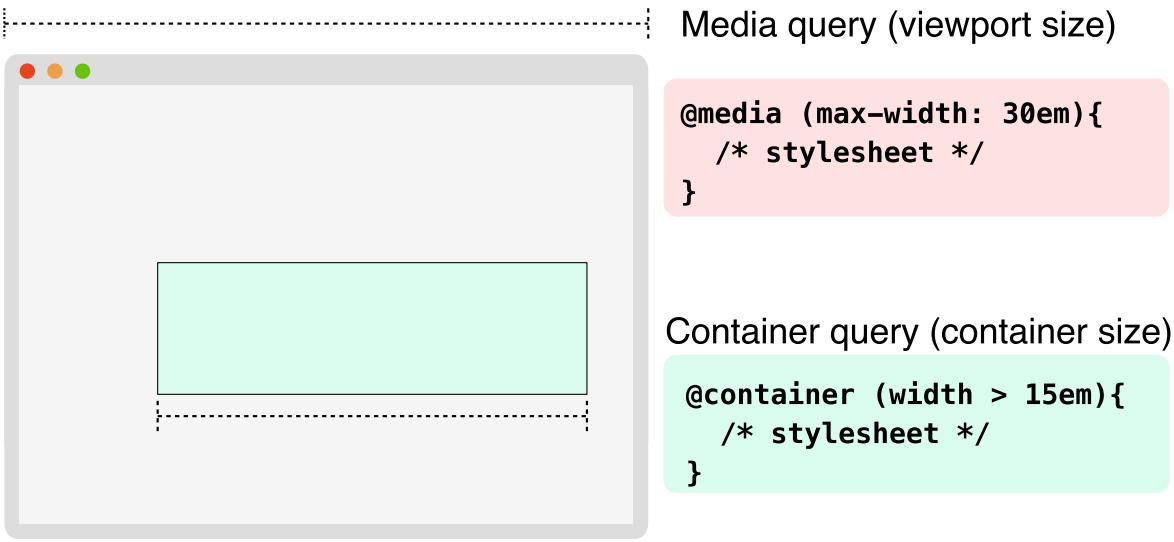
Container queries enable you to apply styles to an element based on certain attributes of its container:

- The `container-name`.
- The container's size.
- Styles applied to the container.
- The container's scroll-state or that of its scrolling ancestor.
- Whether the container is anchor-positioned and has a position-try fallback option applied to it.

Container queries are an alternative to media queries, which apply styles to elements based on viewport size or other device characteristics.

This article provides an introduction to using container queries, specifically focusing on size container queries. Other guides discuss style, scroll-state, and anchored container queries in detail.



Using container size queries

While container queries apply styles based on the container name or type, container size queries apply styles specifically based on the container's dimensions. To use container size queries, you need to declare a containment context on an element so that the browser knows you might want to query the dimensions of this container later. To do this, use the `container-type` property with a value of `size`, `inline-size`, or `normal`.

These values have the following effects:

`size`

The query will be based on the inline and block dimensions of the container. Applies layout, style, and size containment to the container.

`inline-size`

The query will be based on the inline dimensions of the container. Applies layout, style, and inline-size containment to the element.

`normal`

The default value. The element is not a query container for any container size queries, but can still be used as a query container for name-only container queries or container style queries.

Consider the following example of a card component for a blog post with a title and some text:

```
<div class="post">
  <div class="card">
    <h2>Card title</h2>
    <p>Card content</p>
  </div>
</div>
```

You can create a containment context using the `container-type` property:

```
.post {
  container-type: inline-size;
}
```

Next, use the `@container` at-rule to define a container query. The query in the following example will apply styles to elements based on the size of the nearest ancestor with a containment context. Specifically, this query will apply a larger font size for the card title if the container is wider than `700px`:

```
/* Default heading styles for the card title */
.card h2 {
  font-size: 1em;
}

/* If the container is larger than 700px */
@container (width > 700px) {
  .card h2 {
    font-size: 2em;
  }
}
```

Using container queries, the card can be reused in multiple areas of a page without needing to know specifically where it will be placed each time. If the container with the card is narrower than `700px`, the font of the card title will be small, and if the card is in a container that's wider than `700px`, the font of the card title will be bigger.

For more information on the syntax of container queries, see the `@container` page.

Naming containment contexts

In the previous section, a container query applied styles based on the nearest ancestor with a containment context. It's possible to give a containment context a name using the `container-name` property. Once named, the name can be used in a `@container` query so as to target a specific container. The following example creates a containment context with the name `sidebar`:

```
.post {
  container-type: inline-size;
  container-name: sidebar;
}
```

You can then target this containment context using the `@container` at-rule:

```
@container sidebar (width > 700px) {
  .card {
    font-size: 2em;
  }
}
```

More information on naming containment contexts is available on the `container-name` page.

Name-only container queries

As well as using a `container-name` along with a `<container-query>`, you can query a container using just its name. These so-called **name-only container queries** enable selectively applying styles to elements based on whether they have an ancestor with a specific `container-name` set.

For example, consider the following HTML:

```
<div id="container">
  <p>I'm in the container.</p>
  <p>I'm also in the container.</p>
</div>
<p>I'm not in the container.</p>
```

If we assign a name to the container:

```
#container {
  container-name: my-container;
}
```

We can then selectively apply styles only to elements inside that container:

```
@container my-container {
  p {
    background-color: lime;
    font-size: 1.3rem;
    width: 50vw;
    padding: 0.5rem;
    font-family: sans-serif;
  }
}
```

In this example, the specified styles would be applied only to the first and second `<p>` elements, but not to the third.

Shorthand container syntax

The shorthand way of declaring a containment context is to use the `container` property:

```
.post {
  container: sidebar / inline-size;
}
```

For more information on this property, see the `container` reference.

Container query length units

When applying styles to the descendants of a container using size container queries (that is, its `container-type` is set to `size` or `inline-size`), you can use container query length units. These units specify a length relative to the dimensions of a query container. Components that use units of length relative to their container are more flexible to use in different containers without having to recalculate concrete length values.

If no eligible container is available for the query, the container query length unit defaults to the small viewport unit for that axis (`sv*`).

The container query length units are:

- `cqw`: 1% of a query container's width
- `cqh`: 1% of a query container's height
- `cqi`: 1% of a query container's inline size
- `cqb`: 1% of a query container's block size
- `cqmin`: The smaller value of either `cqi` or `cqb`
- `cqmax`: The larger value of either `cqi` or `cqb`

The following example uses the `cqi` unit to set the font size of a heading based on the inline size of the container:

```
@container (width > 700px) {
  .card h2 {
    font-size: max(1.5em, 1.23em + 2cqi);
  }
}
```

For more information on these units, see the Container query length units reference.

Fallbacks for container queries

For browsers that don't yet support container queries, `grid` and `flex` can be used to create a similar effect for the card component used on this page. The following example uses a `grid-template-columns` declaration to create a two-column layout for the card component.

```
.card {
  display: grid;
  grid-template-columns: 2fr 1fr;
}
```

If you want to use a single-column layout for devices with a smaller viewport, you can use a media query to change the grid template:

```
@media (width <= 700px) {
  .card {
    grid-template-columns: 1fr;
  }
}
```

Using container size and style queries

Container queries enable you to apply styles to elements nested within a specific container based on the features of that container. The query returns true or false depending on whether the query condition is true for the container.

Container queries are similar to media queries. The `@media` at-rule enables applying styles to elements based on viewport size or other device characteristics. Similarly, the `@container` at-rule enables applying styles to elements based on a containing element's size or other features, rather than the viewport's. Container queries have the same syntax rules and logical operators as media queries.

```
@container <container-condition># {
  /* <stylesheet> */
}
```

There are five types of container queries:

Container size queries

Size queries enable applying styles to elements based on the current size of a containing element, including the orientation and aspect ratio. The containing elements need to be explicitly declared as *size query containers*.

Container style queries

Style queries enable applying styles to elements based on a containing element's style features, where any non-empty element can be a style query container. A style feature can be a CSS property, CSS custom property, or a valid CSS declaration. This allows you to apply styles to any container element's descendants based on its style features — such as whether it has a `display: inline` flex declaration set, or the value of a custom property.

Name-only container queries

Name-only container queries enable selectively applying styles to an element based on whether it has a specific `container-name` set.

Container scroll-state queries

Scroll-state queries allow you to selectively apply CSS rules to a container's descendants based on scroll-state conditions, such as whether the queried element is partially scrolled or whether the container is snapped to a scroll snap container. The containing elements need to be explicitly declared as *scroll-state query containers*.

Anchored container queries

Anchored container queries enable querying whether the container is anchor-positioned and has a position-try fallback option applied to it.

In this guide, we learn the basics of container queries by looking at:

1. container size queries,
2. naming containers to limit their scope, and
3. using the `style()` functional notation within the `@container` at rule's `<container-condition>` to create style queries with custom properties.

Container size queries

Container size queries are filtered by a size condition. The associated styles are applied to contained elements if the container element has been declared to be a container and the container condition is true for that element. An element's size container is the nearest ancestor with containment.

Elements are declared as *size query containers* by setting their `container-type` property (or the `container` shorthand) to `size` or `inline-size`.

```
@container (orientation: landscape) {
  /* styles applied to descendants of this size container */
}

.sizeContainer {
  container-type: size;
}
```

Declaring size query containers adds containment to them. This is a performance necessity — querying the size of every element in the DOM, all the time, would be bad for performance and user experience. Additionally, if a descendant style changed the size of the container element, an infinite loop could occur.

In a container size query, the `<container-condition>` includes one or more `<size-query>`s. Each size query includes a size feature name, a comparison operator, and a value. The size features that can be queried are limited to `width`, `height`, `inline-size`, `block-size`, `aspect-ratio`, and `orientation`. The boolean syntax and logic combining one or more `<size-query>`s is the same as for `@media` size feature queries.

```
form {
  container-type: inline-size;
}

@container (10em <= width <= 20em) {
  /* styles */
}
```

The `<container-condition>` in this example contains a single `<size-query>` — `(10em <= width <= 20em)`. In this case, all `<form>` elements are potential matches for any unnamed container query. The styles declared within our container query apply to the descendants of all forms between `10em` and `30em` wide, inclusive.

Naming containers

A `<container-condition>` can include an optional case-sensitive `container-name`. A container name makes the container condition more specific — it is evaluated only against elements that have that name set in the `container-name` property.

The `container-name` property specifies a list of query `<container-name>` values that can be used in `@container` rules to target specific query containers; these are case-sensitive `<ident>` values. Without a `<container-name>`, the query matches only the nearest container ancestor, and without a `<container-query>`, the query will match elements with the specified `container-name` set on them (see Name-only container queries).

```
@container [ <container-name>? <container-query>? ]!# {
  /* <stylesheet> */
}
```

Styles inside the named `@container` at rules will be applied only to matching elements inside containers with those names set, which satisfy the container queries.

```
@container card (orientation: landscape) {
  /* styles */
}

.todo-panel > li {
  container-type: inline-size;
  container-name: card;
}
```

In the above example, the styles within the container query block will apply to the descendants of all `<li>` elements with a width that is greater than their height. Note that other elements with `container-name: card` applied to them that match the size query will also have these styles applied to their elements' descendants.

```
@container wide (width >= 20em) {
  /* styles applied to descendants of wide .sizeContainer */
}

@container narrow (width < 20em) {
  /* styles applied to descendants of narrow .sizeContainer */
}

.sizeContainer {
  container-type: size;
  container-name: wide narrow;
}
```

In the above example, the element has two container names, `wide` and `narrow`. The descendants of any elements with `class="sizeContainer"` will get the styles from the `wide` or `narrow` query applied.

The default value `container-type: normal` prevents the container from being a size container, but it can still be a style container, and it can still be targeted by a name-only container query. The default value `container-name: none` states the container has no name, but it does not prevent the element from matching unnamed queries.

Container style queries

A *container style query* is a `@container` query that evaluates computed styles of the container element as defined in one or more `style()` functional notations. The boolean syntax and logic used to combine style features into a style query are the same as in CSS feature queries. The only difference is the function name — `style()` within a `<style-feature>` as opposed to `supports()` within a `<support-condition>`:

```
@container style(<style-feature>),
    not style(<style-feature>),
    style(<style-feature>) and style(<style-feature>),
    style(<style-feature>) or style(<style-feature>) {
  /* <stylesheet> */
}
```

The parameter of each `style()` function is a single **`<style-feature>`**. Per the CSS containment specification, a `<style-feature>` can be a valid CSS declaration, a CSS property, or a `<custom-property-name>`. The only style feature currently supported is custom properties, with or without a value. See the browser compatibility table for `@container`.

If the `<style-feature>` includes a value, the style query evaluates to true if the computed value of the custom property (or, in the future, the CSS declaration) passed as the `style()` argument is true for the container being queried. Otherwise, it resolves to false. A style feature without a value evaluates to true if the computed value is different from the initial value for the given property.

In the future, we'll be able to write style queries like so:

```
@container style(color: green) and style(background-color: transparent),
    not style(background-color: red),
    style(--themeBackground),
    style(--themeColor: blue) or style(--themeColor: purple),
    (width <= 100vw) and style(max-width: 600px) {
  /* <stylesheet> */
}
```

The `style()` functional notation is used to differentiate style queries from size queries. While not yet supported, we will eventually be able to query regular CSS declarations such as `max-width: 600px`. Querying `@container (max-width: 600px)` is a size query; containment with `container-type`, or the `container` shorthand, is needed. That query will return true if the container is 600px or less. That is different from querying `@container style(max-width: 600px)`, which is a style query; when supported, this query will return true if the container has a `max-width` value of `600px`.

Until style queries for regular CSS declarations and properties are supported, we are limited to including only custom properties as the `style()` parameter, with or without a value:

```
@container style(--themeBackground),
    style(--themeColor: blue) or style(--themeColor: purple) {
  /* <stylesheet> */
}
```

A few things to note that have already been mentioned but are important to remember:

- All elements can be style query containers; setting a `container-type` is not required. When descendant styles don't impact the computed styles of an ancestor, containment is not needed.
- A `<container-condition>` can include both style and size features. If including size features in your query, make sure your container elements have a `container-type` of `size` or `inline-size` set.
- If you don't want an element to be considered as a container, ever, give it a `container-name` that will not be used. Setting `container-name: none` removes any query names associated with a container; it does not prevent the element from being a style container.
- At the time of this writing (February 2024), container style queries only work with CSS custom property values in the `style()` query.

Now, let's dive in and take a look at the different `<style-feature>` types.

Style queries for custom properties

Style queries for custom properties allow you to query the custom properties, also called "CSS variables", of a parent element. They are included within a `<style-query>` just as you would include any regular CSS property within a feature query: either with or without a value.

Standalone custom property queries

The `<style-query>` parameter of the `style()` functional notation can include just a CSS variable name; a custom property with no value. When no value is included, the query will return false if the value is the same as the value of the `initial-value` descriptor within the `@property` at-rule, if there is one. The style query will return true and match all elements that have a custom property value that differs from the `initial-value` or for all elements that have a custom property of any value if the custom property was declared without being registered.

Unregistered custom properties

When CSS variables are introduced via a CSS custom property value assignment, valueless custom property queries always return true.

```
:root {
  --theme-color: rebeccapurple;
}

@container style(--theme-color) {
  /* <stylesheet> */
}
```

In this example, the container query matches the element on which the `--theme-color` property was declared and all of its descendants. As the CSS variable `--theme-color` was declared on the `:root`, the style query `style(--theme-color)` will be true for every element within that DOM node.

Registered properties

The behavior of registered custom properties is different. When explicitly defined with the `@property` CSS at-rule or via JavaScript with `CSS.registerProperty()`, the style query `style(--theme-color)` only returns true for elements if the element's computed value for `--theme-color` is different from the `initial-value` set in the original definition of that custom property.

```
@property --theme-color {
  initial-value: rebeccapurple;
  inherits: true;
}

:root {
  --theme-color: rebeccapurple;
}

main {
  --theme-color: blue;
}

@container style(--theme-color) {
  /* <stylesheet> */
}
```

In this example, the `:root` element does NOT match the style query because the value of the custom property is the same as the `initial-value` value. The custom property value for the element (and all the elements inheriting the value) is still `rebeccapurple`. Only elements that differ from the initial value, in this case, the `<main>` and its descendants that inherit that changed value, are a match.

Custom property with a value

If a style query includes a value for the custom property, the element's computed value for that property must be an exact match, with equivalent values only being a match if the custom property was defined with a `@property` at rule (or a `CSS.registerProperty()` method call) containing a `syntax` descriptor.

```
@container style(--accent-color: blue) {
  /* <stylesheet> */
}
```

This container style query matches any element that has `blue` as the computed value of the `--accent-color` custom property.

In this case, other color values equivalent to sRGB `blue` (such as the hexadecimal code `#0000ff`) will match only if the `--accent-color` property was defined as a color with `@property` or `CSS.registerProperty()`, for example:

```
@property --accent-color {
  syntax: "<color>";
  inherits: true;
  initial-value: #0000ff;
}
```

In this case, if the value of `--accent-color` were set to `blue`, `#00f`, `#0000ff`, `rgb(0 0 255 / 1)`, or `rgb(0% 0% 100%)` it would return true for `@container style(--accent-color: blue)`.

Example

In this example, we have a `<fieldset>` with four radio buttons. The fourth option includes a text `<input>` for entering a custom color.

```
<fieldset>
  <legend>Change the value of <code>--theme</code></legend>
  <ol>
    <li>
      <input type="radio" name="selection" value="red" id="red" />
      <label for="red">--theme: red;</label>
    </li>
    <li>
      <input type="radio" name="selection" value="green" id="green" />
      <label for="green">--theme: green</label>
    </li>
    <li>
      <input type="radio" name="selection" value="blue" id="blue" />
      <label for="blue">--theme: blue</label>
    </li>
    <li>
      <input type="radio" name="selection" value="currentColor" id="other" />
      <label for="other">Other</label>
      <label for="color">color:</label>
      <input name="selection-value" value="currentColor" id="color" />
    </li>
  </ol>
</fieldset>
<output>I change colors</output>
```

JavaScript updates the value of the CSS `--theme` variable on the `<body>` element, which is an ancestor of the `<fieldset>` and `<output>` elements, whenever a radio button is selected. When the text `<input>` is updated, the `value` of the `other` radio button is updated only if the `other` radio button is checked, which in turn updates the value of `--theme`.

```
const radios = document.querySelectorAll('input[name="selection"]');
const body = document.querySelector("body");
const other = document.getElementById("other");
const color = document.getElementById("color");

for (const radio of radios) {
  radio.addEventListener("change", (e) => {
    body.style.setProperty("--theme", e.target.value);
  });
}
color.addEventListener("input", (e) => {
  other.style.setProperty("value", e.target.value);
  if (other.checked) {
    body.style.setProperty("--theme", e.target.value);
  }
});
```

We use the `@property` at-rule to define a CSS variable `--theme` to be a `<color>` value and set the `initial-value` to `red`, ensuring equivalent colors are a match regardless of what syntax is used (for example, `red` is equal to `rgb(255 0 0)`, `#ff0000`, and `#f00`).

```
@property --theme {
  syntax: "<color>";
  inherits: true;
  initial-value: red;
}
```

```
output {
  padding: 3px 5px;
  margin-top: 5px;
}
```

The first style feature query is a custom property with no value. This query type returns true when the computed value for the custom property value is different from the `initial-value` for that property. In this case, it will be true when the value of `--theme` is any value other than any syntax equivalent value of `red` (such as `#ff0000`). When true, the `<output>` will have a 5px dotted outline. The outline color is the current value of `--theme`. The default text `color` is gray.

```
@container style(--theme) {
  output {
    outline: 5px dotted var(--theme);
    color: #777777;
  }
}
```

The second and third style queries include values for the custom property. These will match if the container's `--theme` value is an equivalent color to the value listed, even if that value is the same as the `initial-value`. The first query matches elements whose `--theme` value is equivalent to `red`, `blue`, or `green`. When it is, the `color` will be the color current value of `--theme` (in the case of `blue` and `green`, overriding the gray set in the first style query).

The second style query states that when `--theme` is equivalent to `red`, the `<output>`'s contents will also be bold. We did this to better demonstrate that the container query is a match.

```
@container style(--theme: green) or style(--theme: blue) or style(--theme: red) {
  output {
    color: var(--theme);
  }
}

@container style(--theme: red) {
  output {
    font-weight: bold;
  }
}
```

Try entering different color values into the text box. You may notice that values that are sRGB equivalents of `red` will make the `<output>` red — as it matches `style(--theme: red)` — while removing the outline, because `style(--theme)` returns false if the element's value for `--theme` is the same as the initial value for `--theme` defined by the `@property` at-rule. Any non-red sRGB valid color value, including `currentColor` or `hsl(180 100% 50%)`, etc., makes the first style query return true; they are values that are different from the `initial-value`.

Because we set `syntax: "<color>";`, the CSS variable can only be assigned valid `<color>` values. Valid values for the `color` property that aren't value `<color>` values, such as `unset` or `inherit`, are invalid for this custom property, and will be ignored.

If you enter `unset` or `gibberish`, the JavaScript updates the `style` on the `<body>` to `--theme: unset` or `--theme: gibberish`. Neither of these are colors. Both are invalid and ignored. This means the initial value is inherited and unchanged, with `style(--theme)` returning false and `style(--theme: red)` returning true.

> **Note:** When declaring custom properties, consider using `@property` with the `syntax` descriptor so the browser can properly compare computed values.

Plain versus range syntax in style queries

When a `<style-feature>` includes a value, you can express the comparison in two different ways. They look similar but behave very differently, and choosing the right one matters.

The **plain syntax** uses a colon, the same syntax used in a CSS declaration:

```
@container style(--n: 3) {
  /* … */
}
```

This form is true if the computed value of the property matches the value on the right. For an unregistered custom property, the computed value is the property's value as written: the browser doesn't evaluate `calc()` or other expressions inside it. The match is essentially a comparison of the two values' tokens. To match equivalent values (such as `blue` and `#0000ff`), register the custom property with `@property` and a `syntax` descriptor.

The **range syntax** uses a comparison operator (`=`, `<`, `<=`, `>`, or `>=`):

```
@container style(--n = 3) {
  /* … */
}
```

To evaluate this form, the browser:

1. Resolves each side (custom property names are looked up as if used with `var()`).
2. Parses each side as one of `<number>`, `<percentage>`, `<length>`, `<angle>`, `<time>`, `<frequency>`, or `<resolution>`. If either side can't be parsed as one of those types, the query is false.
3. If both sides have the same type, computes each side (evaluating any `calc()` expressions) and performs the numeric comparison. Otherwise, the query is false.

Consider the following example, where `--n` is set to a `calc()` expression:

```
.box {
  --n: calc(6/2);
}

/* Evaluates to FALSE: */
/* the computed value of --n is the string `calc(6/2)`, which is */
/* not equal to the string `3`. */
@container style(--n: 3) {
  /* … */
}

/* Evaluates to TRUE: */
/* both sides are parsed as <integer>, calc(6/2) is computed to 3, */
/* and 3 = 3. */
@container style(--n = 3) {
  /* … */
}
```

The range syntax also supports a three-value form for testing whether a value falls within an interval. Both comparators must point the same way:

```
@container style(0 < --n < 10) {
  /* true when --n is greater than 0 and less than 10 */
}

@container style(100px > --width > 50px) {
  /* true when --width is less than 100px and greater than 50px */
}
```

The range syntax is also more flexible in how each side is written. Either side can be a custom property name, a `var()` reference, a literal value, or a `calc()` expression, and the operands can appear in any order. The following are all valid:

```
@container style(3 = --n) {
  /* … */
}
@container style(var(--n) = 3) {
  /* … */
}
@container style(calc(6/2) = var(--n)) {
  /* … */
}
```

The plain syntax is more restrictive: the left-hand side must be the custom property name (without `var()`), and the value goes on the right. The following are all **invalid**:

```
@container style(var(--n): 3) {
  /* … */
}
@container style(3: --n) {
  /* … */
}
```

Because the range syntax requires both sides to parse as one of the listed numeric types, it can't be used to compare keyword-like values. For example, given `--s: new`, the query `style(--s = new)` is false (because `new` isn't a number, length, etc.), while `style(--s: new)` is true.

In short:

- Use **`style(--variable: value)`** for keyword-like or string-like matching, such as `style(--stock: low)` or `style(--theme: dark)`.
- Use **`style(--variable = value)`** (or `<`, `<=`, `>`, `>=`) for numeric comparisons, such as `style(--columns >= 3)` or `style(--gap = 1rem)`.

Nested queries

Container queries can be nested within other container queries. The styles defined inside multiple nested container queries are applied when all of the wrapping container queries are true.

```
@container style(--theme: red) {
  output {
    outline: 1px dotted;
  }
  @container style(--theme: purple) {
    output {
      outline: 5px dotted;
    }
  }
}
```

In this case, the `<output>` will have a 5px dotted border if it's nested in a container where `--theme: purple` is set, and that container is nested within a container whose `--theme` value is `red`.

Style query CSS declarations and properties

Not yet supported in any browser, the `style()` functional notation can include regular CSS declarations including CSS properties and property value pairs.

```
@container style(font-weight: bold) {
  b,
  strong {
    background: yellow;
  }
}
```

When supported, this basic example will make the background color of any `<b>` and `<strong>` elements yellow when the parent is already `bold`.

The matching is done against the computed value of the parent container; if the parent's computed `font-weight` is `bold` (not `bolder` or `900`), there is a match. Just as with custom property container style queries, we did not have to define any elements as style containers as all elements are style containers by default. As long as an element doesn't have a `container-name` set, if it has `font-weight: bold` set or inherited, it

will match.

Style features that query a shorthand property will be true if the computed values match for each of its longhand properties, and false otherwise. For example, `@container style(border: 2px solid red)` will resolve to true if all 12 longhand properties (`border-bottom-style`, etc.) that make up that shorthand are set to the same equivalent values.

The global CSS values `revert` and `revert-layer` are invalid as values in a `<style-feature>` and cause the container style query to be false.

Do not apply the styles you are querying in the style query to the element you are styling with that query as this may cause an infinite loop.

It is expected that style queries will also accept properties in a boolean context. The style query will return false if the value of the property is the initial value for that property (if it has not been changed), and true otherwise.

```
@container style(font-weight) {
}
```

The above example will return true for any element that has a value for `font-weight` that differs from its initial value. User-agent stylesheets set `font-weight: bold` for heading and `<th>` elements, for example. Some browsers set `<strong>` and `<b>` to `bold`, others to `bolder`. `<optgroup>` also sometimes has a `font-weight` other than `normal` set by the user agent. As long as the element's `font-weight` is not the default value for that user-agent, the style query will return true.

These features are not yet supported in any browser.

Using CSS containment

CSS containment improves the performance of web pages by allowing the browser to isolate a subtree of the page from the rest of the page. If the browser knows that a part of the page is independent from the rest of the content, rendering can be optimized and performance improved.

The `contain` and `content-visibility` properties enable developers to inform user agents whether or not an element should render its contents at all, and whether it should render its contents when it is offscreen. The user agent then applies containment to elements when appropriate, potentially deferring layout and rendering until needed.

This guide describes the basic aims of CSS containment and how to leverage `contain` and `content-visibility` for a better user experience.

Basic example

Web pages often contain multiple sections which are, logically, independent of each other. CSS containment enables them to be treated truly independently from each other when it comes to rendering.

For example, blogs usually contain several articles, each containing a headline and content, as in the markup below.

```
<h1>My blog</h1>
<article>
  <h2>Heading of a nice article</h2>
  <p>Content here.</p>
</article>
<article>
  <h2>Another heading of another article</h2>
  <p>More content here.</p>
</article>
```

With CSS, we apply the `contain` property with a value of `content` to each article. The `content` value is shorthand for `contain: layout paint style`:

```
article {
  contain: content;
}
```

Logically, each article is independent of the other articles on the page. This information is something that is usually known, and likely quite obvious, to the web developer creating the page. However, browsers don't know the intent of your content and cannot assume that an article or other section of content will be entirely self-contained.

This property provides a way of explaining this to the browser and giving it explicit permission to make performance optimizations. It tells the browser that the internal layout of the element is completely separate from the rest of the page, and that everything about the element is painted inside its bounds. Nothing can visibly overflow.

By setting `contain: content` on each `<article>` we have indicated this; we have told the browser that each article is independent. The browser can then use this information to make decisions about how to render each `<article>` of content. For example, it might not render articles that are outside the viewable area.

When additional articles are appended at the end of the page, the browser does not need to recalculate layout or repaint the preceding content; it also doesn't need to touch any area outside of the containing element's subtree. If box model properties are dependent, however, the browser will need to recalculate layout and repaint. For example, if the `<article>` is styled such that its size depends on its contents (e.g., with `height: auto`), then the browser will need to account for its size changing.

Key concepts and terminology

<code>contain</code> values

There are four types of containment: layout, paint, size, and style. Use the `contain` property to specify the type or types you want to apply to an element by including any combination of these types.

Layout containment

```
article {
  contain: layout;
}
```

Layout is normally scoped to the entire document, which means that if you move one element the entire document needs to be treated as if things could have moved anywhere. By using `contain: layout` you can tell the browser it only needs to check this element — everything inside the element is scoped to that element and does not affect the rest of the page, with the containing box establishing an independent formatting context.

In addition:

- `float` layout will be performed independently inside the specified element.

- Margins won't collapse across a layout containment boundary.
- The layout container is a containing block for `absolute-` and `fixed`-positioned descendants.
- The containing box creates a stacking context, therefore `z-index` can be used.

> **Note:** The `style` and `layout` values of `contain` are automatically applied when using the `container-type` and `container-name` properties.

Paint containment

```
article {
  contain: paint;
}
```

Paint containment essentially clips the box to the padding edge of the principal box. There can be no visible overflow. The same additional notes are true for `paint` containment as `layout` containment (see above).

Another advantage is that if the element with containment applied is offscreen, the browser does not need to paint its child elements — these are also offscreen as they are contained completely by that box.

Size containment

```
article {
  contain: size;
}
```

Size containment does not offer much in the way of performance optimizations when used on its own. However, size containment means that the size of the size-contained element's children cannot affect the size of the element itself — its size is computed as if it had no children.

If you set `contain: size` on an element, you need to specify the size of the element using `contain-intrinsic-size`, or the longhand properties `contain-intrinsic-width` and `contain-intrinsic-height`, in that order. If no size is set, the element risks being zero-sized in most cases.

```
article {
  contain: size;
  contain-intrinsic-size: 100vw auto none;
}
```

Style containment

```
article {
  contain: style;
}
```

Despite the name, style containment does not provide scoped styles such as you would get with the Shadow DOM or `@scope`. The main use case for the `style` value is to prevent situations where a CSS counter could be changed in an element, which could then affect the rest of the tree.

Using `contain: style` ensures the `counter-increment` and `counter-set` properties create new counters scoped to that subtree only.

You can include more than one containment type by including multiple space-separated values, such as `contain: layout paint` or by using one of the two special values.

Special values

There are two special values of `contain` that are shorthand for the first three or all four of the containment types:

- `content`
- `strict`

We encountered the first in the example above. Using `contain: content` turns on `layout`, `paint`, and `style` containment. As it omits `size`, it is a safe value to apply widely.

The `contain: strict` declaration, which behaves the same as the declaration `contain: size layout paint style` (which includes four space-separated values), provides the most containment. It is riskier to use as it applies `size` containment; the risk exists that a box could end up zero-sized due to a reliance on the size of its children.

To remove this risk, always set a size when using `strict`:

```
article {
  contain: strict;
  contain-intrinsic-size: 80vw auto none;
}
```

The above is the same as:

```
article {
  contain: size layout paint style;
  contain-intrinsic-size: 80vw auto none;
}
```

<code>content-visibility</code>

When you have a lot of content that would benefit from heavy containment that will often be offscreen — for example if all your blog posts are viewable on the blog home pages as an infinitely scrollable blog — `content-visibility: auto` can be used to apply all of the containments at once.

The `content-visibility` property controls whether or not an element renders its contents at all, along with forcing a strong set of containments, allowing user agents to potentially omit large swathes of layout and rendering work until it becomes needed. It enables the user agent to skip an element's rendering work (including layout and painting) until it is needed — which makes the initial page load much faster.

Its possible values are:

- `visible`: The default behavior — an element's contents are laid out and rendered as normal.
- `hidden`: The element skips its contents. The skipped contents will not be accessible to user agent features such as find-in-page, tab-order navigation, etc., nor be selectable or focusable.
- `auto`: The element turns on layout containment, style containment, and paint containment, as if `contain: content` was set. If the element is not relevant to the user, it also skips its contents. Unlike `hidden`, the skipped content is still available for user interactions, remaining focusable, selectable, in regular tab order, and available to in-content search.

Relevant to the user

User-agents have a concept of content being relevant to the user. An element becomes "relevant to the user" if any of the following are true:

- The element appears in the viewport, or a user-agent-defined margin around the viewport (50% of the viewport dimensions, to give the app time to prepare for when the element visibility changes).
- The element or its contents receive focus.
- The element or its contents are selected, for example by dragging over the text with the mouse cursor or by some other highlight operation.

- The element or its contents are placed in the top layer.

When `content-visibility: auto` is set, and the browser determines that content is relevant to the user, the browser will render that content.

Skips its contents

When you set `content-visibility: hidden` on an element, you are telling the browser that it is not relevant to the user, and therefore its contents should be skipped and not rendered. This helps to improve performance.

The browser will also skip an element's contents when `content-visibility: auto` is set on it, and the browser determines that its content is *not* relevant to the user.

When an element skips its contents:

- It has layout, style, paint, and size containment turned on.
- Its contents are not painted, as if `visibility: hidden` was set on it.
- Its contents do not receive pointer events, as if `pointer-events: none` was set on it.

This happens in both the cases mentioned above, but with `content-visibility: auto` the content can be searched, receive focus, and otherwise move from not relevant to relevant. This is not the case for `content-visibility: hidden`.

> **Note:** To animate the transition from `content-visibility: hidden` to a visible value, you will need to set `transition-behavior: allow-discrete` and `@starting-style` styles. See transitioning `display` and `content-visibility` to learn more.

CSS counter styles

The **CSS counter styles** module lets you define your own counter styles to manage the appearance of markers in lists and counters in generated content. It also enables you to extend native browser list styles with your own customizations.

While we think of counters as numbers, they are actually strings with components that can be incremented. The counter styles module defines the `@counter-style` rule with ten descriptors, which enable developers to precisely define how counters are converted into strings. This module enables defining which characters to use for the counter bullets, the prefix to put before the counter and postfix that comes after, along with how to handle negative values. The descriptors can also set a range to limit the values a counter style can handle, while also providing fallback styles for when the counter value falls outside the defined range or otherwise can't render the counter value. The module also enables defining how the counter is read out loud by speech synthesizers.

Using CSS counters

CSS counters let you adjust the appearance of content based on its location in a document. For example, you can use counters to automatically number the headings on a webpage or to change the numbering on ordered lists.

Counters are, in essence, variables maintained by CSS whose values may be incremented or decremented by CSS rules that track how many times they're used. The following things affect the counter values on an element:

1. Counters are inherited from the parent element or received from a previous sibling.
2. New counters are instantiated using `counter-reset` property.
3. Counters are incremented using `counter-increment` property.
4. Counters are directly set to a value using the `counter-set` property.

You can define your own named counters, and you can also manipulate the `list-item` counter that is created by default for all ordered lists.

Using counters

To use a counter, it must first be initialized to a value with the `counter-reset` property. The counter's value can be increased or decreased using the `counter-increment` property and can be directly set to a specific value using the `counter-set` property. The current value of a counter is displayed using the `counter()` or `counters()` function, typically within a pseudo-element `content` property.

Counters can only be set, reset, or incremented in elements that generate boxes. For example, if an element is set to `display: none`, then any counter operation on that element is ignored.

The properties of counters can be scoped to specific elements using style containment, which is described in more detail in the `contain` property.

Manipulating a counter's value

To use a CSS counter, it must first be initialized to a value with the `counter-reset` property. The property can also be used to change the counter value to any specific number.

The following declaration initializes a counter named `section` to the default value (`0`):

```
counter-reset: section;
```

You can also initialize multiple counters, optionally specifying an initial value for each. The following declaration initializes the `section` and `topic` counters to the default value, and the `page` counter to `3`:

```
counter-reset: section page 3 topic;
```

Once initialized, a counter's value can be increased or decreased using `counter-increment`. For example, the following declaration increments the value of the `section` counter by `1` on every `<h3>` element:

```
h3 {
  counter-increment: section;
}
```

You can specify the increment or decrement amount after the counter name. It can be a positive or negative number, but defaults to `1` if no integer is provided.

Apart from being incremented or decremented, counters can also be explicitly set to a value using the `counter-set` property.

```
.done {
  counter-set: section 20;
}
```

The counter's name must not be `none`, `inherit`, or `initial`; otherwise the declaration is ignored.

Displaying a counter

The value of a counter can be displayed using either the `counter()` or `counters()` function in a `content` property.

For example, the following declaration uses `counter()` to prefix each `h3` heading with the text `Section <number>:`, where `<number>` is the value of the count in decimal (the default display style):

This creates a counter named `section` on the `<body>` element and sets its initial value to `0`. The counter increments by `1` on every `<h3>` element. Before the content of each `<h3>` heading, `Section <n>:` is displayed, where `<n>` is the default decimal value of the `section` counter.

```
body {
  counter-reset: section;
}

h3 {
  counter-increment: section;
}

h3::before {
  content: "Section " counter(section) ": ";
}
```

Comparing <code>counter()</code> and <code>counters()</code>

The `counter()` function is used when the numbering of nesting levels does not include the context of parent levels. For example, here each nested level restarts from one:

```
1 One
  1 Nested one
  2 Nested two
2 Two
  1 Nested one
```

```
  2 Nested two
  3 Nested three
3 Three
```

The `counters()` function is used when the count for nested levels must include the count from parent levels. For example, you might use this to lay out sections as shown:

```
1 One
  1.1 Nested one
  1.2 Nested two
2 Two
  2.1 Nested one
  2.2 Nested two
  2.3 Nested three
3 Three
```

The `counter()` function has two forms: `counter(<counter-name>)` and `counter(<counter-name>, <counter-style>)`. The generated text is the value of the innermost counter of the given name in scope at the pseudo-element.

The `counters()` function also has two forms: `counters(<counter-name>, <separator>)` and `counters(<counter-name>, <separator>, <counter-style>)`. The generated text is the value of all counters with the given name in scope at the given pseudo-element, from outermost to innermost, separated by the specified string (`<separator>`).

The counter is rendered in the specified `<counter-style>` for both methods (`decimal` by default). You can use any of the `list-style-type` values or your own custom styles.

The use of the `counter()` and `counters()` functions is demonstrated later in the Basic example and Nested counters sections, respectively.

Reversed counters

A reversed counter is one that is intended to count down (decrement) rather than up (increment). Reversed counters are created using the `reversed()` function notation when naming the counter in `counter-reset`.

Reversed counters have a default initial value equal to the number of elements (unlike normal counters, which have a default value of 0). This enables implementing a counter that counts from the number of elements down to one.

For example, to create a reversed counter named `section` with a default initial value, you would use the following syntax:

```
counter-reset: reversed(section);
```

You can, of course, specify any initial value that you like.

The counter value is decreased by specifying a negative value for `counter-increment`.

> **Note:** You can also use `counter-increment` to decrement a non-reversed counter. The main benefit of using a reversed counter is the default initial value, and that the `list-item` counter automatically decrements reversed counters.

Counter inheritance and propagation

Each element or pseudo-element has a set of counters in the scope of that element. Initial counters in the set are received from the element's parent and the preceding sibling. The counter values are received from the last descendant of the previous sibling, the last sibling, or the parent.

When an element declares a counter, the counter is nested inside the counter with the same name received from the parent. If the parent doesn't have a counter with the same name, then the counter is added to the element's counters set as it is. A counter with the same name received from the previous sibling is removed from the element's set of counters.

The `counter()` function retrieves the innermost counter with the provided name. The `counters()` function retrieves the entire counter tree with the given name.

The following example demonstrates an inherited counter named `primary` and a sibling counter named `secondary`. All the `<div>` elements display their counters using the `counters()` function. Note that all the counters have been created using the `counter-reset` property, and none of the counters have been incremented.

```
<section>
  counter-reset: primary 3
  <div>A</div>
  <div>B</div>
  <div>C</div>
  <div class="same-primary-name">D</div>
  <span> counter-reset: primary 6</span>
  <div>E</div>
  <div class="new-secondary-name">F</div>
  <span> counter-reset: secondary 5</span>
  <div>G</div>
  <div>H</div>
  <div class="same-secondary-name">I </div>
  <span> counter-reset: secondary 10</span>
  <div>J </div>
  <div>K</div>
  <section></section>
</section>
```

```
.same-primary-name,
.new-secondary-name,
.same-secondary-name {
  display: inline-block;
}

@counter-style style {
  system: numeric;
  symbols: "" "1" "2" "3" "4" "5" "6" "7" "8" "9" "10";
}
```

We create the `primary` counter on divs' parent, then create a new `primary` counter on `D`. We create the `secondary` counter on `F`, then override the sibling `secondary` counter on `I`.

```
section {
  counter-reset: primary 3;
}

div::after {
  content: " ('primary' counters: " counters(primary, "-", style)
    ", 'secondary' counters: " counters(secondary, "-", style) ")";
  color: blue;
```

```
}

.same-primary-name {
  counter-reset: primary 6;
}

.new-secondary-name {
  counter-reset: secondary 5;
}

.same-secondary-name {
  counter-reset: secondary 10;
}
```

The section element initializes a counter named `primary` with value `3`, and all the child `<div>`s receive the inherited `primary` counter. The element 'D' creates a new `primary` (value `6`) counter which gets nested in the counter received from the parent, so the element has two counters named `primary` with values `3` and `6`.

The element 'F' creates the `secondary` (value `5`) counter for the first time, and it passes the counter to the next sibling 'G'. The element 'G' passes the counter to the next element 'H' and so on. Next, the element 'I' creates a new counter with the same name `secondary` (value `10`), but it drops the `secondary` (value `5`) counter received from the previous sibling 'H' and passes its own counter to 'J'.

Difference between counter-set and counter-reset

The `counter-set` property updates an existing counter. If no counter with that name exists, then a new counter is instantiated. The `counter-reset` property *always* creates a new counter.

In the following example, we have two sub-lists inside a parent list. Each list item has been numbered using a counter named 'item'. The first sub-list uses `counter-set` property and the second sub-list uses `counter-reset` property to change the 'item' counter.

```
<ul class="parent">
  <li>A</li>
  <li>B</li>
  <li>
    C (the counter updated using `counter-set`)
    <ul class="sub-list-one">
      <li>sub-A</li>
      <li>sub-B</li>
    </ul>
  </li>
  <li>D</li>
  <li>
    E (a new counter created using `counter-reset`)
    <ul class="sub-list-two">
      <li>sub-A</li>
      <li>sub-B</li>
      <li>sub-C</li>
    </ul>
  </li>
  <li>F</li>
  <li>G</li>
</ul>
```

```
ul {
  list-style: none;
}
```

We create a new counter on `parent` and increment it on each list item, then show the numbers on the list items using generated content. We update the existing counter value with `counter-set`, then reset it with `counter-reset` on `.sub-list-one` and `.sub-list-two`, respectively.

```
.parent {
  counter-reset: item 0;
}

li {
  counter-increment: item;
}

li::before {
  content: counter(item) " ";
}

.sub-list-one {
  counter-set: item 10;
}

.sub-list-two {
  counter-reset: item 0;
}
```

Notice how the first sub-list starts at `11`, and its numbering continues in the parent list. This is because the `counter-set` property updates the same `item` counter declared on `.parent`. The second sub-list starts at `1` and the parent list items after it don't carry forward the numbering. This is because the `counter-reset` property creates a new counter with the same name, so the parent list items use the original counter.

List item counters

Ordered lists, as created using `<ol>` elements, implicitly have a counter named `list-item`.

Like other counters, this has a default initial value of 0 for upward counters and "number of items" for reversed counters. Unlike author-created counters, `list-item` *automatically* increments or decrements by one for each list element, depending on whether or not the counter is reversed.

You can use the `list-item` counter to manipulate the default behavior of ordered lists with CSS. For example, you can change the default initial value, or use `counter-increment` to change the way in which the list items increment or decrement.

Examples

Basic example

This example adds "Section [the value of the counter]:" to the beginning of each heading.

HTML

We include three `<h3>` elements.

```
<h3>Introduction</h3>
<h3>Body</h3>
<h3>Conclusion</h3>
```

CSS

We create a counter named 'section', letting its initial value default to `0`. We increment the value of `section` counter by `1` at each `<h3>` and display the word "Section", the value of `section` counter, and a colon before the content of each `<h3>`.

```
body {
  counter-reset: section;
}

h3::before {
  counter-increment: section;
}
h3::before {
  content: "Section " counter(section) ": ";
}
```

Result

Reversed counter

This example uses the same HTML as the previous example but uses a reversed counter, numbering the elements from 3 to 1.

```
<h3>Introduction</h3>
<h3>Body</h3>
<h3>Conclusion</h3>
```

CSS

We use the `reversed()` function to create a counter named 'section', letting the initial value default so that when we decrement the value of `section` counter by `1` on each `<h3>`, the last element in the set will have the counter set to `1`. We use generated content to display the word 'Section ' and the value of the counter before the content of each `<h3>`.

```
body {
  counter-reset: reversed(section);
}

h3 {
  counter-increment: section -1;
}
h3::before {
  content: "Section " counter(section) ": ";
}
```

```
@supports not (counter-reset: reversed(section)) {
  body::before {
    content: "Your browser doesn't support the reversed() function.";
    background-color: wheat;
    display: block;
    text-align: center;
    padding: 1rem 0;
  }
}
```

Result

A more elaborate example

A counter need not necessarily be shown every time it is incremented. This example counts all links but shows the counter as generated content only when a link has no text.

HTML

We include three paragraphs, each with a link, but the first and last links contain no text.

```
<p>See <a href="https://www.mozilla.org/" aria-label="Mozilla"></a></p>
<p>Do not forget to <a href="contact-me.html">leave a message</a>!</p>

CSS

We create and initialize the counter on `:root`, increment it on every link, and generate content only when the link is `:empty`.

```
:root {
  counter-reset: link;
}

a[href] {
  counter-increment: link;
}

a[href]:empty::after {
  content: "[" counter(link) "]";
}
```

Result

Nested counters

A CSS counter can be especially useful for making outlined lists, because a new instance of the counter is automatically created in child elements. Using the `counters()` function, separating text can be inserted between different levels of nested counters.

CSS

We create a new instance of the section counter with each `<ol>` element, incrementing only the current instance of the section counter on each `<li>`. Using the `counters()` function, we combine the values of all instances of the section counter, separated by a period.

```
ol {
  counter-reset: section;
  list-style-type: none;
}

li {
  counter-increment: section;
}

li::before {
  content: counters(section, ".") " ";
}
```

HTML

```
<ol>
  <li>item</li>          <!-- 1     -->
  <li>item               <!-- 2     -->
    <ol>
      <li>item</li>      <!-- 2.1   -->
      <li>item</li>      <!-- 2.2   -->
      <li>item           <!-- 2.3   -->
        <ol>
          <li>item</li>  <!-- 2.3.1 -->
          <li>item</li>  <!-- 2.3.2 -->
        </ol>
        <ol>
          <li>item</li>  <!-- 2.3.1 -->
          <li>item</li>  <!-- 2.3.2 -->
          <li>item</li>  <!-- 2.3.3 -->
        </ol>
      </li>
      <li>item</li>      <!-- 2.4   -->
    </ol>
  </li>
  <li>item</li>          <!-- 3     -->
  <li>item</li>          <!-- 4     -->
</ol>
<ol>
  <li>item</li>          <!-- 1     -->
  <li>item</li>          <!-- 2     -->
</ol>
```

Viewport concepts

This article explains the concept of the viewport — what it is and its impact in terms of CSS, SVG, and mobile devices. This article defines the initial viewport and actual viewport, and differentiates between the visual viewport and the layout viewport.

What is a viewport?

A **viewport** is a user agent feature used to establish the initial containing block for continuous media.

The generic *viewport* term generally refers to the area in computer graphics being currently viewed. In web browser terms, that is generally the same as the browser window, excluding the UI, menu bar, etc. That is the part of the document you are viewing.

As a document loads, the viewport goes through two stages:

Initial viewport

> The *initial viewport* refers to the window or viewing area of the UA before user agent styles, HTML `<meta>` tags, or CSS styles have overridden its size. The initial viewport size is based on the size of the window or viewing area, and not the content. The size of a full-screen user agent's initial viewport will differ between orientations and devices, but will always be the same for the same device in the same orientation.

Actual viewport

> The *actual viewport* is the viewport you get after processing the viewport `<meta>` tag. Content designed for large viewports may exhibit a variety of bugs when viewed in smaller viewports, including unintended wrapping, clipped content, and incorrectly sized scroll containers. The viewport meta tag provides hints about the initial size of the viewport. The actual viewport is the size defined by its `content` attribute. If this tag is omitted, some mobile browsers render content using a fixed initial containing block width, typically `980px`. They set the width of the actual viewport to this value, then scale the content down to fit it, making the CSS pixel size smaller than an actual pixel.

Documents, like this article, may be very long. Your viewport is everything that is currently visible; notably, the "what is a viewport" section, and perhaps some of the navigation menu. The size of the viewport depends on the size of the screen, whether the browser is in fullscreen mode or not, and whether or not the browser is zoomed in. Content outside the viewport, such as the *See Also* section in this document, is likely to not be visible onscreen until scrolled into view.

- On larger monitors where applications aren't necessarily full screen, the viewport is the size of the browser window.
- On most mobile devices and when the browser is in fullscreen mode, the viewport is the entire screen.
- In fullscreen mode, the viewport is the device screen, the window is the browser window, which can be as big as the viewport or smaller, and the document is the website, which can be much taller or wider than the viewport.

For paged media, the initial containing block is based on the page area. The page area can be set through `@page` rules.

To recap, the viewport is basically the part of the document that is currently visible.

Viewport sizes are mutable

The width of the viewport is not always the width of the window. If you query the width or height of the window and document in Chrome or Firefox, you may get:

```
document.documentElement.clientWidth; /* 1200 */
window.innerWidth; /* 1200 */
window.outerWidth; /* 1200 */
```

```
document.documentElement.clientHeight; /* 800 */
window.innerHeight; /* 800 */
window.outerHeight; /* 900 */
```

There are several DOM properties that can help you query viewport size, and other similar lengths:

- The document element's `Element.clientWidth` is the inner width of a document in CSS pixels, including padding (but not borders, margins, or vertical scrollbars, if present). **This is the viewport width**.
- The `Window.innerWidth` is the width, in CSS pixels, of the browser window viewport including, if rendered, the vertical scrollbar.
- The `Window.outerWidth` is the width of the outside of the browser window including all the window chrome.

In an experiment with these, the `innerWidth` and `outerWidth` was seen to be the same, but the `outerHeight` was 100px taller than the `innerHeight`. This is because the `outerHeight` includes the browser chrome: measurements were taken on a browser with an address bar and bookmarks bar totaling 100px in height, but no chrome on the left or right of the window.

The area within the `innerHeight` and `innerWidth` is generally considered the **layout viewport**. The browser chrome is not considered part of the viewport.

When zoomed in, both Firefox and Chrome report the new CSS pixel size for `innerWidth` and `clientWidth`. The values returned for the `outerWidth` and `outerHeight` depend on the browser: Firefox reports the new value in CSS pixels, but Chrome returns the length in the default pixel size. When zoomed in you may get:

```
document.documentElement.clientWidth; /* 800 */
window.innerWidth; /* 800 */
window.outerWidth; /* 800 in Firefox, 1200 in chrome */
```

```
document.documentElement.clientHeight; /* 533 */
window.innerHeight; /* 533 */
window.outerHeight; /* 596 in Firefox, 900 in chrome */
```

The viewport was originally 1200 x 800 pixels. Upon zooming in, the viewport became 800 x 533 pixels. This is the *layout viewport*. Sticky headers or footers, with the following styles, will stick to the top and bottom of the *layout viewport* respectively.

```
body > header {
  position: fixed;
  top: 0;
}
body > footer {
  position: fixed;
  bottom: 0;
}
```

We got the 800 x 533 measurement when we zoomed in using the keyboard. The header and footer stayed flush against the top and bottom of the window. But what if we had pinched-zoomed on a tablet? What if a dynamic keyboard pops open on a phone?

Layout and visual viewports

The web contains two viewports, the **layout viewport** and the **visual viewport**. The visual viewport is the part of the web page that is currently visible in the browser and can change. When the user pinch-zooms the page, pops open a dynamic keyboard, or when a previously hidden address bar becomes visible, the visual viewport shrinks but the layout viewport is unchanged.

Fixed sticky headers or footers, as discussed above, stick to the top and bottom of the *layout viewport*, and therefore remain in view when we zoom in with the keyboard. If you pinch-zoom, the layout viewport may not be fully visible. If you magnify from the middle of the layout viewport, the content will expand in all four directions. If you have a sticky header or footer, they will still be stuck to the top or bottom of the layout viewport, but they may not be visible at the top and bottom of the device's screen — which is the visual viewport. The visual viewport is the currently visible portion of the layout viewport. If you scroll down, you are changing the contents of the visual viewport and bringing the bottom of the layout viewport into view, displaying the sticky footer, which will then stay stuck at the bottom.

The visual viewport is the visual portion of a screen not including on-screen keyboards, areas outside of a pinch-zoom area, or other feature that doesn't scale with the dimensions of a page. The visual viewport is the same size as the layout viewport or smaller.

For a page containing iframes, objects, or external SVG, both the containing pages and each included file has their own unique window object. Only the top-level window has a visual viewport that may be distinct from the layout viewport. For included documents, the visual viewport and layout viewport are the same.

CSS

The layout viewport and visual viewport described above are not the only viewports you will encounter. Any sub-viewport that is fully or partially displayed within the layout viewport is considered a visual viewport.

We generally think of `width` and `height` media queries as being relative to the width and height of the browser window. They are actually relative to the viewport, which is the window in the main document but is the intrinsic size of the element's parent in a nested browsing context like objects, iframes and SVG. In CSS, we also have length units based on the viewport size. A `vh` unit is 1% of the layout viewport's height. Similarly, the `vw` unit is 1% of the layout viewport's width.

`<iframe>`

Inside an `<iframe>`, the visual viewport is the size of the inner width and height of the iframe, rather than the parent document. You can set any height and width on an iframe, but the whole document may not be visible.

If you use viewport length units in your CSS within the iframe document, `1vh` will be 1% of the height of the iframe, and `1vw` will be 1% of the width of the document.

```
iframe {
  width: 50vw;
}
```

If the iframe is set to 50vw, it will be 50% of the width of the `1200px` parent document in our example above, or `600px`, with `1vw` being `6px`. When zoomed in, the iframe shrinks to `400px` and `1vw` becomes `4px`.

A width-based media query within the iframe document is relative to the iframe's viewport.

```
@media screen and (width <= 500px) {
  p {
    color: red;
  }
}
```

If the above CSS is included in the iframe, the paragraphs will become red when the user has zoomed in, but this style does not apply in the non-zoomed-in state.

SVG

In an SVG document, the viewport is the visible area of the SVG image. You can set any height and width on an `<svg>`, but the whole image might not be visible. The area that is visible is called the viewport. The size of the viewport can be defined using the width and height attributes of the `<svg>` element.

```
<svg height="300" width="400"></svg>
```

In this example, the viewport has an aspect ratio of 3:4 and is, by default, 400 by 300 units, with a unit generally being a CSS pixel.

SVG also has an internal coordinate system defined via the viewBox attribute, which is not related to this viewport discussion.

If you include an SVG file in your HTML, the viewport of the SVG is the initial containing block, or the width and height of the SVG container. Using the `@media` query in your SVG's CSS is relative to that container, not the browser.

```
@media screen and (400px <= width <= 500px) {
  /* CSS goes here */
}
```

Generally, when you write the above media query, the styles are applied if the viewport, generally the browser window, is between 400px and 500px, inclusive. The width media query in the SVG is based on the element in which the SVG is contained — the `<img>` if the source is an SVG file, the SVG itself if the SVG is included directly into the HTML, or the parent if the parent element has a width assigned and — not the viewport's width. With the above media query being in our SVG file, the CSS is applied if the SVG container is between 400px and 500px.

JavaScript

The `VisualViewport` interface provides a mechanism for querying and modifying the properties of the visual viewport.

The `Viewport` interface provides a mechanism for querying and modifying the properties of the visual viewport.

Mobile viewports

Mobile devices come in all shapes and sizes, with screens of differing device pixel ratios. The mobile browser's viewport is the area of the window in which web content can be seen, which is not necessarily the same size as the rendered page. Mobile browsers render pages in a virtual window or viewport, generally at 980px, which is usually wider than the screen, and then shrink the rendered result down so it can all be seen at once. Users can then pan and zoom to see different areas of the page. For example, if a mobile screen has a width of 320px, a website might be rendered with a virtual viewport of 980px, and then it will

be shrunk down to fit into the 320px space, which, depending on the design, is illegible for many if not everyone. To tell a mobile browser to use the viewport width instead of the default 980px as the width of the screen, developers can include a viewport meta tag, like the following:

```
<meta name="viewport" content="width=device-width" />
```

The `width` property controls the size of the viewport. It should preferably be set to `device-width`, which is the width of the screen in CSS pixels at a scale of 100%. There are other properties, including `maximum-scale`, `minimum-scale`, and `user-scalable`, which control whether users can zoom the page in or out, but the default values are the best for accessibility and user experience, so these can be omitted.

CSS custom functions and mixins

The **CSS custom functions and mixins** module allows developers to create reusable blocks of CSS code that can accept arguments, contain complex logic (defined using features such as CSS `if()` functions and `@media` at-rules), and return values based on that logic.

CSS custom functions are defined in `@function` at-rules and called using `<dashed-function>` syntax, which looks very similar to CSS custom property syntax except that it includes parentheses at the end containing arguments (for example, `--my-function(30px, 3)`). CSS custom functions can be called within any property value, and will return a value based on the arguments passed into the function and the logic inside it.

CSS mixins are defined in `@mixin` at-rules and applied using `@apply` at-rules nested inside rulesets. CSS mixins define a set of properties that can be reused inside multiple rulesets and customized with arguments and logic.

CSS custom functions and mixins can be assigned optional data types for their arguments and return values, to restrict the values passed into them and returned from them.

> **Note:** Currently, only CSS custom functions have browser support. CSS mixins are not currently supported in any browser.

Using CSS custom functions

CSS custom functions enable you to create reusable blocks of CSS code that can accept arguments, contain complex logic (defined using features such as CSS `if()` functions and `@media` at-rules), and return values based on that logic. They work similarly to CSS custom properties, but provide more flexibility.

In this article, we'll show you how to use them and present some real-world examples.

Function basics

A basic CSS custom function definition looks like this:

```
@function --half-opacity() {
  result: 0.5;
}
```

After the `@function` syntax, we define a name for the function: `--half-opacity`. This must be a `<dashed-ident>` type — it must start with a double-dash, and is case-sensitive. The function name is immediately followed by a set of parentheses (`()`) and a set of curly braces (`{}`).

> **Note:** If multiple CSS functions are given the same name, the function in the stronger cascade `@layer` wins. If all of them are in the same layer, the function defined last in the source order wins.

Inside the curly braces is the function **body**, which is where the function logic is defined. This can contain multiple declarations, including custom properties (which will be locally scoped to the function body), at-rules such as `@media`, and the `result` descriptor. The value of the `result` descriptor is evaluated to determine the value returned by the function.

Here, we are setting `result` to the value `0.5`: the `--half-opacity()` function will always return `0.5`.

Why "result" and not "return"?

The `result` descriptor sounds similar in functionality to the JavaScript function `return` statement. However, `return` is not used in CSS functions. This is because, unlike JavaScript `return` statements, CSS functions do not return a value as soon as a `result` declaration is reached.

The body of a CSS function is evaluated from start to finish. If there are multiple `result` declarations included in the body, the last one in the source order overrides the earlier ones.

Calling a CSS function

A CSS function can be called in place of any suitable property value using the `<dashed-function>` syntax, which consists of the function name followed by parentheses containing the arguments to pass to the function, if any. For example, we can call our `--half-opacity()` function like this:

```
h2 {
  opacity: --half-opacity();
}
```

Since this function always returns the value `0.5`, the previous declaration is the equivalent of `opacity: 0.5`. This isn't very useful. You might as well just use a custom property, or the literal value `0.5`.

Let's move on to look at how we can use CSS functions.

Feature detecting CSS functions

One practical use of CSS functions with no parameters is in feature detection. In all of the examples we'll be looking at in this article, we define a `--supports()` function that looks like this:

```
@function --supports() {
  result: none;
}
```

You can then define a "feature not supported" banner, and set its `display` property to `--supports()`:

```
<p class="support">
  ⚠️ Your browser doesn't currently support CSS custom functions.
</p>
```

```
.support {
  /* ... */
  display: --supports();
}
```

In browsers that support custom functions, `display` will be set to `none`, and the support banner will be hidden. In non-supporting browsers, the `display: --supports()` declaration will be invalid and therefore ignored; therefore, the banner will be displayed.

Specifying function parameters

CSS function parameters are specified as comma-separated custom properties inside the parentheses following the function name. For example:

```
@function --transparent(--color, --alpha) {
  result: oklch(from var(--color) l c h / var(--alpha));
}
```

This function has a name of `--transparent` and takes two custom properties as parameters, `--color` and `--alpha`, which can be used locally inside the function body. The body contains a `result` descriptor, which uses CSS relative color syntax to convert the input `--color` value into an `oklch()` color with an alpha channel value as specified in the input `--alpha` value.

You can then call this function anywhere you want to produce a semi-transparent version of an existing color.

For example:

```
section {
  --base-color: #faa6ff;
  background-color: --transparent(var(--base-color), 0.8);
}
```

Specifying data types

It is possible to specify permitted data types for the function parameters and return value. When you don't specify these, the function will accept any type for these values.

Let's modify our previous function to provide data types:

```
@function --transparent(--color type(<color>), --alpha type(<number>)) returns
  type(<color>) {
```

```
  result: oklch(from var(--color) l c h / var(--alpha));
}
```

The data type of each parameter is specified after the parameter name, and the data type of the `result` is specified just before the opening curly brace, preceded by the `returns` keyword. The `type()` function is used to specify a data type.

Note that, in cases where you are only specifying a single data type, you can omit the `type()` syntax and just write the type as a shorthand:

```
@function --transparent(--color <color>, --alpha <number>) returns <color> {
  result: oklch(from var(--color) l c h / var(--alpha));
}
```

Now the function will only produce a valid value if the input arguments are a `<color>` and a `<number>`, respectively, and the `result` is a `<color>`. If not, for example:

```
section {
  --base-color: #faa6ff;
  background-color: --transparent(var(--base-color), 50%);
}
```

then the value will become invalid at computed-value time (since `50%` is not a `<number>` but a `<percentage>`) and the `background-color` will end up being set to `transparent`.

Specifying multiple permitted types

You can specify multiple accepted data types using the `|` symbol as a separator, for example:

```
@function --transparent(--color <color>, --alpha type(<number> | <percentage>))
  returns <color> {
  result: oklch(from var(--color) l c h / var(--alpha));
}
```

In such cases, the full `type()` syntax must be used.

With this adjustment, the `--transparent(var(--base-color), 50%)` function call is now valid.

Specifying default values

You can also specify default values for parameters, after a colon at the end of their definition. For example:

```
@function --transparent(--color <color>, --alpha <number>: 0.8) returns <color> {
  result: oklch(from var(--color) l c h / var(--alpha));
}
```

The `--alpha` parameter's default value is now `0.8`. If you want to use this value, you can omit the second argument when calling the function:

```
section {
  --base-color: #faa6ff;
  background-color: --transparent(var(--base-color));
}
```

> **Note:** If an invalid value is passed in as a function argument and a default value is specified in that parameter definition, the invalid value will be ignored, and the default value will be used instead.

Color adjust functions example

You can see the `--transparent()` function in action in our color-adjust-functions example (see the source code).

This example also includes functions called `--lighter()` and `--darker()` that work similarly to `--transparent()`, but return lighter and darker variants of a color, respectively:

```
@function --transparent(--color <color>, --alpha <number>: 0.8) returns <color> {
  result: oklch(from var(--color) l c h / var(--alpha));
}

@function --lighter(--color <color>, --lightness-adjust <number>: 0.2) returns
  <color> {
  result: oklch(from var(--color) calc(l + var(--lightness-adjust)) c h);
}

@function --darker(--color <color>, --lightness-adjust <number>: 0.2) returns
  <color> {
  result: oklch(from var(--color) calc(l - var(--lightness-adjust)) c h);
}
```

A library of functions like these can become very useful for defining color schemes based on a single color:

```
:root {
  --base-color: #faa6ff;
}

section {
  background-color: --transparent(var(--base-color));
  border: 3px solid --lighter(var(--base-color), 0.1);
  color: --darker(var(--base-color), 0.55);
}
```

Including complex logic

You can include more complex logic in functions using constructs such as `@media` at-rules and `if()` functions.

Our responsive-narrow-wide example (see the source code) features a function called `--narrow-wide()`, which can be used to provide two value options for any property. One will be set if the viewport is below a specific breakpoint, and the other will be set if it is above.

The `--narrow-wide()` function accepts two parameters, `--narrow` and `--wide`. The returned `result` is the `--wide` property, unless the viewport is less than `700px` wide, in which case `--narrow` is returned.

```
@function --narrow-wide(--narrow, --wide) {
  result: var(--wide);
  @media (width < 700px) {
```

```
    result: var(--narrow);
  }
}
```

This function can be used to provide responsive value options in multiple contexts:

```
body {
  display: grid;
  grid-template-columns: repeat(--narrow-wide(1, 3), 1fr);
  gap: --narrow-wide(0, 20px);
  padding: 0 20px;
}

h2 {
  font-size: --narrow-wide(2.5rem, 2rem);
}

p {
  font-size: --narrow-wide(1.4rem, 1rem);
  line-height: 1.5;
}
```

Using an <code>if()</code> function

We could rewrite the `--narrow-wide()` function to use an `if()` function instead:

```
@function --narrow-wide(--narrow, --wide) {
  result: if(media(width < 700px): var(--narrow) ; else: var(--wide));
}
```

Writing complex syntax once, then reusing it

A key use case for CSS functions is to define a complex section of syntax once, and be able to reuse it multiple times with a much simpler function call.

Our gradient-function example (see the source code) provides an example of this. It features a function called `--shippo-pattern()` that accepts length and color arguments, and returns a complex `background` value featuring multiple `radial-gradient()` backgrounds:

```
@function --shippo-pattern(--size <length>, --tint <color>) {
  result:
    radial-gradient(closest-side, transparent 98%, rgb(0 0 0 / 0.3) 99%) 0 0 /
      var(--size) var(--size),
    radial-gradient(closest-side, transparent 98%, rgb(0 0 0 / 0.3) 99%)
      calc(var(--size) / 2) calc(var(--size) / 2) / var(--size) var(--size)
      var(--tint);
}
```

With this function defined, we can now create variants of this background value with different color tints and circle sizes:

```
#one {
  background: --shippo-pattern(100px, #ddeeff);
}

#two {
  background: --shippo-pattern(3.5rem, lime);
}

#three {
  background: --shippo-pattern(10vw, purple);
}
```

CSS custom highlight API

The **CSS custom highlight API** module provides a programmatic way to target specific ranges of text defined by range objects, without affecting the underlying DOM structure. The range objects can then be selected via `::highlight()` pseudo-elements, and have highlight styles added and removed. The features of this module can create highlight effects similar to how text editors highlight spelling or grammar errors, and code editors highlight syntax errors.

The CSS Custom Highlight API extends the concept of other highlight pseudo-elements such as `::selection`, `::spelling-error`, `::grammar-error`, and `::target-text` by providing a way to create arbitrary text ranges (defined as `Range` objects in JavaScript) and style them via CSS, rather than being limited to browser-defined ranges.

Custom highlight API in action

To enable styling text ranges on a webpage using the CSS Custom Highlight API, you create a `Range` object, then a `Highlight` object for the range. After registering the highlight using the `HighlightRegistry.set()` method, you can then select the range using the `::highlight()` pseudo-element. The name defined in the `set()` method is used as the parameter of the `::highlight()` pseudo-element selector to select that range. The range selected by the `::highlight()` pseudo-element can be styled using a limited number of properties.

```
<h1>Directions</h1>
<h2>Lincoln Memorial to Martin Luther King, Jr. Memorial</h2>
<ol><li>Head south on Lincoln Memorial Circle</li
  ><li>Turn right toward Independence Ave</li
  ><li>Turn left onto Independence Ave</li
  ><li>Turn right onto West Basin Dr</li
  ><li>Look up when you reach 64 Independence Ave!</li>
</ol>
<hr />
<label
  >Number of steps completed:
  <input type="number" min="0" max="5" value="0" id="currentStep" />
</label>
```

This example uses the `text-decoration` property to strike through the `steps` highlight range defined by our JavaScript:

```
::highlight(steps) {
  text-decoration: line-through;
  color: blue;
}
```

We create a `Range` with a start and end node (which is the same node in this case). We then set this range as the `Highlight` using the `set()` method of the CSS `HighlightRegistry` interface.

```
const rangeToHighlight = new Range();
const list = document.querySelector("ol");
rangeToHighlight.setStart(list, 0);
rangeToHighlight.setEnd(list, 0);

CSS.highlights.set("steps", new Highlight(rangeToHighlight));
```

An event listener updates the end of the highlighted range when the number of completed steps changes:

```
const currentPositionSlider = document.querySelector("input");
currentPositionSlider.addEventListener("change", (e) => {
  rangeToHighlight.setEnd(list, e.target.value);
});
```

Block and inline layout in normal flow

In this guide, we will explore the basics of how Block and Inline elements behave when they are part of the normal flow.

Normal Flow is defined in the CSS 2.1 specification, which explains that any boxes in normal flow will be part of a *formatting context*. They can be either block or inline, but not both at once. We describe block-level boxes as participating in a *block formatting context*, and inline-level boxes as participating in an *inline formatting context*.

The behavior of elements which have a block or inline formatting context is also defined in this specification. For elements with a block formatting context, the spec says:

> "In a block formatting context, boxes are laid out one after the other, vertically, beginning at the top of a containing block. The vertical distance between two sibling boxes is determined by the 'margin' properties. Vertical margins between adjacent block-level boxes in a block formatting context collapse.
> In a block formatting context, each box's left outer edge touches the left edge of the containing block (for right-to-left formatting, right edges touch)." - 9.4.1

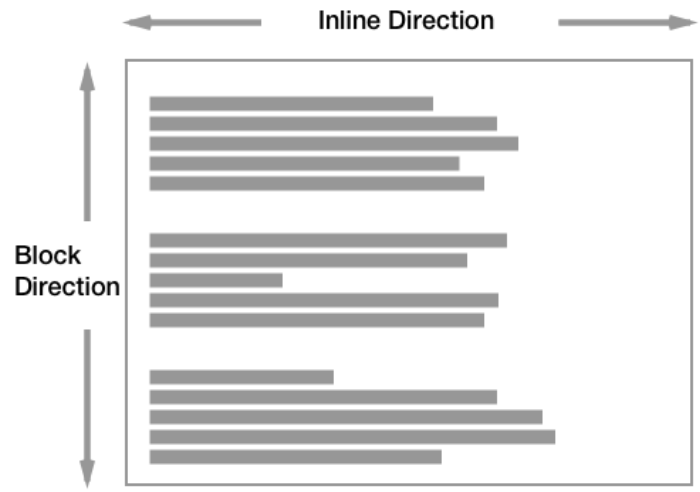
For elements with an inline formatting context:

> "In an inline formatting context, boxes are laid out horizontally, one after the other, beginning at the top of a containing block. Horizontal margins, borders, and padding are respected between these boxes. The boxes may be aligned vertically in different ways: their bottoms or tops may be aligned, or the baselines of text within them may be aligned. The rectangular area that contains the boxes that form a line is called a line box." - 9.4.2

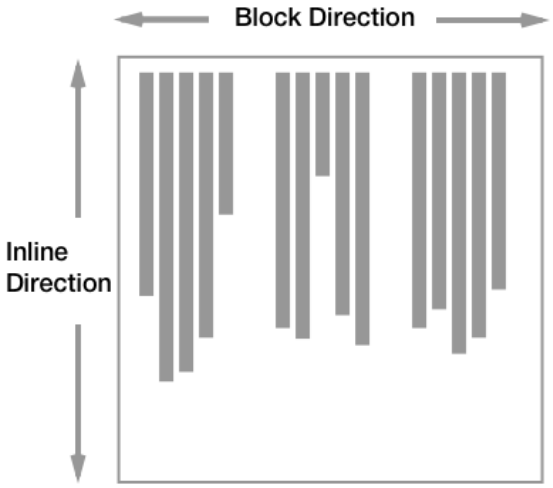
Note that the CSS 2.1 specification describes documents as being in a horizontal, top-to-bottom writing mode. For example, by describing the vertical distance between block boxes. The behavior on block and inline elements is the same when working in a vertical writing mode; we explore this in our Flow layout and writing modes guide.

Elements participating in a block formatting context

Block elements in a horizontal writing mode such as English, lay out vertically, one below the other.



In a vertical writing mode they would lay out horizontally.



In this guide, we will be working in English and therefore a horizontal writing mode. However, everything described should work in the same way if your document is in a vertical writing mode.

As defined in the specification, the margins between two block boxes are what creates separation between the elements. We can see this with the layout of two paragraphs, to which I have added a border. The default browser stylesheet adds spacing between the paragraphs by way of adding a margin to the top and bottom.

```
<div class="box">
  <p>
    One November night in the year 1782, so the story runs, two brothers sat
    over their winter fire in the little French town of Annonay, watching the
    grey smoke-wreaths from the hearth curl up the wide chimney. Their names
    were Stephen and Joseph Montgolfier, they were papermakers by trade, and
    were noted as possessing thoughtful minds and a deep interest in all
    scientific knowledge and new discovery.
  </p>
  <p>
    Before that night—a memorable night, as it was to prove—hundreds of millions
    of people had watched the rising smoke-wreaths of their fires without
    drawing any special inspiration from the fact.
  </p>
</div>
```

```
p {
  border: 2px solid green;
}
```

If we set margins on the paragraph element to `0` then the borders will touch.

```
<div class="box">
  <p>
    One November night in the year 1782, so the story runs, two brothers sat
    over their winter fire in the little French town of Annonay, watching the
    grey smoke-wreaths from the hearth curl up the wide chimney. Their names
    were Stephen and Joseph Montgolfier, they were papermakers by trade, and
    were noted as possessing thoughtful minds and a deep interest in all
    scientific knowledge and new discovery.
  </p>
  <p>
    Before that night—a memorable night, as it was to prove—hundreds of millions
```

```
    of people had watched the rising smoke-wreaths of their fires without
    drawing any special inspiration from the fact.
  </p>
</div>
```

```
p {
  border: 2px solid green;
  margin: 0;
}
```

By default block elements will consume all of the space in the inline direction, so our paragraphs spread out and get as big as they can inside their containing block. If we give them a width, they will continue to lay out one below the other - even if there would be space for them to be side by side. Each will start against the start edge of the containing block, so the place at which sentences would begin in that writing mode.

```
<div class="box">
  <p>
    One November night in the year 1782, so the story runs, two brothers sat
    over their winter fire in the little French town of Annonay, watching the
    grey smoke-wreaths from the hearth curl up the wide chimney. Their names
    were Stephen and Joseph Montgolfier, they were papermakers by trade, and
    were noted as possessing thoughtful minds and a deep interest in all
    scientific knowledge and new discovery.
  </p>
  <p>
    Before that night—a memorable night, as it was to prove—hundreds of millions
    of people had watched the rising smoke-wreaths of their fires without
    drawing any special inspiration from the fact.
  </p>
</div>
```

```
p {
  border: 2px solid green;
  width: 40%;
}
```

Margin collapsing

The spec explains that margins between block elements *collapse*. This means that if you have an element with a top margin immediately after an element with a bottom margin, rather than the total space being the sum of these two margins, the margin collapses, and so will essentially become as large as the larger of the two margins.

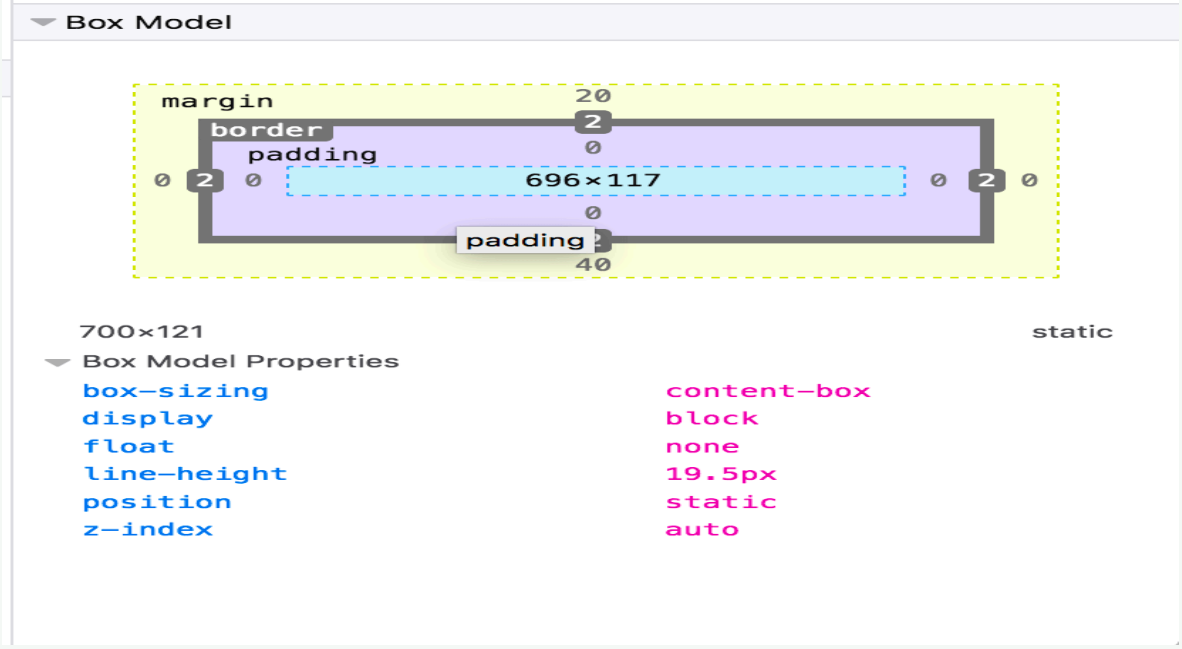
In the example below, the paragraphs have a top margin of `20px` and a bottom margin of `40px`. The size of the margin between the paragraphs is `40px` as the smaller top margin on the second paragraph has collapsed with the larger bottom margin of the first.

```
<div class="box">
  <p>
    One November night in the year 1782, so the story runs, two brothers sat
    over their winter fire in the little French town of Annonay, watching the
    grey smoke-wreaths from the hearth curl up the wide chimney. Their names
    were Stephen and Joseph Montgolfier, they were papermakers by trade, and
    were noted as possessing thoughtful minds and a deep interest in all
    scientific knowledge and new discovery.
  </p>
  <p>
    Before that night—a memorable night, as it was to prove—hundreds of millions
    of people had watched the rising smoke-wreaths of their fires without
    drawing any special inspiration from the fact.
  </p>
</div>
```

```
p {
  border: 2px solid green;
  margin: 20px 0 40px 0;
}
```

You can read more about margin collapsing in our article Mastering Margin Collapsing.

> **Note:** If you are not sure whether margins are collapsing, check the Box Model values in your browser DevTools. This will give you the actual size of the margin which can help you to identify what is happening.



Elements participating in an inline formatting context

Inline elements display one after the other in the direction that sentences run in that particular writing mode. While we don't tend to think of inline elements as having a box, as with everything in CSS they do. These inline boxes are arranged one after the other. If there is not enough space in the containing block for all of the boxes a box can break onto a new line. The lines created are known as line boxes.

In the following example, we have three inline boxes created by a paragraph with a `<strong>` element inside it.

```
<p>
  Before that night—<strong>a memorable night</strong>, as it was to
  prove—hundreds of millions of people had watched the rising smoke-wreaths of
  their fires without drawing any special inspiration from the fact.
</p>
```

The boxes around the words before the `<strong>` element and after the `</strong>` element are referred to as anonymous boxes, boxes introduced to ensure that everything is wrapped in a box, but ones that we cannot target directly.

The line box size in the block direction (so the height when working in English) is defined by the tallest box inside it. In the next example, the `<strong>` element is 300%; since that content spans two lines, it now defines the height of the line boxes of those two lines.

```
<p>
  Before that night—<strong>a memorable night</strong>, as it was to
  prove—hundreds of millions of people had watched the rising smoke-wreaths of
  their fires without drawing any special inspiration from the fact.
</p>
```

```
strong {
  font-size: 300%;
}
```

Find out more about how block and inline boxes behave in our guide to the visual formatting model.

The display property and flow layout

In addition to the rules existing in CSS2.1, new levels of CSS further describe the behavior of block and inline boxes. The `display` property defines how a box and any boxes inside it behave. In the CSS Display Model Level 3, we can learn more about how the `display` property changes the behavior of boxes and the boxes they generate.

The display type of an element defines the outer display type; this dictates how the box displays alongside other elements in the same formatting context. It also defines the inner display type, which dictates how boxes inside this element behave. We can see this very clearly when considering a flex layout. In the example below I have a `<div>`, which I have given `display: flex`. The flex container behaves like a block element: it displays on a new line and takes up all of the space it can in the inline direction. This is the outer display type of `block`.

The flex items however are participating in a flex formatting context, because their parent is the element with `display: flex`, which has an inner display type of `flex`, establishing the flex formatting context for the direct children.

```
<div class="container">
  <div>Flex Item</div>
  <div>Flex Item</div>
  <div>
    <div>Children</div>
    <div>are in</div>
    <div>normal flow</div>
  </div>
</div>
```

```
.container {
  display: flex;
}

.container > * {
  border: 1px solid green;
}
```

Therefore you can think of every box in CSS working in this way. The box itself has an outer display type, so it knows how to behave alongside other boxes. It then has an inner display type which changes the way its children behave. Those children then have an outer and inner display type too. The flex items in the previous example become flex level boxes, so their outer display type is dictated by way of them being

part of the flex formatting context. They have an inner display type of *flow* however, meaning that their children participate in normal flow. Items nested inside our flex item lay themselves out as block and inline elements unless something changes their display type.

This concept of the outer and inner display type is important as this tells us that a container using a layout method such as flexbox (`display: flex`) and grid layout (`display: grid`) is still participating in block and inline layout, due to the outer display type of those methods being `block`.

Changing the Formatting Context an element participates in

Browsers display items in block or inline formatting contexts based on what normally makes sense for that element. For example, a `<strong>` element is used to strongly emphasize a span of content and is displayed in bold in browsers by default. It would not generally make sense for that `<strong>` element to be displayed as a block-level element, breaking onto a new line. If you did want all `<strong>` elements to display as block boxes, you could do so by setting `strong { display: block; }`. The ability to style content with CSS means you can always use the most appropriate semantic HTML elements to mark up your content and then change how they are displayed with CSS.

```
<p>
  Before that night—<strong>a memorable night</strong>, as it was to
  prove—hundreds of millions of people had watched the rising smoke-wreaths of
  their fires without drawing any special inspiration from the fact.
</p>
```

```
strong {
  display: block;
}
```

Summary

In this guide, we have looked at how elements display in normal flow, as block and inline elements. An HTML document with no CSS styling at all will display in a readable way due to this default behavior. Understanding how normal flow works is an important starting point for understanding CSS layout as a whole.

Block formatting context

A **block formatting context** (BFC) is a part of a visual CSS rendering of a web page. It's the region in which the layout of block boxes occurs and in which floats interact with other elements.

A block formatting context is created by at least one of the following:

- The root element of the document (`<html>`).
- Floats (elements where `float` isn't `none`).
- Absolutely positioned elements (elements where `position` is `absolute` or `fixed`).
- Inline-blocks (elements with `display: inline-block`). This is the default display type for `<button>` and button `<input>` elements.
- Table cells (elements with `display: table-cell`, which is the default for HTML table cells).
- Table captions (elements with `display: table-caption`, which is the default for HTML table captions).
- Anonymous table cells implicitly created by the elements with `display: table`, `table-row`, `table-row-group`, `table-header-group`, `table-footer-group` (which is the default for HTML tables, table rows, table bodies, table headers, and table footers, respectively), or `inline-table`.
- Elements with `display: flow-root`.
- Flex items (direct children of the element with `display: flex` or `inline-flex`) if they are neither flex nor grid nor table containers themselves.
- Grid items (direct children of the element with `display: grid` or `inline-grid`) if they are neither flex nor grid nor table containers themselves.
- Block elements where `overflow` has a value other than `visible` and `clip`.
- Elements with `contain: layout`, `content`, or `paint`.
- Query containers (elements where `container-type` isn't `normal`).
- Multicol containers (elements where `column-count` or `column-width` isn't `auto`, including elements with `column-count: 1`).
- `column-span: all`, even when the `column-span: all` element isn't contained by a multicol container.

Formatting contexts affect layout because an element that establishes a new block formatting context will:

- contain internal floats.
- exclude external floats.
- suppress margin collapsing.

Flex and grid containers, defined by setting an element's `display` to `flex`, `grid`, `inline-flex`, or `inline-grid`, establishes a new flex or grid formatting context. These are similar to block formatting context except there are no floating children available inside a flex or grid container, but these formatting contexts do exclude external floats and suppress margin collapsing.

Examples

Let's have a look at a couple of these in order to see the effect creating a new BFC.

Contain internal floats

In the following example, we have float content that is the same height as the content alongside it. We have a floated element inside a `<div>` with a `border` applied. The content of that `<div>` has floated alongside the floated element. As the content of the float is taller than the content alongside it, the border of the `<div>` now runs through the float. As explained in the guide to in flow and out of flow elements, the float has been taken out of flow so the `background` and `border` of the `<div>` only contain the content and not the float.

using `overflow: auto`

Setting `overflow: auto` or set other values than the initial value of `overflow: visible` created a new BFC containing the float. Our `<div>` now becomes a mini-layout inside our layout. Any child element will be contained inside it.

The problem with using `overflow` to create a new BFC is that the `overflow` property is meant for telling the browser how you want to deal with overflowing content. There are some occasions in which you will find you get unwanted scrollbars or clipped shadows when you use this property purely to create a BFC. In addition, it is potentially not readable for a future developer, as it might not be obvious why you used `overflow` for this purpose. If you use `overflow`, it is a good idea to comment the code to explain.

using `display: flow-root`

The `display: flow-root` value lets us create a new BFC without any other potentially problematic side-effects. Using `display: flow-root` on the containing block creates a new BFC.

With `display: flow-root;` on the `<div>`, everything inside that container participates in the block formatting context of that container, and floats will not poke out of the bottom of the element.

The value name of `flow-root` makes sense when you understand you are creating something that acts like the `root` element (`<html>` element in browser) in terms of how it creates a new context for the flow layout inside it.

HTML

```
<section>
  <div class="box1">
    <div class="float">I am a floated box!</div>
    <p>I am content inside the container.</p>
  </div>
</section>
<section>
  <div class="box2">
    <div class="float">I am a floated box!</div>
    <p>I am content inside the <code>overflow:auto</code> container.</p>
  </div>
</section>
<section>
  <div class="box3">
    <div class="float">I am a floated box!</div>
    <p>I am content inside the <code>display:flow-root</code> container.</p>
  </div>
</section>
```

CSS

```
section {
  height: 150px;
}
.box1 {
  background-color: rgb(224 206 247);
  border: 5px solid rebeccapurple;
}
.box2,
.box3 {
  background-color: aliceblue;
  border: 5px solid steelblue;
}
.box2 {
  overflow: auto;
}
.box3 {
  display: flow-root;
}
.float {
  float: left;
  width: 200px;
  height: 100px;
  background-color: rgb(255 255 255 / 50%);
  border: 1px solid black;
  padding: 10px;
}
```

Exclude external floats

In the following example, we are using `display: flow-root` and floats, creating two side-by-side boxes demonstrating that an element in the normal flow establishes a new BFC and does not overlap the margin box of any floats in the same block formatting context as the element itself.

HTML

```
<section>
  <div class="float">Try to resize this outer float</div>
  <div class="box"><p>Normal</p></div>
</section>
<section>
  <div class="float">Try to resize this outer float</div>
  <div class="box2">
    <p><code>display:flow-root</code></p>
  </div>
</section>
```

CSS

```
section {
  height: 150px;
}
.box {
  background-color: rgb(224 206 247);
  border: 5px solid rebeccapurple;
}
.box2 {
  background-color: aliceblue;
  border: 5px solid steelblue;
  display: flow-root;
}
.float {
  float: left;
  overflow: hidden; /* required by resize:both */
  resize: both;
  margin-right: 25px;
  width: 200px;
  height: 100px;
  background-color: rgb(255 255 255 / 75%);
  border: 1px solid black;
  padding: 10px;
}
```

Prevent margin collapsing

You can create a new BFC to avoid margin collapsing between two neighbor elements.

Margin collapsing example

In this example we have two adjacent `<div>` elements, which each have a vertical margin of `10px`. Because of margin collapsing, the vertical gap between them is `10px`, not the `20px` we might expect.

```
<div class="blue"></div>
<div class="red"></div>
```

```
.blue,
.red {
  height: 50px;
  margin: 10px 0;
}

.blue {
  background: blue;
}

.red {
  background: red;
}
```

Preventing margin collapsing

In this example, we wrap the second `<div>` in an outer `<div>`, and create a new BFC by using `overflow: hidden` on the outer `<div>`. This new BFC prevents the margins of the nested `<div>` from collapsing with those of the outer `<div>`.

```
<div class="blue"></div>
<div class="outer">
  <div class="red"></div>
</div>
```

```
.blue,
.red {
  height: 50px;
  margin: 10px 0;
}

.blue {
  background: blue;
}

.red {
  background: red;
}

.outer {
  overflow: hidden;
  background: transparent;
}
```

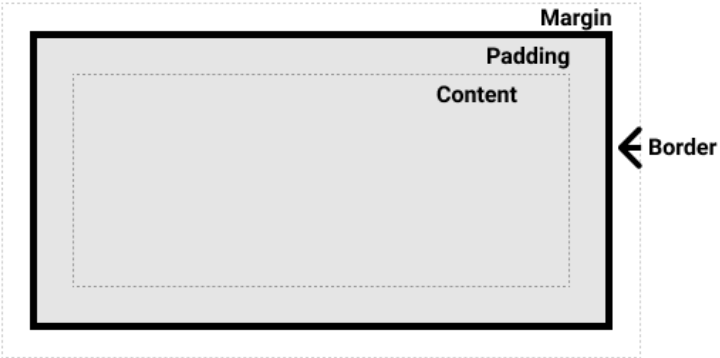
Layout and the containing block

The size and position of an element are often impacted by its **containing block**. Most often, the containing block is the content area of an element's nearest block-level ancestor, but this is not always the case. In this article, we examine the factors that determine an element's containing block.

When a user agent (such as your browser) lays out a document, it generates a box for every element. Each box is divided into four areas:

1. Content area
2. Padding area
3. Border area
4. Margin area



Many developers believe that the containing block of an element is always the content area of its parent, but that isn't necessarily true. Let's investigate the factors that determine what an element's containing block is.

Effects of the containing block

Before learning what determines the containing block of an element, it's useful to know why it matters in the first place.

The size and position of an element are often impacted by its containing block. Percentage values that are applied to the `width`, `height`, `padding`, `margin`, and offset properties of an absolutely positioned element (i.e., which has its `position` set to `absolute` or `fixed`) are computed from the element's containing block.

Identifying the containing block

The process for identifying the containing block depends entirely on the value of the element's `position` property:

1. If the `position` property is **`static`**, **`relative`**, or **`sticky`**, the containing block is formed by the edge of the *content box* of the nearest ancestor element that is either **a block container** (such as an inline-block, block, or list-item element) or **establishes a formatting context** (such as a table container, flex container, grid container, or the block container itself).
2. If the `position` property is **`absolute`**, the containing block is formed by the edge of the *padding box* of the nearest ancestor element that has a `position` value other than `static` (`fixed`, `absolute`, `relative`, or `sticky`).
3. If the `position` property is **`fixed`**, the containing block is established by the viewport (in the case of continuous media) or the page area (in the case of paged media).
4. If the `position` property is **`absolute`** or **`fixed`**, the containing block may also be formed by the edge of the *padding box* of the nearest ancestor element that has any of the following:
    - A `filter`, `backdrop-filter`, `transform`, `perspective`, `rotate`, `scale`, or `translate` value other than `none`.
    - A `contain` value of `layout`, `paint`, `strict` or `content` (e.g., `contain: paint;`).
    - A `will-change` value containing a property for which a non-initial value would form a containing block (e.g., `filter` or `transform`).
    - A `content-visibility` value of `auto`.

> **Note:** The containing block in which the root element (`<html>`) resides is a rectangle called the **initial containing block**. It has the dimensions of the viewport (for continuous media) or the page area (for paged media).

> **Note:** There are browser inconsistencies with `perspective` and `filter` contributing to containing block formation.

Calculating percentage values from the containing block

As noted above, when certain properties are given a percentage value, the computed value depends on the element's containing block. The properties that work this way are **box model properties** and **offset properties**:

1. The `height`, `top`, and `bottom` properties compute percentage values from the `height` of the containing block.
2. The `width`, `left`, `right`, `padding`, and `margin` properties compute percentage values from the `width` of the containing block.

> **Note:** A **block container** (such as an inline-block, block, or list-item element) either contains only inline-level boxes participating in an inline formatting context, or only block-level boxes participating in a block formatting context. An element is a block container only if it contains block-level or inline-level boxes.

Some examples

The HTML code for all our examples is:

```
<body>
  <section>
    <p>This is a paragraph!</p>
  </section>
</body>
```

Only the CSS is altered in each instance below.

Example 1

In this example, the paragraph is statically positioned, so its containing block is `<section>` because it's the nearest ancestor that is a block container (because of `display: block`).

```
<body>
  <section>
    <p>This is a paragraph!</p>
  </section>
</body>
```

```
body {
  background: beige;
}

section {
  display: block;
  width: 400px;
  height: 160px;
  background: lightgray;
}

p {
  width: 50%; /* == 400px * .5 = 200px */
  height: 25%; /* == 160px * .25 = 40px */
  margin: 5%; /* == 400px * .05 = 20px */
  padding: 5%; /* == 400px * .05 = 20px */
  background: cyan;
}
```

Example 2

In this example, the paragraph's containing block is the `<body>` element, because `<section>` is not a block container (because of `display: inline`) and doesn't establish a formatting context.

```
<body>
  <section>
    <p>This is a paragraph!</p>
  </section>
</body>
```

```
body {
  background: beige;
}
```

```
section {
  display: inline;
  background: lightgray;
}

p {
  width: 50%; /* == half the body's width */
  height: 200px; /* Note: a percentage would be 0 */
  background: cyan;
}
```

Example 3

In this example, the paragraph's containing block is `<section>` because the latter's `position` is `absolute`. The paragraph's percentage values are affected by the `padding` of its containing block, though if the containing block's `box-sizing` value were `border-box` this would not be the case.

```
<body>
  <section>
    <p>This is a paragraph!</p>
  </section>
</body>
```

```
body {
  background: beige;
}

section {
  position: absolute;
  left: 30px;
  top: 30px;
  width: 400px;
  height: 160px;
  padding: 30px 20px;
  background: lightgray;
}

p {
  position: absolute;
  width: 50%; /* == (400px + 20px + 20px) * .5 = 220px */
  height: 25%; /* == (160px + 30px + 30px) * .25 = 55px */
  margin: 5%; /* == (400px + 20px + 20px) * .05 = 22px */
  padding: 5%; /* == (400px + 20px + 20px) * .05 = 22px */
  background: cyan;
}
```

Example 4

In this example, the paragraph's `position` is `fixed`, so its containing block is the initial containing block (on screens, the viewport). Thus, the paragraph's dimensions change based on the size of the browser window.

```
<body>
  <section>
    <p>This is a paragraph!</p>
  </section>
</body>
```

```
body {
  background: beige;
}

section {
  width: 400px;
  height: 480px;
  margin: 30px;
  padding: 15px;
  background: lightgray;
}

p {
  position: fixed;
  width: 50%; /* == (50vw - (width of vertical scrollbar)) */
  height: 50%; /* == (50vh - (height of horizontal scrollbar)) */
  margin: 5%; /* == (5vw - (width of vertical scrollbar)) */
  padding: 5%; /* == (5vw - (width of vertical scrollbar)) */
  background: cyan;
}
```

Example 5

In this example, the paragraph's `position` is `absolute`, so its containing block is `<section>`, which is the nearest ancestor with a `transform` property that isn't `none`.

```
<body>
  <section>
    <p>This is a paragraph!</p>
  </section>
</body>
```

```
body {
  background: beige;
}

section {
  transform: rotate(0deg);
  width: 400px;
  height: 160px;
  background: lightgray;
}
```

```
p {
  position: absolute;
  left: 80px;
  top: 30px;
  width: 50%; /* == 200px */
  height: 25%; /* == 40px */
  margin: 5%; /* == 20px */
  padding: 5%; /* == 20px */
  background: cyan;
}
```

CSS flow layout

Normal Flow, or Flow Layout, is the way that block and inline elements are displayed on a page before any changes are made to their layout. The flow is essentially a set of things that are all working together and know about each other in your layout. Once something is taken *out of flow* it works independently.

In normal flow, **inline** elements display in the inline direction, that is in the direction words are displayed in a sentence according to the Writing Mode of the document. **block** elements display one after the other, as paragraphs do in the Writing Mode of that document. In English therefore, inline elements display one after the other, starting on the left, and block elements start at the top and move down the page.

Basic Example

The following example demonstrates Block and Inline Level boxes. The two paragraph elements with a green border are Block Level, displaying one under the other.

The first sentence also includes a span element with a blue background. This is inline level and therefore displays in place in the sentence.

```
<div class="box">
  <p>
    One <span>November</span> night in the year 1782, so the story runs, two
    brothers sat over their winter fire in the little French town of Annonay,
    watching the grey smoke-wreaths from the hearth curl up the wide chimney.
    Their names were Stephen and Joseph Montgolfier, they were papermakers by
    trade, and were noted as possessing thoughtful minds and a deep interest in
    all scientific knowledge and new discovery.
  </p>
  <p>
    Before that night—a memorable night, as it was to prove—hundreds of millions
    of people had watched the rising smoke-wreaths of their fires without
    drawing any special inspiration from the fact.
  </p>
</div>
```

```
body {
  font: 1.2em sans-serif;
}

p {
  border: 2px solid green;
}
span {
  background-color: lightblue;
}
```

Flow layout and overflow

When there is more content than can fit into a container, an overflow situation occurs. Understanding how overflow behaves is important in dealing with any element with a constrained size in CSS. This guide explains how overflow works when working with normal flow. The HTML is the same in each example, so it's visible in the first section, and hidden in others for brevity.

What is overflow?

Giving an element a fixed height and width, then adding significant content to the box, creates a basic overflow example:

```
<div class="box">
  <p>
    One November night in the year 1782, so the story runs, two brothers sat
    over their winter fire in the little French town of Annonay, watching the
    grey smoke-wreaths from the hearth curl up the wide chimney.
  </p>
</div>
<p>
  Their names were Stephen and Joseph Montgolfier. They were papermakers by
```

```
  trade, and were noted as possessing thoughtful minds and a deep interest in
  all scientific knowledge and new discovery.
</p>
<p>
  Before that night—a memorable night, as it was to prove—hundreds of millions
  of people had watched the rising smoke-wreaths of their fires without drawing
  any special inspiration from the fact.
</p>
```

```
body {
  font: 1.2em / 1.5 sans-serif;
}

.box {
  width: 300px;
  height: 100px;
  border: 5px solid rebeccapurple;
  padding: 10px;
}
```

The content goes into the box. Once it fills the box, it continues to overflow in a visible way, displaying content outside the box, potentially displaying under subsequent content. The property that controls how overflow behaves is the `overflow` property which has an initial value of `visible`. This is why we can see the overflow content.

Controlling overflow

There are other values that control how overflow content behaves. To hide overflowing content use a value of `hidden`. This may cause some of your content to not be visible.

```
<div class="box">
  <p>
    One November night in the year 1782, so the story runs, two brothers sat
    over their winter fire in the little French town of Annonay, watching the
    grey smoke-wreaths from the hearth curl up the wide chimney.
  </p>
</div>
<p>
  Their names were Stephen and Joseph Montgolfier. They were papermakers by
  trade, and were noted as possessing thoughtful minds and a deep interest in
  all scientific knowledge and new discovery.
</p>
<p>
  Before that night—a memorable night, as it was to prove—hundreds of millions
  of people had watched the rising smoke-wreaths of their fires without drawing
  any special inspiration from the fact.
</p>
```

```
body {
  font: 1.2em / 1.5 sans-serif;
}
.box {
  width: 300px;
  height: 100px;
  border: 5px solid rebeccapurple;
  padding: 10px;
  overflow: hidden;
}
```

Using a value of `scroll` contains the content in its box and add scrollbars to enable viewing it. Scrollbars will be added even if the content fits in the box.

```
<div class="box">
  <p>
    One November night in the year 1782, so the story runs, two brothers sat
    over their winter fire in the little French town of Annonay, watching the
    grey smoke-wreaths from the hearth curl up the wide chimney.
  </p>
</div>
<p>
  Their names were Stephen and Joseph Montgolfier; they were papermakers by
  trade and were noted as possessing thoughtful minds and a deep interest in all
  scientific knowledge and new discoveries.
</p>
<p>
  Before that night—a memorable night, as it was to prove—hundreds of millions
  of people had watched the rising smoke-wreaths of their fires without drawing
  any special inspiration from the fact.
</p>
```

```
body {
  font: 1.2em / 1.5 sans-serif;
}
.box {
  width: 300px;
  height: 100px;
  border: 5px solid rebeccapurple;
  padding: 10px;
  overflow: scroll;
}
```

Using a value of `auto` will display the content with no scrollbars if the content fits inside the box. If it doesn't fit then scrollbars will be added. Comparing the next example, you should see `overflow: scroll` example above has horizontal and vertical scrollbars even though it only needs vertical scrolling. The `auto` example below only adds the scrollbar in the direction we need to scroll.

```
<div class="box">
  <p>
    One November night in the year 1782, so the story runs, two brothers sat
    over their winter fire in the little French town of Annonay, watching the
    grey smoke-wreaths from the hearth curl up the wide chimney.
  </p>
</div>
<p>
  Their names were Stephen and Joseph Montgolfier, they were papermakers by
```

```
  trade, and were noted as possessing thoughtful minds and a deep interest in
  all scientific knowledge and new discovery.
</p>
<p>
  Before that night—a memorable night, as it was to prove—hundreds of millions
  of people had watched the rising smoke-wreaths of their fires without drawing
  any special inspiration from the fact.
</p>
```

```
body {
  font: 1.2em / 1.5 sans-serif;
}
.box {
  width: 300px;
  height: 100px;
  border: 5px solid rebeccapurple;
  padding: 10px;
  overflow: auto;
}
```

As we have already learned, using any of these values, other than the default of `visible`, will create a new block formatting context.

`overflow: clip` acts like `overflow: hidden`, but it does not allow programmatic scrolling; the box becomes non-scrollable. It also does not create a block formatting context.

The overflow property is in reality a shorthand for the `overflow-x` and `overflow-y` properties. If you specify only one value for overflow, this value is used for both axes. However, you can specify both values in which case the first is used for `overflow-x` and therefore the horizontal direction, and the second for `overflow-y` and the vertical direction. In the below example, I have only specified `overflow-y: scroll` so we do not get the unwanted horizontal scrollbar.

```
<div class="box">
  <p>
    One November night in the year 1782, so the story runs, two brothers sat
    over their winter fire in the little French town of Annonay, watching the
    grey smoke-wreaths from the hearth curl up the wide chimney.
  </p>
</div>
<p>
  Their names were Stephen and Joseph Montgolfier, they were papermakers by
  trade, and were noted as possessing thoughtful minds and a deep interest in
  all scientific knowledge and new discovery.
</p>
<p>
  Before that night—a memorable night, as it was to prove—hundreds of millions
  of people had watched the rising smoke-wreaths of their fires without drawing
  any special inspiration from the fact.
</p>
```

```
body {
  font: 1.2em / 1.5 sans-serif;
}
.box {
  width: 300px;
  height: 100px;
  border: 5px solid rebeccapurple;
  padding: 10px;
  overflow-y: scroll;
}
```

Flow Relative Properties

In the guide to Writing Modes and Flow Layout, we looked at the `block-size` and `inline-size` properties, which make more sense when working with different writing modes than tying our layout to the physical dimensions of the screen. The CSS overflow module also includes flow relative properties for overflow - `overflow-block` and `overflow-inline`. These correspond to `overflow-x` and `overflow-y` but the mapping depends on the writing mode of the document.

Indicating Overflow

In the CSS overflow module, there are some properties that can help improve the way content looks in an overflow situation.

Inline-Axis Overflow

The `text-overflow` property deals with text overflowing in the inline direction. It takes one of two values `clip`, in which case content is clipped when it overflows, this is the initial value and therefore the default behavior. We also have `ellipsis` which renders an ellipsis, which may be replaced with a better character for the language or writing mode in use.

```
<div class="box">
  <p>
    One November night in the year 1782, so the story runs, two brothers sat
    over their winter fire in the little French town of Annonay, watching the
    grey smoke-wreaths from the hearth curl up the wide chimney.
  </p>

  <p>
    Their names were Stephen and Joseph Montgolfier, they were papermakers by
    trade, and were noted as possessing thoughtful minds and a deep interest in
    all scientific knowledge and new discovery.
  </p>
  <p>
    Before that night—a memorable night, as it was to prove—hundreds of millions
    of people had watched the rising smoke-wreaths of their fires without
    drawing any special inspiration from the fact.
  </p>
</div>
```

```
body {
  font: 1.2em / 1.5 sans-serif;
}
.box {
  width: 300px;
  border: 5px solid rebeccapurple;
  padding: 10px;
}
```

```
.box p {
  white-space: nowrap;
  text-overflow: ellipsis;
  overflow: hidden;
}
```

Block-Axis Overflow

The Overflow Module Level 4 specification adds a `block-ellipsis` property (previously called `block-overflow`). This property enables adding an ellipsis (or custom strings) when text overflows in the block dimension, although there is no browser support for this at the time of writing.

This is useful in the situation where you have a listing of articles, for example, and you display the listings in fixed height boxes which only take a limited amount of text. It may not be obvious to the reader that there is more content to click through to when clicking the box or the title. An ellipsis indicates clearly the fact there is more content. The specification would allow a string of content or a regular ellipsis to be inserted.

Summary

Whether you are in continuous media on the web or in a Paged Media format such as print or EPUB, understanding how content overflows is useful when dealing with any layout method. Understanding how overflow works in normal flow enables a greater understanding of the implications of overflow content in layout methods such as grid and flexbox.

Flow layout and writing modes

The CSS 2.1 specification, which details how normal flow behaves, assumes a horizontal writing mode. Layout properties should work in the same way in vertical writing modes. In this guide, we look at how flow layout behaves when used with different document writing modes.

This is not a comprehensive guide to the use of writing modes in CSS, the aim here is to document the areas where flow layout interacts with writing modes in possibly unanticipated ways. The See also section provides links to more writing modes resources.

Writing modes specification

The CSS Writing Modes Level 3 Specification defines the impact a change the document writing mode has on flow layout. In the writing modes introduction, the specification says,

> "A writing mode in CSS is determined by the `writing-mode`, `direction`, and `text-orientation` properties. It is defined primarily in terms of its inline base direction and block flow direction."

The specification defines the *inline base direction* as the direction in which content is ordered on a line. This defines the start and end of the inline direction. The start is where sentences start and the end is where a line of text ends before it would begin to wrap onto a new line.

The *block flow direction* is the direction in which boxes, for example paragraphs, stack in that writing mode. The CSS `writing-mode` property controls the block flow direction. If you want to change your page, or part of your page, to `vertical-lr` then you can set `writing-mode: vertical-lr` on the element and this will change the direction of the blocks and therefore the inline direction as well.

While certain languages will use a particular writing mode or text direction, we can also use these properties for creative effect, such as running a heading vertically.

```
<div class="box">
  <h1>A heading</h1>
  <p>
    One November night in the year 1782, so the story runs, two brothers sat
    over their winter fire in the little French town of Annonay, watching the
    grey smoke-wreaths from the hearth curl up the wide chimney. Their names
    were Stephen and Joseph Montgolfier, they were papermakers by trade, and
    were noted as possessing thoughtful minds and a deep interest in all
    scientific knowledge and new discovery.
  </p>
</div>
```

```
body {
  font: 1.2em sans-serif;
}
h1 {
  writing-mode: vertical-lr;
  float: left;
}
```

Block flow direction

The `writing-mode` property accepts the values `horizontal-tb`, `vertical-rl` and `vertical-lr`. These values control the direction that blocks flow on the page. The initial value is `horizontal-tb`, which is a top to bottom block flow direction with a horizontal inline direction. Left to right languages, such as English, and Right to left languages, such as Arabic, are all `horizontal-tb`.

The following example shows blocks using the initial `horizontal-tb` value explicitly:

```
<div class="box">
  <p>
    One November night in the year 1782, so the story runs, two brothers sat
    over their winter fire in the little French town of Annonay, watching the
    grey smoke-wreaths from the hearth curl up the wide chimney. Their names
    were Stephen and Joseph Montgolfier, they were papermakers by trade, and
    were noted as possessing thoughtful minds and a deep interest in all
    scientific knowledge and new discovery.
  </p>
  <p>
    Before that night—a memorable night, as it was to prove—hundreds of millions
    of people had watched the rising smoke-wreaths of their fires without
    drawing any special inspiration from the fact.
  </p>
</div>
```

```
body {
  font: 1.2em sans-serif;
}
.box {
  writing-mode: horizontal-tb;
}
```

Compare this with the value `vertical-rl`, which gives you a right-to-left block flow direction with a vertical inline direction, as shown in the next example.

```
<div class="box">
  <p>
    One November night in the year 1782, so the story runs, two brothers sat
    over their winter fire in the little French town of Annonay, watching the
    grey smoke-wreaths from the hearth curl up the wide chimney. Their names
    were Stephen and Joseph Montgolfier, they were papermakers by trade, and
    were noted as possessing thoughtful minds and a deep interest in all
    scientific knowledge and new discovery.
  </p>
  <p>
    Before that night—a memorable night, as it was to prove—hundreds of millions
    of people had watched the rising smoke-wreaths of their fires without
    drawing any special inspiration from the fact.
  </p>
</div>
```

```
body {
  font: 1.2em sans-serif;
}
.box {
  writing-mode: vertical-rl;
}
```

The final example demonstrates the third possible value for `writing-mode` — `vertical-lr`. This gives you a left-to-right block flow direction and a vertical inline direction.

```
<div class="box">
  <p>
    One November night in the year 1782, so the story runs, two brothers sat
    over their winter fire in the little French town of Annonay, watching the
    grey smoke-wreaths from the hearth curl up the wide chimney. Their names
    were Stephen and Joseph Montgolfier, they were papermakers by trade, and
    were noted as possessing thoughtful minds and a deep interest in all
    scientific knowledge and new discovery.
  </p>
  <p>
    Before that night—a memorable night, as it was to prove—hundreds of millions
    of people had watched the rising smoke-wreaths of their fires without
    drawing any special inspiration from the fact.
  </p>
</div>
```

```
body {
  font: 1.2em sans-serif;
}
.box {
  writing-mode: vertical-lr;
}
```

Nested writing modes

When a nested box is assigned a different writing mode to its parent, then an inline level box will display as if it has `display: inline-block`.

```
<div class="box">
  <p>
    One <span>November</span> night in the year 1782, so the story runs, two
    brothers sat over their winter fire in the little French town of Annonay,
    watching the grey smoke-wreaths from the hearth curl up the wide chimney.
    Their names were Stephen and Joseph Montgolfier, they were papermakers by
    trade, and were noted as possessing thoughtful minds and a deep interest in
    all scientific knowledge and new discovery.
  </p>
</div>
```

```
body {
  font: 1.2em sans-serif;
}
.box {
  writing-mode: vertical-rl;
}
.box span {
  writing-mode: horizontal-tb;
  padding: 10px;
  border: 1px solid rebeccapurple;
}
```

A block-level box will establish a new block formatting context (BFC), meaning that if its inner display type would be `flow`, it will get a computed display type of `flow-root`. This is shown in the next example where the box which displays as `horizontal-tb` contains a float which is contained due to its parent establishing a new BFC.

```
<div class="box">
  <p>
    One November night in the year 1782, so the story runs, two brothers sat
    over their winter fire in the little French town of Annonay, watching the
    grey smoke-wreaths from the hearth curl up the wide chimney.
  </p>

  <div>
    <div class="float"></div>
    This box should establish a new BFC.
  </div>

  <p>
    Their names were Stephen and Joseph Montgolfier, they were papermakers by
    trade, and were noted as possessing thoughtful minds and a deep interest in
    all scientific knowledge and new discovery.
  </p>
</div>
```

```
body {
  font: 1.2em sans-serif;
}
.box {
  writing-mode: vertical-rl;
}
.box > div {
  writing-mode: horizontal-tb;
  padding: 10px;
  border: 1px solid rebeccapurple;
}
.float {
  width: 100px;
  height: 150px;
  background-color: rebeccapurple;
  float: left;
}
```

Replaced elements

Replaced elements such as images will not change their orientation based on the `writing-mode` property. However, replaced elements such as form controls which include text, should match the writing mode in use.

```
<div class="box">
  <p>
    One November night in the year 1782, so the story runs, two brothers sat
    over their winter fire in the little French town of Annonay, watching the
    grey smoke-wreaths from the hearth curl up the wide chimney.
  </p>

  <img
    alt="a colorful hot air balloon against a clear sky"
    src="https://mdn.github.io/shared-assets/images/examples/balloon.jpg" />

  <p>
    Their names were Stephen and Joseph Montgolfier, they were papermakers by
    trade, and were noted as possessing thoughtful minds and a deep interest in
    all scientific knowledge and new discovery.
  </p>
</div>
```

```
body {
  font: 1.2em sans-serif;
}
.box {
  writing-mode: vertical-rl;
}
```

Logical properties and values

Once you are working in writing modes other than `horizontal-tb` many of the properties and values that are mapped to the physical dimensions of the screen seem strange. For example, if you give a box a width of 100px, in `horizontal-tb` that would control the size in the inline direction. In `vertical-lr` it controls the size in the block direction because it does not rotate with the text.

```
<div class="box">
  <div class="box1">Box 1</div>
  <div class="box2">Box 2</div>
</div>
```

```
body {
  font: 1.2em sans-serif;
}
.box1 {
  writing-mode: horizontal-tb;
  border: 5px solid rebeccapurple;
  width: 100px;
  margin: 10px;
}
.box2 {
  writing-mode: vertical-lr;
  border: 5px solid rebeccapurple;
  width: 100px;
  margin: 10px;
}
```

Therefore, we have the `block-size` and `inline-size` properties. If we give our block an `inline-size` of 100px, it doesn't matter whether we are in a horizontal or vertical writing mode; `inline-size` will always mean the size in the inline direction.

```
<div class="box">
  <div class="box1">Box 1</div>
  <div class="box2">Box 2</div>
</div>
```

```
body {
  font: 1.2em sans-serif;
}
.box1 {
  writing-mode: horizontal-tb;
  border: 5px solid rebeccapurple;
  inline-size: 100px;
  margin: 10px;
}
.box2 {
  writing-mode: vertical-lr;
  border: 5px solid rebeccapurple;
  inline-size: 100px;
  margin: 10px;
}
```

The CSS logical properties and values module includes logical versions of the properties that control margins, padding and borders as well as other mappings for things that we have typically used physical directions to specify.

Summary

In most cases, flow layout works as expected when changing the writing mode of whole documents or individual sections. This can be used to properly typeset vertical languages or for creative reasons. With CSS logical properties and values, vertical writing mode sizing can be based on an element's inline and block size. This is useful for creating components that work in different writing modes.

Introduction to formatting contexts

This article introduces the concept of formatting contexts, of which there are several types, including block formatting contexts, inline formatting contexts, and flex formatting contexts. The basics of how they behave and how you can make use of these behaviors are also introduced.

Everything on a page is part of a **formatting context**, or an area which has been defined to lay out content in a particular way. A **block formatting context** (BFC) will lay child elements out according to block layout rules, a **flex formatting context** will lay its children out as flex items, etc. Each formatting context has specific rules about how layout behaves when in that context.

Block formatting contexts

The outermost element in a document that uses block layout rules establishes the first, or **initial block formatting context**. This means that every element inside the `<html>` element's block is laid out according to normal flow following the rules for block and inline layout. Elements participating in a BFC use the rules outlined by the CSS Box Model, which defines how an element's margins, borders, and padding interact with other blocks in the same context.

Creating a new block formatting context

The `<html>` element is not the only element capable of creating a block formatting context. Any block-level element can be made to create a BFC by the application of certain CSS properties.

A new BFC is created in the following situations:

- elements made to float using `float`
- absolutely positioned elements
- elements with `display: inline-block`
- table cells or elements with `display: table-cell`, including anonymous table cells created when using the `display: table-*` properties
- table captions or elements with `display: table-caption`
- block elements where `overflow` has a value other than `visible`
- elements with `display: flow-root` or `display: flow-root list-item`
- elements with `contain: layout`, `content`, or `strict`
- query containers (elements where `container-type` isn't `normal`)
- flex items
- grid items
- multicol containers
- elements with `column-span` set to `all`

This is useful because a new BFC will behave much like the outermost document in that it becomes a mini-layout inside the main layout. A BFC contains everything inside it, `float` and `clear` only apply to items inside the same formatting context, and margins only collapse between elements in the same formatting context.

BFC creation examples

Let's have a look at a couple of these in order to see the effect creating a new BFC.

In the example below, we have a floated element inside a `<div>` with a border applied. The content of that `<div>` has floated alongside the floated element. As the content of the float is taller than the content alongside it, the border of the `<div>` now runs through the float. As explained in the guide to in-flow and out of flow elements, the float has been taken out of flow so the background and border of the div only contain the content and not the float.

```
<div class="box">
  <div class="float">I am a floated box!</div>
  <p>I am content inside the container.</p>
</div>
```

```
body {
  font: 1.2em sans-serif;
}

.box {
  background-color: rgb(224 206 247);
  border: 5px solid rebeccapurple;
}

.float {
  float: left;
  width: 200px;
  height: 100px;
  background-color: white;
  border: 1px solid black;
  padding: 10px;
}
```

Creating a new BFC would contain the float. A typical way to do this in the past has been to set `overflow: auto` or set other values than the initial value of `overflow: visible`.

```
<div class="box">
  <div class="float">I am a floated box!</div>
  <p>I am content inside the container.</p>
</div>
```

```
body {
  font: 1.2em sans-serif;
}
.box {
  background-color: rgb(224 206 247);
  border: 5px solid rebeccapurple;
  overflow: auto;
}
```

```
.float {
  float: left;
  width: 200px;
  height: 150px;
  background-color: white;
  border: 1px solid black;
  padding: 10px;
}
```

Setting `overflow: auto` created a new BFC containing the float. Our `<div>` now becomes a mini-layout inside our layout. Any child element will be contained inside it.

The problem with using `overflow` to create a new BFC is that the `overflow` property is meant for telling the browser how you wish to deal with overflowing content. There are some occasions in which you will find you get unwanted scrollbars or clipped shadows when you use this property purely to create a BFC. In addition, it is potentially not very readable for a future developer, as it may not be obvious why you used `overflow` for this purpose. If you do this, it would be a good idea to comment the code to explain.

Explicitly creating a BFC using display: flow-root

Using `display: flow-root` (or `display: flow-root list-item`) on the containing block will create a new BFC without any other potentially problematic side-effects.

```
<div class="box">
  <div class="float">I am a floated box!</div>
  <p>I am content inside the container.</p>
</div>
```

```
body {
  font: 1.2em sans-serif;
}
.box {
  background-color: rgb(224 206 247);
  border: 5px solid rebeccapurple;
  display: flow-root;
}
```

```
.float {
  float: left;
  width: 200px;
  height: 100px;
  background-color: white;
  border: 1px solid black;
  padding: 10px;
}
```

With `display: flow-root` on the `<div>`, everything inside that container participates in the block formatting context of that container, and floats will not poke out of the bottom of the element.

The name of the `flow-root` keyword refers to the fact that you're creating something that serves, in essence, like a new root element (like `<html>` does), given how the new context is created and its flow layout functions.

Inline formatting contexts

Inline formatting contexts exist inside other formatting contexts and can be thought of as the context of a paragraph. The paragraph creates an inline formatting context inside which such things as `<strong>`, `<a>`, or `<span>` elements are used on text.

The box model does not fully apply to items participating in an inline formatting context. In a horizontal writing mode line, horizontal padding, borders and margin will be applied to the element and push the text away left and right. However, margins above and below the element will not be applied. Vertical padding and borders will be applied but may overlap content above and below as, in the inline formatting context, the line boxes will not be pushed apart by padding and borders.

```
<p>
  Before that night—<strong>a memorable night</strong>, as it was to
  prove—hundreds of millions of people had watched the rising smoke-wreaths of
  their fires without drawing any special inspiration from the fact.
</p>
```

```
body {
  font: 1.2em sans-serif;
}
p {
  margin-top: 2em;
}
strong {
  margin: 20px;
  padding: 20px;
  border: 5px solid rebeccapurple;
}
```

Other formatting contexts

This guide covers flow layout and is therefore not referring to other possible formatting contexts. As such, it is useful to understand that creating any kind of formatting context will change the way elements inside that formatting context behave. This behavior is always described in the specification and also here on MDN.

Summary

In this guide, we have looked in more detail at the block and Inline formatting contexts and the important subject of creating a block formatting context (BFC). In the next guide, we will find out how normal flow interacts with different writing modes.

In flow and out of flow

The previous guide explained block and inline layout in normal flow. All elements that are in flow will be laid out using this method.

Example of elements in flow

The following example contains a heading, a paragraph, a list, and a final paragraph that contains a `strong` element. The heading and paragraphs are block level, the `strong` element inline. The list, which is displayed using flexbox to arrange the items into a row, is also participating in block and inline layout - the container has an outside `display` type of `block`.

```
<div class="box">
  <h1>A heading</h1>
  <p>
    One November night in the year 1782, so the story runs, two brothers sat
    over their winter fire in the little French town of Annonay, watching the
    grey smoke-wreaths from the hearth curl up the wide chimney.
  </p>

  <ul>
    <li>One</li>
    <li>Two</li>
    <li>Three</li>
  </ul>
  <p>
    Their names were <strong>Stephen and Joseph Montgolfier</strong>, they were
    papermakers by trade, and were noted as possessing thoughtful minds and a
    deep interest in all scientific knowledge and new discovery.
  </p>
</div>
```

```
body {
  font: 1.2em sans-serif;
}
.box > * {
  border: 1px solid green;
}

ul {
  display: flex;
  justify-content: space-around;
  list-style: none;
  margin: 0;
}
```

All of the elements are considered "in flow"; they appear on the page in the order that they are in the source.

Taking an item out of flow

All elements are in-flow apart from:

- floated items
- items with `position: absolute` (including `position: fixed` which acts in the same way)
- the root element (`html`)

Out-of-flow items create a new Block Formatting Context (BFC), and therefore, everything inside them can be seen as a mini layout, separate from the rest of the page. The root element, therefore, is out of flow, as the container for everything in our document, and establishes the Block Formatting Context for the document.

Floated items

In this example, there is a `div` and then two paragraphs. A background color has been added to the paragraphs, and the `div` is floated left. The `div` is now out of flow.

As a float it is first laid out according to where it would be in normal flow, then taken out of flow and moved to the left as far as possible.

```
<div class="box">
  <div class="float">I am a floated box!</div>
  <p>
    One November night in the year 1782, so the story runs, two brothers sat
    over their winter fire in the little French town of Annonay, watching the
    grey smoke-wreaths from the hearth curl up the wide chimney. Their names
    were Stephen and Joseph Montgolfier, they were papermakers by trade, and
    were noted as possessing thoughtful minds and a deep interest in all
    scientific knowledge and new discovery.
  </p>
  <p>
    Before that night—a memorable night, as it was to prove—hundreds of millions
    of people had watched the rising smoke-wreaths of their fires without
    drawing any special inspiration from the fact.
  </p>
</div>
```

```
body {
  font: 1.2em sans-serif;
}
p {
  background-color: #cccccc;
}

.float {
  float: left;
  font-weight: bold;
  width: 200px;
  border: 2px dotted black;
  padding: 10px;
}
```

You can see the background color of the following paragraph running underneath, it is only the line boxes of that paragraph that have been shortened to cause the effect of wrapping content around the float. The box of our paragraph is still displaying according to the rules of normal flow. This is why, to make space around a floated item, you must add a margin to the item, in order to push the line boxes away from it. You cannot apply anything to the following in-flow content to achieve that.

Absolute positioning

Giving an item `position: absolute` or `position: fixed` removes it from flow, and any space that it would have taken up is removed. In the next example I have three paragraph elements, the second element has `position: absolute`, with offset values of `top: 30px` and `right: 30px`. It has been removed from document flow.

```
<div class="box">
  <p>
    One November night in the year 1782, so the story runs, two brothers sat
    over their winter fire in the little French town of Annonay, watching the
    grey smoke-wreaths from the hearth curl up the wide chimney.
  </p>
  <p class="abspos">
    Their names were Stephen and Joseph Montgolfier, they were papermakers by
    trade, and were noted as possessing thoughtful minds and a deep interest in
    all scientific knowledge and new discovery.
  </p>
  <p>
    Before that night—a memorable night, as it was to prove—hundreds of millions
    of people had watched the rising smoke-wreaths of their fires without
    drawing any special inspiration from the fact.
  </p>
</div>
```

```
body {
  font: 1.2em sans-serif;
}
.box {
  width: 70%;
}
p {
  border: 2px solid green;
}

.abspos {
  position: absolute;
  background-color: green;
  color: white;
  top: 30px;
  right: 30px;
  width: 400px;
}
```

Using `position: fixed` also removes the item from flow, however the offsets are based on the viewport rather than the containing block.

When taking an item out of flow with positioning, you will need to manage the possibility of content overlapping. Out of flow essentially means that the other elements on your page no longer know that element exists so will not respond to it.

Relative positioning and flow

If you give an item relative positioning with `position: relative`, it remains in flow. However, you are then able to use the offset values to push it around. The space that it would have been placed in normal flow is reserved however, as you can see in the example below.

```
<div class="box">
  <p>
    One November night in the year 1782, so the story runs, two brothers sat
    over their winter fire in the little French town of Annonay, watching the
    grey smoke-wreaths from the hearth curl up the wide chimney.
  </p>
  <p class="relative">
    Their names were Stephen and Joseph Montgolfier, they were papermakers by
    trade, and were noted as possessing thoughtful minds and a deep interest in
    all scientific knowledge and new discovery.
  </p>
  <p>
    Before that night—a memorable night, as it was to prove—hundreds of millions
    of people had watched the rising smoke-wreaths of their fires without
    drawing any special inspiration from the fact.
  </p>
</div>
```

```
body {
  font: 1.2em sans-serif;
}
.box {
  width: 70%;
}
p {
  border: 2px solid green;
}

.relative {
  position: relative;
  background-color: green;
  color: white;
  bottom: 50px;
  left: 50px;
  width: 400px;
}
```

When you do anything to remove or shift an item from where it would be placed in normal flow, you can expect to need to do some managing of the content and the content around it to prevent overlaps. Whether that involves clearing floats, or ensuring that an element with `position: absolute` does not sit on top of some other content. For this reason methods which remove elements from being in-flow should be used with understanding of the effect that they have.

Summary

In this guide, we have explained how to take an element out of flow to achieve some very specific types of positioning. In the next guide we will look at a related issue, that of creating a Block Formatting Context, in Introduction to formatting contexts.

- Learn: Positioning

Using the multi-keyword syntax with CSS display

The CSS display module defines a multi-keyword syntax for the CSS `display` property. This guide explains the multi-keyword syntax.

> **Note:** Multi-keyword syntax is also referred to as "two-value syntax" or "multi-value syntax."

What happens when we change the value of the display property?

One of the first things we learn about CSS is that some elements are block-level and some are inline-level. These are their outer display types. For example, an `<h1>` or a `<p>` are block-level by default, and a `<span>` is inline-level. Using the `display` property we can switch between block and inline. For example to make a heading inline we would use the following CSS:

```
h1 {
  display: inline;
}
```

The `display` property also lets us use CSS grid layout and Flexbox when `display: grid` or `display: flex` is set. The important concept to understand is that changing an element's `display` value can change the formatting context of its direct children. When you use `display: flex` or `display: grid`, the element's children become flex or grid items and respond to the properties in grid and flexbox specifications.

What grid and flexbox demonstrate, however, is that an element has both an **outer** and an **inner** display type. The outer display type describes whether the element is block-level or inline-level. The inner display type describes how the children of that box behave.

As an example, when we use `display: flex` we create a block-level container, with flex children. The children are described as participating in a flex formatting context. You can see this if you take a `<span>` — normally an inline-level element — and apply `display: flex` to it. The `<span>` becomes a block-level element. It behaves as block-level things do in relationship to other boxes in the layout. It's as if you had applied `display: block` to the span, however we also get the changed behavior of the children.

The live example below has a `<span>` with `display: flex` applied. It has become a block-level box taking up all available space in the inline direction. You can now use `justify-content: space-between` to put this space between the two flex items.

```
<span class="flex"> Some text <em>emphasized text</em> </span>
```

```
body {
  font: 1.2em / 1.5 sans-serif;
}
.flex {
  border: 5px solid #cccccc;
  display: flex;
  justify-content: space-between;
}
```

It's also possible to create inline flex containers. If you use the single value `inline-flex` you will have an inline-level box with flex children. The children behave in the same way as the flex children of a block-level container. The only thing that has changed is that the parent is now an inline-level box. It therefore behaves like other inline-level things, and doesn't take up the full width (or size in the inline dimension) that a block-level box does. This means that some following text could come up alongside the flex container.

```
<div class="flex">
  <div>One</div>
  <div>Two</div>
</div>
Text following the flex container.
```

```
body {
  font: 1.2em / 1.5 sans-serif;
}
.flex > div {
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
  background-color: rgb(96 139 168 / 0.2);
}

.flex {
  border: 5px solid #cccccc;
  display: inline-flex;
}
```

The same is true when working with grid layout. Using `display: grid` will give you a block-level box, which creates a grid formatting context for the direct children. Using `display: inline-grid` will create an inline-level box, which creates a grid formatting context for the children.

Using the multi-keyword syntax

As you can see from the above explanation, the `display` property has considerable powers. In addition to indicating whether something is block-level or inline-level in relationship to other boxes on the page, it also indicates the formatting context inside the box it is applied to. To better describe this behavior, the `display` property allows for two values — an outer and inner value — to be set on it. The original single-value syntax is also valid.

This means that instead of setting `display: flex` to create a block-level box with flex children, we use `display: block flex`. Instead of `display: inline-flex` to create an inline-level box with flex children, we use `display: inline flex`. The example below demonstrates these values.

```
<h1>Multiple values for display</h1>

<div class="flex flex1">
  <div>Item One</div>
  <div>Item Two</div>
  <div>Item Three</div>
</div>

<p>The first example is a block element with flex children.</p>

<div class="flex flex2">
  <div>Item One</div>
  <div>Item Two</div>
  <div>Item Three</div>
</div>
The second example is an inline element with flex children.
```

```
body {
  font: 1.2em / 1.5 sans-serif;
}
```

```
.flex {
  border: 5px solid #cccccc;
  gap: 10px;
}

.flex > * {
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
  background-color: rgb(96 139 168 / 0.2);
}

.flex1 {
  display: block flex;
}

.flex2 {
  display: inline flex;
}
```

There are mappings for all of the existing values of `display`; the most common ones are listed in the table below. To see a full list take a look at the table found in the `display` property specification.

Single value	Multi value
block	block flow
flow-root	block flow-root
inline	inline flow
inline-block	inline flow-root
flex	block flex
inline-flex	inline flex
grid	block grid
inline-grid	inline grid

display: block flow-root and display: inline flow-root

Regarding how this multi-value syntax helps clarify CSS layout, we can look at some values in the table above that might be less familiar to you. The multi-keyword `display: block flow-root` maps to a single value; `display: flow-root`. This value's only purpose is to create a new Block Formatting Context (BFC). A BFC ensures that everything inside your box stays inside, and things outside the box cannot intrude into it.

In the example below, two `<p>` elements, one inside a `<div>` demonstrate how display values affect formatting contexts. The first `<div>` element with the demo controls is hidden so we can focus on the elements that follow instead. The elements that we should focus on are the "parent", "child", and "sibling" `<div>` and `<p>` elements which you can differentiate by their IDs.

What's notable about this layout is that there is no content between the parent and child elements, and the child element has a top margin applied. You might expect the top margin to effectively push the child element down within the parent element, but what happens instead is something called *margin collapse*. In this case, the margin of the child element extends well above the parent's bounding box and pushes the parent element further down the page. This is easier to see if you inspect the box model of the child element in your browser's developer tools.

Change the selected option in the `<select>` element to see the effect of different `display` values. You can use any value with `flow-root` to create a new formatting context for the parent, making the child element margin relative to its parent's outer edge and avoiding the margin collapse. Changing between `display: flow-root` and `display: block flow-root` will achieve the same effect as the single-value `flow-root` keyword.

```
const parentDiv = document.getElementById("parent");
const siblingDiv = document.getElementById("sibling");
const displayTypeSelect = document.getElementById("displayType");

function changeDisplayType() {
  parentDiv.style.display = displayTypeSelect.value;
  siblingDiv.style.display = displayTypeSelect.value;
}

displayTypeSelect.addEventListener("change", changeDisplayType);
```

```
#controls {
  padding: 1rem;
  outline: 2px dashed black;
}
body {
  margin: 10px;
  font-family: sans-serif;
}
```

```
div,
p {
  outline: 2px solid black;
  background-color: cornflowerblue;
  display: block;
  margin-bottom: 2rem;
}

#parent {
  background-color: oldlace;
  min-height: 2rem;
}

#child {
  margin-top: 4rem;
  outline: 2px dashed red;
}

#sibling {
  background-color: lavender;
}
```

```
<div id="controls">
  <label for="displayType">display:</label>
  <select id="displayType">
    <option value="block">block</option>
```

```
    <option value="flow-root">flow-root</option>
    <option value="block flow-root">block flow-root</option>
    <option value="inline">inline</option>
    <option value="inline flow-root">inline flow-root</option>
  </select>
</div>
```

```
<div id="parent">
  <p id="child">The #child paragraph (nested in #parent).</p>
</div>
<p id="sibling">The #sibling paragraph (sibling of #parent).</p>
```

The `flow-root` value makes sense if you think about block and inline layout, which is sometimes called normal flow. Our HTML page creates a new formatting context (floats and margins cannot extend out from the boundaries) and our content lays out in normal flow, using block and inline layout, unless we change the value of `display` to use some other formatting context. Creating a grid or flex container also creates a new formatting context (a grid or flex formatting context, respectively.) These also contain everything inside them. However, if you want to contain floats and margins but continue using block and inline layout, you can create a new flow root, and start over with block and inline layout. From that point downwards everything is contained inside the new flow root.

This is why `display: flow-root` can be written using the multi-keyword syntax `display: block flow-root`. You are creating a block formatting context, with a block-level box and children participating in normal flow. What about the matched pair `display: inline flow-root`? This is the current way of describing `display: inline-block`.

The value `display: inline-block` has been around since the early days of CSS. The reason we tend to use it is to allow padding to push inline items away from an element, when creating navigation items for example, or when wanting to add a background with padding to an inline element as in the example below.

```
<p>
  This paragraph has a span <span class="inline-block">with padding</span> it is
  an inline-block so the padding is contained and pushes the other line boxes
  away.
</p>
```

```
body {
  font: 1.2em / 1.5 sans-serif;
}
p {
  border: 2px dashed;
  width: 300px;
}
.inline-block {
  background-color: rgb(0 0 0 / 0.4);
  color: white;
  padding: 10px;
  display: inline-block;
}
```

An element with `display: inline-block` however, will also contain floats. It contains everything inside the inline-level box. Therefore `display: inline-block` does exactly what `display: flow-root` does, but with an inline-level, rather than a block-level box. The two-value syntax accurately describes what is happening with this value. In the example above, you can change `display: inline-block` to `display: inline flow-root` and get the same result.

What about the old values of display?

The single values of `display` are described in the specification as legacy values, and currently you gain no benefit from using the multi-keyword versions, as there is a direct mapping for each multi-keyword version to a legacy version, as demonstrated in the table above.

To deal with single values of `display` the specification explains what to do if only the outer value of `block` or `inline` is used:

> "If a `<display-outside>` value is specified but `<display-inside>` is omitted, the element's inner display type defaults to flow."

This means that the behavior is exactly as it is in a single value world. If you specify `display: block` or `display: inline`, that changes the outer display value of the box but any children continue in normal flow. If only an inner value of `flex`, `grid`, or `flow-root` is specified then the specification explains that the outer value should be set to `block`:

> "If a `<display-inside>` value is specified but `<display-outside>` is omitted, the element's outer display type defaults to block—except for ruby, which defaults to inline."

Finally, we have some legacy pre-composed inline-level values of:

- `inline-block`
- `inline-table`
- `inline-flex`
- `inline-grid`

If a supporting browser comes across these as single values then it treats them the same as the multi-keyword versions:

- `inline flow-root`
- `inline table`
- `inline flex`
- `inline grid`

So all of the current situations are neatly covered, meaning that we maintain compatibility of existing and new sites that use the single values, while allowing the spec to evolve.

Visual formatting model

In CSS, the **visual formatting model** describes how user agents take the document tree, and process and display it for visual media. This includes continuous media such as a computer screen and paged media such as a book or document printed by browser print functions. Most of the information applies equally to continuous and paged media.

In the visual formatting model, each element in the document tree generates zero or more boxes according to the box model. The layout of these boxes is governed by:

- Box dimensions and type.
- Positioning scheme (normal flow, float, and absolute positioning).
- Relationships between elements in the document tree.
- External information (e.g., viewport size, intrinsic dimensions of images, etc.).

Much of the information about the visual formatting model is defined in CSS2, however, various CSS layout modules have expanded upon this information. When reading specifications you will often find references to the model as defined in CSS2, so an understanding of the model and the terms used to describe it in CSS2 is valuable when reading other layout specifications.

In this document we define the model and introduce some of the related terms and concepts, linking to more specific pages for further details.

The role of the viewport

In continuous media, the viewport is the viewing area of the browser window. User agents can change the layout of the page when the viewport size changes — for example, if you resize your window, or change the orientation of a mobile device.

If the viewport is smaller than the size of the document then the user agent needs to offer a way to scroll to the parts of the document that are not displayed. We most often see this as scrolling in the **block dimension** — vertically in a horizontal, top-to-bottom language. However, you might design something that requires scrolling in the **inline dimension** too.

Box generation

Box generation is the part of the CSS visual formatting model that creates boxes from the document's elements. Generated boxes are of different types, which affect their visual formatting. The type of the box generated depends on the value of the CSS `display` property.

Initially defined in CSS2, the `display` property was extended in the CSS display, CSS flexible box layout, CSS grid layout, and CSS ruby layout modules. In addition, some of the terminologies around the display have been updated and clarified in the years since CSS2.

CSS takes your source document and renders it onto a canvas. To do this, it generates an intermediary structure, the **box tree**, which represents the formatting structure of the rendered document. Each box in the box tree represents its corresponding element (or pseudo-element) in space and/or time on the canvas, while each text run in the box tree likewise represents the contents of its corresponding text nodes.

Then, for each element, CSS generates zero or more boxes as specified by that element's `display` property value.

> **Note:** Boxes are often referred to by their display type — e.g., a box generated by an element with `display: block` is called a "block box" or just a "block". Note however that block boxes, block-level boxes, and block containers are all subtly different; see the block boxes section below for more details.

The principal box

When an element generates one or more boxes, one of them is the **principal box**, which contains its descendant boxes and generated content in the box tree, and is also the box involved in any positioning scheme.

Some elements may generate additional boxes in addition to the principal box, for example `display: list-item` generates more than one box (e.g., a **principal block box** and a **child marker box**). And some values (such as `none` or `contents`) cause the element and/or its descendants to not generate any boxes at all.

Anonymous boxes

An **anonymous box** is created when there is not an HTML element to use for the box. This situation happens when, for example, you declare `display: flex` on a parent element, and directly inside there is a run of text not contained in another element. In order to fix the box tree, an anonymous box is created around that run of text. It will then behave as a flex item, however, it cannot be targeted and styled like a regular box because there is no element to target.

```
<div class="flex">
  I am wrapped in an anonymous box
  <p>I am in the paragraph</p>
  I am wrapped in an anonymous box.
</div>
```

```
body {
  font: 1.2em sans-serif;
  margin: 20px;
}

.flex {
  display: flex;
}

.flex > * {
  background-color: rebeccapurple;
  color: white;
}
```

The same thing happens when you have text runs interspersed with block elements. In the next example I have a string inside a `<div>`; in the middle of my string is a `<p>` element containing part of the text.

```
<div class="example">
  I am wrapped in an anonymous box
  <p>I am in the paragraph</p>
  I am wrapped in an anonymous box.
</div>
```

```
body {
  font: 1.2em sans-serif;
  margin: 20px;
}

.example > * {
  background-color: rebeccapurple;
  color: white;
}
```

The string is split into three boxes in the box tree. The part of the string before the paragraph element is wrapped in an anonymous box, then we have the `<p>`, which generates a box, and then another anonymous box.

Something to consider about these anonymous boxes is that they inherit styles from their direct parent, but you cannot change how they look by targeting the anonymous box. In my examples, I am using a direct child selector to target the children of the container. This does not change the anonymous boxes, as they are not "elements" as such.

Inline anonymous boxes are created when a string is split by an inline element, for example, a sentence that includes a section wrapped with `<em></em>`. This splits the sentence into three inline boxes — an anonymous inline box before the emphasized section, the section wrapped in the `<em>` element, then a final anonymous inline box. As with the anonymous block boxes, these anonymous inline boxes cannot be styled independently in the way the `<em>` can; they just inherit the styles of their container.

Other formatting contexts also create anonymous boxes. Grid layout behaves in the same way as the flexbox example above, turning strings of text into a grid item with an anonymous box. Multiple-column layout creates anonymous column boxes around the columns; these also cannot be styled or otherwise targeted. Table layout will add anonymous boxes to create a proper table structure — for example adding an anonymous table row — if there was no box with `display: table-row`.

Line boxes

Line boxes are the boxes that wrap each line of text. You can see the difference between line boxes and their containing block if you float an item and then follow it by a block that has a background color.

In the following example, the line boxes following the floated `<div>` are shortened to wrap around the float. The background of the box runs behind the float, as the floated item has been taken out of flow.

```
<div class="float"></div>
<p class="following">
  This text is following the float, the line boxes are shortened to make room
  for the float but the box of the element still takes position in normal flow.
</p>
```

```
body {
  font: 1.2em sans-serif;
  margin: 20px;
}

.float {
  float: left;
  width: 150px;
  height: 150px;
  background-color: rebeccapurple;
  margin: 20px;
}

.following {
  background-color: #cccccc;
}
```

Positioning schemes and in-flow and out-of-flow elements

In CSS, a box may be laid out according to three positioning schemes — **normal flow**, **floats**, or **absolute positioning**.

Normal flow

In CSS, the normal flow includes block-level formatting of block boxes, inline-level formatting of inline boxes, and also includes relative and sticky positioning of block-level and inline-level boxes.

Read more about flow layout in CSS.

Floats

In the float model, a box is first laid out according to the normal flow, then taken out of the flow and positioned, typically to the left or right. Content may flow along the side of a float.

Find out more about floats.

Absolute positioning

In the absolute positioning model (which also includes `fixed` positioning), a box is removed from the normal flow entirely and assigned a position relative to a containing block (which is the viewport in the case of fixed positioning) or to one or more anchor elements in CSS anchor positioning.

An element is called **out of flow** if it is floated, absolutely positioned, or is the root element. An element is called **in-flow** if it is not out of the flow.

Read about CSS positioned layout.

Formatting contexts and the display property

Boxes can be described as having an **outer display type**, which is `block` or `inline`. This outer display type refers to how the box behaves alongside other elements on the page.

Boxes also have an inner display type, dictating how their children behave. For normal block and inline layout, or normal flow, this display type is `flow`. This means that the child elements will also be either `block` or `inline`.

However, the inner display type might be something like `grid` or `flex`, in which case the direct children will display as a grid, or flex items. In such a case the element is described as creating a grid or flex formatting context. In many ways, this is similar to a block formatting context, however, the children behave as flex or grid items rather than items in normal flow.

The interactions between block-level and inline-level boxes are described in the `display` property reference.

In addition, the references for specific values of display explain how these formatting contexts work in terms of box layout.

- CSS grid layout module
- CSS flexible box layout module
- CSS multi-column layout module
- CSS table module
- CSS lists and counters module

Independent formatting contexts

Elements either participate in the formatting context of their containing block or establish an independent formatting context. A grid container, for example, establishes a new **grid formatting context** for its children.

Independent formatting contexts contain floats, and margins do not collapse across formatting context boundaries. Therefore, creating a new block formatting context can ensure that floats and margins remain inside a box. To do this, add `display: flow-root` to the box on which you wish to create a new block formatting context.

The following example shows the effect of `display: flow-root`. The box with the black background appears to wrap around the floated item and text. If you remove `display: flow-root`, the floated item will poke out of the bottom of the box as it is no longer contained.

```
<div class="container">
  <div class="item">Floated</div>
  <p>Text following the float.</p>
</div>
```

```
body {
  font: 1.2em sans-serif;
  margin: 20px;
}
.container {
  background-color: #333333;
  color: white;
}

.item {
  background-color: white;
  border: 1px solid #999999;
  color: #333333;
  width: 100px;
  height: 100px;
```

```
  padding: 10px;
}
```

```
.container {
  display: flow-root;
}

.item {
  margin: 10px;
  float: left;
}
```

Block boxes

In specifications, block boxes, block-level boxes, and block containers are all referred to as **block boxes** in certain places. These things are somewhat different and the term block box should only be used if there is no ambiguity.

Block containers

A **block container** either contains only inline-level boxes participating in an inline formatting context, or only block-level boxes participating in a block formatting context. For this reason, we see the behavior explained above, where anonymous boxes are introduced to ensure all of the items can participate in a block or inline formatting context. An element is a block container only if it contains block-level or inline-level boxes.

Inline-level and block-level boxes

These are the boxes contained inside the block container that are participating in inline or block layout, respectively.

Block boxes

A block box is a block-level box that is also a block container. As described in CSS `display`, a box can be a block-level box, but not also a block container (it might be a flex or grid container for example).

CSS easing functions

The **CSS easing functions** module defines easing functions, which provide a means to control the transformation of values. The functions defined include linear, cubic bezier, and step easing functions. These easing functions can be applied to animations and transitions.

Gradually increasing the speed at which an element moves can give the element a sense of weight as it appears to gather momentum. Easing functions enable you to control the rate of change. Cubic bezier easing functions can be used to produce intuitive user interface elements or convincing cartoon props that behave like their physical counterparts.

Alternatively, you may want an animation to move forward in distinct steps, to create robot-like movement, or the effect of a segmented wheel that rotates such that the segments always appear in the same position. For this, step easing functions can be used.

CSS environment variables

The **CSS environment variables** module defines the concept of environment variables and the `env()` function. Environment variables work similarly to custom properties and the `var()` function, except that they are globally defined; they are global variables scoped to the entire document. They are user agent values, provided by the browser or operating system, you can access using the `env()` function enabling you to adapt your styles to the user's device or context.

Environment variables provide values that can be used on the page based on information the user agent has access to, such as the size of the titlebar, dynamic keyboard, and safe area insets. Safe area insets define a rectangle that is guaranteed to be visible on non-rectangular displays, based on its distance from the edges of the viewport. You can include the user-agent sizes in your styles, enabling you to modify the layout of essential content based on the available space inside the safe area rectangle, next to a visible dynamic keyboard, or adjacent to a visible title bar.

Using environment variables

The CSS environment variables module introduces the concept of environment variables in CSS and defines the `env()` function to enable using environment variables. In this guide, we look at what environment variables are, the environment variables defined by the browser, and how to use environment variables with the `env()` function.

What are environment variables?

CSS environment variables are global variables; globally scoped to the entire document. They are defined by the user agent. Environment variables are special values provided by the browser or operating system that help your styles adapt to the user's device or context. They are accessed using the `env()` function.

Environment variables work similarly to custom properties and the `var()` function, but are globally defined and scoped. This means they are always scoped to the entire document, unlike custom properties, which are scoped to elements. In addition, environment variables are read-only, whereas custom properties are mutable.

Similar to custom properties, environment variables are case-sensitive. Unlike custom properties, which cannot be used outside of declarations, the `env()` function can be used in place of any part of a property value, or any part of a descriptor (for example, in Media query rules).

History

Apple first introduced environment variables in the iOS Safari browser to enable developers to optimize layouts for irregular device displays. Examples include those with notches and curved edges. The original `safe-area-inset-*` environment variables allow developers to place content in a safe area of the viewport regardless of what device or browser the user has.

Use cases

Common issues that can be solved by using environment variables include:

- Device notifications covering up sections of the app user interface.
- Handling viewport size changes when dynamic keyboards are shown and hidden.
- Positioning elements where the title bar would have been on progressive web apps (PWAs) once they are installed and ensuring that content stays clear of the window control buttons. This is especially an issue on desktop browsers.

Browser-defined environment variables

The CSS environment variables specification defines a few case-sensitive variables, including:

`preferred-text-scale`

The `preferred-text-scale` environment variable represents the user's preferred text scale factor. This is the adjustment made to the "default" font size of the operating system or user agent. On devices and browsers where `text-size-adjust` has an effect, this is the scale factor applied by `text-size-adjust: auto`. For example, if `text-size-adjust: auto` would cause the text size to double, then `env(preferred-text-scale)` would resolve to `2`.

`safe-area-inset-*`

The four safe area inset environment variables - `safe-area-inset-top`, `safe-area-inset-right`, `safe-area-inset-bottom`, and `safe-area-inset-left` - define a rectangular safe area by its top, right, bottom, and left insets from the edge of the viewport. It is safe to place content inside this area without having it cut off by the shape of a non-rectangular display. For rectangular, unobstructed viewports, such as regular desktop and laptop monitors, these four values are all equal to `0`. For non-rectangular displays — including rounded-corner devices with full-size screens and rounded or round-display smart watches — these four values, set by the user agent, form a rectangle such that all content inside the rectangle is visible and unobstructed.

`safe-area-max-inset-*`

The four safe area maximum inset environment variables - `safe-area-max-inset-top`, `safe-area-max-inset-right`, `safe-area-max-inset-bottom`, and `safe-area-max-inset-left` - each represent the static maximum value of their dynamic `safe-area-inset-*` variable counterparts. They represent the maximum value of their `safe-area-inset-*` counterpart when all dynamic user interface features are retracted. For example, on some platforms there may be a button bar displayed when scrolling up or down, changing the `safe-area-inset-*` values. While the `safe-area-inset-*` values change as the currently visible content area changes, the `safe-area-max-inset-*` values always remain the same.

`viewport-segment-*`

These variables are only relevant to devices that have multiple segments, such as foldable phones. The `viewport-segment-bottom`, `viewport-segment-left`, `viewport-segment-right`, and `viewport-segment-top` variables, along with the `viewport-segment-height` and `viewport-segment-width`, define the position and dimensions of logically separated regions of the viewport. These variables are only defined if the viewport is divided into at least two segments. They are used to place different parts of a UI comfortably into different segments of a multi-segment device and avoid having your content cut off by the fold.

Other specifications define additional environment variables.

The Window Controls Overlay API defines the `WindowControlsOverlay` interface, which exposes information about the geometry of the title bar area in progressive web applications (PWAs) installed on desktop devices. When using the `window-controls-overlay` display_override value, the following environment variables are defined:

`titlebar-area-*`

The `titlebar-area-x`, `titlebar-area-y`, `titlebar-area-width`, and `titlebar-area-height` variables define the area that would generally be occupied by the title bar in an installed web application running on a desktop environment. Use the `titlebar-area-*` variables to ensure content doesn't overlap with the window control buttons (that is, minimize, maximize, and close).

`keyboard-inset-*`

The `keyboard-inset-top`, `keyboard-inset-right`, `keyboard-inset-bottom`, `keyboard-inset-left`, `keyboard-inset-width`, and `keyboard-inset-height` variables provide information about the on-screen virtual keyboard's position and size, specifically its top, right, bottom, and left insets from the edge of the viewport (the width and height insets are calculated from the other insets). To learn more, see the VirtualKeyboard API.

You may have noticed that all the previous variable names include the physical terms of left, right, top, bottom, height, and width. Logical equivalents are not needed because the variable names refer to the physical properties of the device hardware rather than the displayed website.

The <code>env()</code> function

The `env()` function is used to insert the value of an environment variable into a CSS context. The `env()` function can be used in place of any part of a value in any property on any element, or any part of a value in any descriptor on any at-rule, including within custom property values. It can be used wherever a CSS value is allowed.

The basic syntax is as follows:

```
env( <environment-variable-name> )
env( <environment-variable-name>, <fallback-value> )
```

The function accepts a case-sensitive environment variable name and an optional, but generally recommended, fallback value.

```
line-height: env(preferred-text-scale, 2);
margin: env(safe-area-inset-top, 0) env(safe-area-inset-right, auto)
  env(safe-area-inset-bottom, 3em) env(safe-area-inset-left, auto);
```

The first argument is the name of the environment variable to be substituted. The argument after the comma, if provided, is the fallback value, which is used if the environment variable referenced in the first argument does not exist. In these examples, if the `preferred-text-scale` environment variable doesn't exist in a browser, the `line-height` will be set to `2`. And, if the browser doesn't have `safe-area-inset-*` values, the `margin` will be set to `margin: 0 auto 3em auto`.

The syntax of the fallback is similar to the custom properties syntax in that it allows for multiple commas. Anything between the first comma and the end of the function is considered the fallback value. However, if the property value or descriptor doesn't support commas, the value is not valid.

If a property or descriptor contains syntactically valid `env()` functions, it is assumed to be valid at parse time. It is only syntax-checked at computed-time, after the `env()` functions have been substituted with their browser-provided values. If the environment variable passed as the first parameter is not a recognized environment variable name, the fallback value is used. The fallback can be another environment variable, even with its own fallback. If no fallback was provided, the property or descriptor containing the `env()` function is invalid at computed-value time.

Using environment variables with <code>env()</code> example

We can use environment variables to ensure that a fixed app toolbar is not obscured by notifications appearing at the bottom of the device. In devices that display notifications at the bottom of the screen, the user agent will set the value of the `safe-area-inset-bottom` environment variable to be the distance from the top of what is blocking the viewport to the bottom of the viewport; in our example, this is likely the height of any visible notifications. On a rectangular desktop monitor, the `safe-area-inset-bottom` is generally `0`. We will use this value to create space at the bottom of the viewport for the notification to display without obscuring the content.

Our `<body>` has two children; the `<main>` contains our entire application other than the `<footer>` toolbar.

```
<body>
  <main>Application</main>
  <footer>Toolbar</footer>
</body>
```

The `<body>` is defined as a flex container that fills the height of the viewport. The `<main>` application is allowed to grow to fill any space not occupied by its sibling `<footer>`.

```
body {
  display: flex;
  flex-flow: column nowrap;
  height: 100vh;
}

main {
  flex: 1;
  padding: 1em;
  overflow-y: auto;
}
```

The `<footer>` is positioned to be stuck to the bottom of the viewport. The declaration `position: sticky` offsets the element relative to the `<body>` (its scrolling ancestor and containing block), based on the `bottom` value of `0`. We give the `<footer>` a `padding` value of `1em` on all four sides. We then add the `safe-area-inset-bottom` value to the `1em` of bottom padding, with a fallback of `1em`.

```
footer {
  position: sticky;
  bottom: 0;
  padding: 1em;
  padding-bottom: calc(1em + env(safe-area-inset-bottom, 1em));
}
```

Additional CSS is hidden for brevity.

```
main {
  background-color: palegoldenrod;
}
footer {
  background-color: black;
  color: white;
```

```
  border-top: 1px solid white;
  display: flex;
  justify-content: space-between;
}

footer::before,
footer::after {
  content: "Button" / "Fake button";
  padding: 3px 0.5em;
  background: white;
  color: black;
  border-radius: 3px;
}
```

The bottom padding of the footer will extend beyond `1em` on devices that have the `safe-area-inset-bottom` environment variable with a value greater than `0`. This CSS provides extra padding to grow the footer as needed, be it because of notifications, a device notch in the screen, or because the device doesn't have square corners.

In the future, we may see support for developer-defined environment variables, but this has not yet been defined or implemented.

Using filter effects

Have you ever hovered over a black-and-white or sepia image and the full-color image came into view instantly? Have you ever encountered a background image with a small blurred-out section that makes the text on top more legible? In the past, these manipulations required image editing software, time, and additional HTTP requests.

Advantages of using CSS filter effects

The Filter effects module in CSS provides properties and functions that let you apply the visual effects described above without using Photoshop or sending extra HTTP requests. The only software required is the user's browser. Moreover, unlike pre-set image effects, CSS filter effects are responsive and animatable.

The CSS filter effects module provides the `filter` and `backdrop-filter` properties that you can use to impact the rendering of text, images, backgrounds, and borders, or any element on which you apply these properties. This module also defines the `<filter-function>` data type that lets you add graphical effects such as blurring or color shifting. Using the filter functions, you can not only alter the appearance of an element but also reference an SVG filter using a filter that you create.

Filter effect properties

The following two filter properties of the CSS filter effects module enable you to apply zero, one, or more graphical effects to an element:

- Using the `filter` property, you can apply filter effects such as blur, drop-shadow, and sepia to an element before the element is rendered. The filters effects are applied directly on the element, including the element's contents, borders, and padding.
- Using the `backdrop-filter` property, you can apply graphical effects to the area behind an element (the element's "backdrop"). The `backdrop-filter` property is often used to make the foreground content more legible, especially when the larger area on which the content is placed otherwise does not provide enough contrast for the content. The filter effects are applied only to the background of the element and not to the element's content.

The `filter` and `backdrop-filter` properties accept a space-separated list of filters, which are applied in the order declared.

Filter functions

The CSS filter effects module provides 10 `<filter-function>` functions, as well as the ability to define an almost endless array of effects using SVG filters applied via a `url()` reference.

The following table lists the 10 filter functions, along with their value types, the minimum valid value if applicable, the largest value that creates an effect, and the initial value used for interpolation.

Filter function	Parameter type	Min value	Max effect	Default value (no effect)
`blur()`	`<length>`	`0`		`0`
`brightness()`	`<number>` or `<percentage>`	`0`		`1` or `100%`
`contrast()`	`<length>`	`0`		`1` or `100%`
`drop-shadow()`	`<shadow>`			`0 0 0 currentColor`
`grayscale()`	`<number>` or `<percentage>`	`0`	`100%`	`0` or `0%`
`hue-rotate()`	`<angle>`			`0deg`
`invert()`	`<number>` or `<percentage>`	`0`	`100%`	`0` or `0%`
`opacity()`	`<number>` or `<percentage>`	`0`	`100%`	`1` or `100%`
`saturate()`	`<number>` or `<percentage>`	`0`	`100%`	`100%`
`sepia()`	`<number>` or `<percentage>`	`0`	`100%`	`0%`

The minimum value allowed is included for filter functions that have a minimum value. Including a value less than the minimum value for any filter function invalidates the entire property declaration, not just the offending filter function in the comma-separated list.

The maximum effect value can be exceeded. Including a value greater than the listed maximum value is valid, but it does not increase the effect over the listed maximum value. In other words, the effect on the element will look the same as when the maximum effect value is set. For example, setting `sepia(400%)` in the sepia example will produce the same effect as `sepia(100%)`, the maximum value.

The default value is a value that creates no effect. While these values create no effect, they provide the initial interpolation values and offer an example of how the value can be set. These default values provide a gauge between the minimum value allowed and the maximum effect value.

Applying filter effects

The `filter` and `backdrop-filter` properties accept a filter function list, which may contain one or more `<filter-function>`s, the default keyword `none`, or an SVG filter as a `url()` value.

Applying sepia filter effect

If you hover over the sepia image below, you'll see the full-color image come into view instantly.

The image is set to be sepia by specifying the value of the `filter` property as the `sepia()` filter function. The filter is removed on `:hover` and `:focus` by setting `filter: none`.

```
<img tabindex="0" alt="Four trans-people, circa 1912" src="activists.jpg" />
```

```
img {
  filter: sepia(100%);
}
img:hover,
img:focus {
  filter: none;
}
```

In the `<img>` element, `tabindex` is set to `0` to enable focus without altering the tabbing order for keyboard users because `<img>` is not an interactive element.

```
img {
  max-width: 100%;
  height: 100%;
}
```

Applying filter effects to other elements

While generally applied to images, the `filter` and `backdrop-filter` properties can be applied to any element or pseudo-element.

In this example, a glow effect is added using a `drop-shadow()` filter with a `3px` blur and `0` offset.

```
h1 {
  color: midnightblue;
  filter: drop-shadow(0 0 3px magenta);
}
```

```
h1 {
  font-family: sans-serif;
  font-size: 2rem;
}
```

```
<h1>Glow created with CSS filter</h1>
```

Applying multiple filters

While the sepia `filter` example included only a single filter function, you can set multiple filters. The `filter` and `backdrop-filter` properties accept a space-separated list of filters, which are applied in the order declared.

This example applies two filters — `hue-rotate()` and `blur()` — via the `backdrop-filter` property. The backdrop, the area behind the `<p>` element, has a color shift and a blur applied.

```
.container {
  background: url("/shared-assets/images/examples/listen_to_black_women.jpg")
    no-repeat left / contain goldenrod;
}
p {
  backdrop-filter: hue-rotate(240deg) blur(5px);
  background-color: rgb(255 255 255 / 10%);
  text-shadow: 2px 2px black;
}
```

```
.container {
  padding: 3rem;
  width: 30rem;
}
p {
  padding: 0.5rem;
  color: white;
  font-size: 2rem;
  font-family: sans-serif;
}
```

```
<div class="container">
  <p>
    Text on images can be illegible and inaccessible even with a drop shadow.
  </p>
</div>
```

Applying repeated filters

As filters are applied in sequential order, you can use filter functions more than once. In this example, the `drop-shadow()` filter has been used four times, each time with a different `<shadow>` value.

```
<img src="mandala.svg" alt="Colorful mandala" role="img" />
<img src="mandala.svg" alt="Plain mandala" role="img" />
```

```
img {
  width: 49%;
}
```

```
img {
  filter: drop-shadow(2px 2px 0 magenta) drop-shadow(-2px -2px 0 royalblue)
    drop-shadow(2px 2px 0 lime) drop-shadow(-2px -2px 0 darkorange);
}
img + img {
  filter: none;
}
```

In the first Mandala example, four drop shadows are applied to a line-drawn SVG. The same SVG, with the filter removed with `filter: none`, is included for comparison.

Specifying filter function order

When creating filter effects, the `filter` or `backdrop-filter` property is provided a space-separated list of filters. These filter effects are applied in the order in which they appear.

In this example, both `magenta` drop shadow and `180deg` hue rotation are applied on the level-one heading. The example shows the effect when these filters are applied in different orders.

```
h1 {
  color: midnightblue;
}
#hueFirst {
  filter: hue-rotate(180deg) drop-shadow(3px 3px magenta);
}
#shadowFirst {
  filter: drop-shadow(3px 3px magenta) hue-rotate(180deg);
}
```

```
h1 {
  font-family: sans-serif;
  font-size: 2rem;
}
```

```
<h1 id="hueFirst">Hue change happens before drop shadow.</h1>
<h1 id="shadowFirst">Drop shadow applied before hue change.</h1>
<h1>No filter effects applied.</h1>
```

The same filters are applied to both the lines of text but in a different order. In the first line, the hue of the text is altered before the shadow is applied, so the shadow is `magenta`. In the second line, the drop shadow is added to the dark blue text, and then the hue of both the text and the shadow are altered.

No filter effect is applied to the third line to show the original effect as a comparison. So the third line stays as `midnightblue` or `#191970`. The `hue-rotate(180deg)` filter changes the text in the first two lines to `#252500`.

> **Note:** The hexadecimal rgb color `#191970` is equal to `hsl(240deg 63.5% 26.9%)`, while `#252500` is `hsl(60deg 100% 7.3%)`. The color rotation takes place in the sRGB color space, which is why the hue has been

> changed as expected while not maintaining the same values for saturation and lightness.

Using SVG filters

In addition to the 10 defined `<filter-function>`s, the CSS filter effects support `url()`, with the parameter being an SVG filter, which may be embedded in an internal or external SVG file.

A single SVG can be used to define several filters, each with an `id`:

```
<svg role="none">
  <defs>
    <filter id="blur1">
      <feGaussianBlur stdDeviation="1" edgeMode="duplicate" />
    </filter>
    <filter id="blur3">
      <feGaussianBlur stdDeviation="3" edgeMode="duplicate" />
    </filter>
    <filter id="hue-rotate90">
      <feColorMatrix type="hueRotate" values="90" />
    </filter>
  </defs>
</svg>
```

The filter's `id` is referenced in the `url()` for both inline and external SVGs:

```
filter: url("#blur3");
filter: url("https://example.com/svg/filters.svg#blur3");
```

Blurring an image

Just like the `blur()` filter function applies a Gaussian blur to the elements on which it is applied, the SVG `<feGaussianBlur>` filter element can also be used to blur content.

In both the cases, the blur radius value, specified as a `<length>` in CSS and as a pixel equivalent `<number>` in SVG, defines the value of the standard deviation to the Gaussian function. In other words, it defines the number of pixels on the screen that blend into each other; a larger value creates more blur.

The `<filter>`'s `stdDeviation` attribute accepts up to two values enabling creating more complex blur values. To create an equivalent blur, we include one value for `stdDeviation`:

```
<table>
  <thead>
    <tr>
      <th>CSS example</th>
      <th>SVG example</th>
      <th>Original image</th>
    </tr>
  </thead>
  <tbody>
    <tr>
      <td>
        <img
          class="filter"
          src="https://mdn.github.io/shared-assets/images/examples/progress-pride-flag.jpg"
          alt="Pride flag" />
      </td>
      <td>
        <img
          src="https://mdn.github.io/shared-assets/images/examples/progress-pride-flag.jpg"
          alt="Pride flag"
          class="svgFilter" />
      </td>
      <td>
        <img
          src="https://mdn.github.io/shared-assets/images/examples/progress-pride-flag.jpg"
          alt="Pride flag" />
      </td>
    </tr>
  </tbody>
</table>
```

```
<svg role="img" aria-label="Flag">
  <filter id="blur">
    <feGaussianBlur stdDeviation="3.5" edgeMode="duplicate" />
  </filter>
  <image
    xlink:href="https://mdn.github.io/shared-assets/images/examples/progress-pride-flag.jpg"
    filter="url(#blur)" />
</svg>
```

The SVG `url()` filter value can be included as the value of the SVG `<image>` element's `filter` attribute or as part of the value of the CSS `filter` and `backdrop-filter` properties.

```
th,
td {
  padding: 5px;
}
```

```
.filter {
  filter: blur(3.5px);
}
.svgFilter {
  filter: url("#blur");
}
```

CSS flexible box layout

The **CSS flexible box layout** module defines a CSS box model optimized for user interface design, and the layout of items in one dimension. In the flex layout model, the children of a flex container can be laid out in any direction, and can "flex" their sizes, either growing to fill unused space or shrinking to avoid overflowing the parent. Both horizontal and vertical alignment of the children can be easily manipulated.

Flexible box layout in action

In the following example, a container has been set to `display: flex`, which means that the three child items become flex items. The value of `justify-content` has been set to `space-between` in order to space the items out evenly on the main axis. An equal amount of space is placed between each item with the left and right items being flush with the edges of the flex container. You can also see that the items are stretching on the cross axis, due to the default value of `align-items` being `stretch`. The items stretch to the height of the flex container, making them each appear as tall as the tallest item.

```
<div class="box">
  <div>One</div>
  <div>Two</div>
  <div>Three <br />has <br />extra <br />text</div>
</div>
```

```
body {
  font-family: sans-serif;
}

.box {
  border: 2px dotted rgb(96 139 168);
  display: flex;
  justify-content: space-between;
}

.box > * {
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
  background-color: rgb(96 139 168 / 0.2);
  padding: 1em;
}
```

Aligning items in a flex container

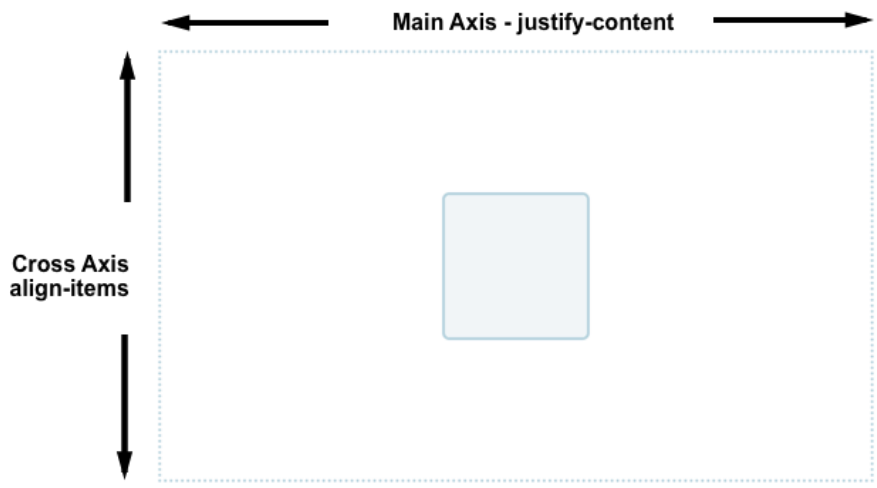
One of the reasons flexbox is so useful is that it enables proper alignment, including providing a quick method of vertically centering elements. In this guide, we will take a thorough look at how the alignment and justification properties work in flexbox.

Using alignment in flexbox

Flexbox provides several properties to control alignment and spacing, with `align-items` and `justify-content` being fundamental for centering elements. To center an element, we use the `align-items` property to align the item on the cross axis, which in this case is the block axis running vertically. We use `justify-content` to align the item on the main axis, which in this case is the inline axis running horizontally.



Change the size of the container or nested element in the code example below. The nested element always remains centered.

```
<div class="box">
  <div></div>
</div>
```

```
.box {
  display: flex;
  align-items: center;
  justify-content: center;
  border: 2px dotted rgb(96 139 168);
}

.box div {
```

```
  width: 100px;
  height: 100px;
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
  background-color: rgb(96 139 168 / 0.2);
}
```

Properties for controlling alignment in flexbox

The properties we will look at in this guide are as follows.

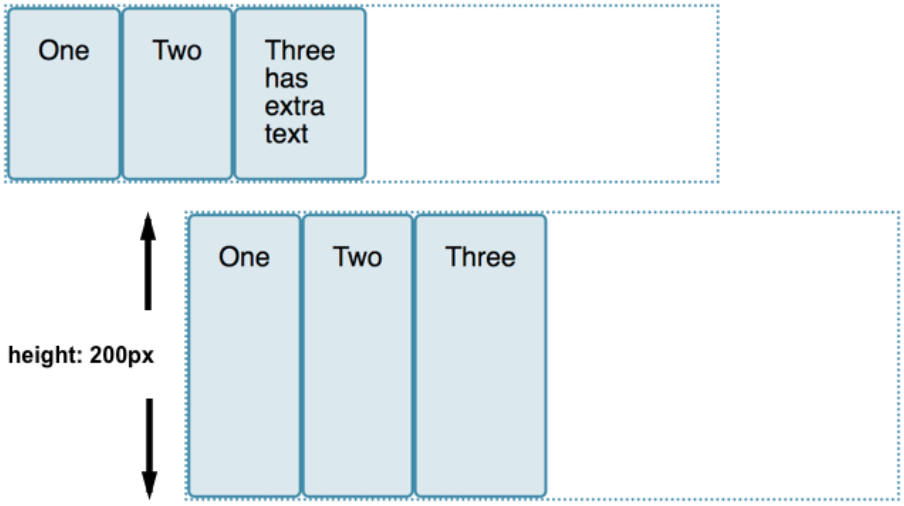
- `justify-content`: Controls the alignment of all items on the main axis.
- `align-items`: Controls the alignment of all items on the cross axis.
- `align-self`: Controls the alignment of an individual flex item on the cross axis.
- `align-content`: Controls the space between flex lines on the cross axis.
- `gap`, `column-gap`, and `row-gap`: Used to create gaps or gutters between flex items.

We will also discover how auto margins can be used for alignment in flexbox.

Aligning items on the cross axis

The `align-items` property, set on the flex container, and the `align-self` property, set on flex items, control the alignment of flex items on the cross axis. The cross axis runs down the columns if `flex-direction` is `row` and along the rows if `flex-direction` is `column`.

In this basic flex example, we're using cross-axis alignment. When we add `display: flex` to a container, the child items become flex items arranged in a row. By default, they will all stretch to match the height of the tallest item, as that item defines the height of the items on the cross axis. If the flex container has a height set, the items will stretch to that height, regardless of how much content is in each item.



The reason the items become the same height is that the initial value of `align-items`, the property that controls alignment on the cross axis, is set to `stretch`.

We can use other values to control how the items align:

- `align-items: stretch`
- `align-items: flex-start`
- `align-items: flex-end`
- `align-items: start`
- `align-items: end`
- `align-items: center`
- `align-items: baseline`
- `align-items: first baseline`
- `align-items: last baseline`

In the example below, the value of `align-items` is `stretch`. Try the other values and see how the items align against each other in the flex container.

```
<div class="box">
  <div>One</div>
  <div>Two</div>
  <div>Three <br />has <br />extra <br />text</div>
</div>
```

```
.box {
  border: 2px dotted rgb(96 139 168);
  display: flex;
  align-items: stretch;
}

.box div {
  width: 100px;
  background-color: rgb(96 139 168 / 0.2);
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
}
```

Aligning one item with <code>align-self</code>

The `align-items` property sets the `align-self` property on all of the flex items as a group. This means you can explicitly declare the `align-self` property to target a single item. The `align-self` property accepts all of the same values as `align-items`, plus a value of `auto`, which resets the value to that defined on the flex container.

In this next live example, the flex container has `align-items: flex-start`, which means the items are all aligned to the start of the cross axis. Using the `first-child` selector, the first item is set to `align-self: stretch`. Another item with the `selected` class has `align-self: center` set. Change the value of `align-items` or change the values of `align-self` on the individual items to see how this works.

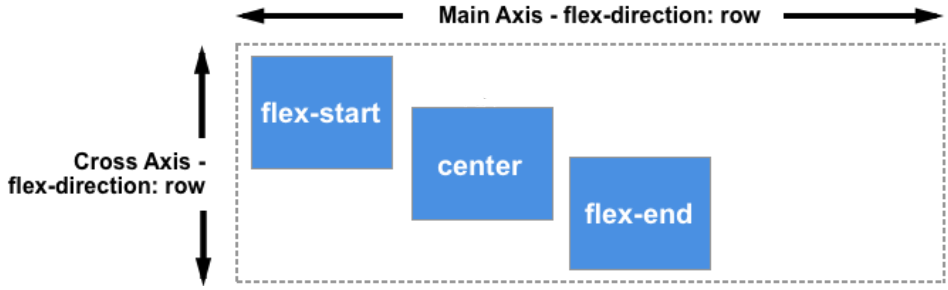
```
<div class="box">
  <div>One</div>
```

```
  <div>Two</div>
  <div class="selected">Three</div>
  <div>Four</div>
</div>
```

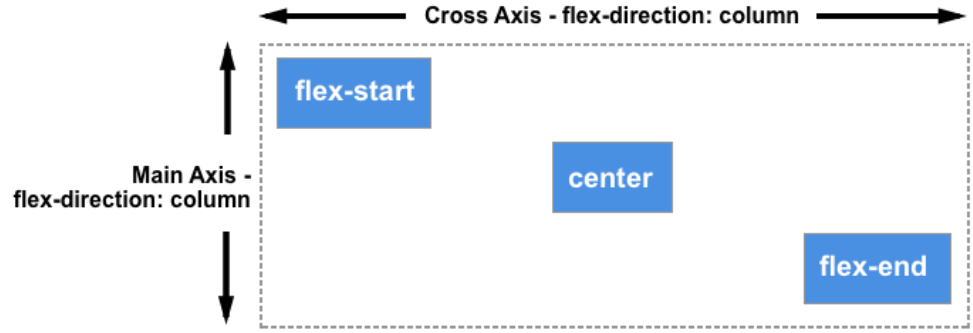
```
.box {
  border: 2px dotted rgb(96 139 168);
  display: flex;
  align-items: flex-start;
  height: 200px;
}
.box div {
  background-color: rgb(96 139 168 / 0.2);
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
  padding: 20px;
}
.box > *:first-child {
  align-self: stretch;
}
.box .selected {
  align-self: center;
}
```

Changing the main axis

Thus far, we have looked at alignment behavior when the `flex-direction` defaults to `row` while working in a language written top to bottom, with a horizontal main axis and vertical cross axis.



Keeping the same writing mode, when the `flex-direction` is changed to `column`, the `align-items` and `align-self` properties will align the items to the left and right instead of top and bottom; these properties are still aligning items along the cross axis, but the cross axis is now horizontal!



You can try this out in the example below, which has a flex container with `flex-direction: column` yet otherwise is exactly the same as the previous example.

```
<div class="box">
  <div>One</div>
  <div>Two</div>
  <div class="selected">Three</div>
  <div>Four</div>
</div>
```

```
.box {
  border: 2px dotted rgb(96 139 168);
  display: flex;
  flex-direction: column;
  align-items: flex-start;
  width: 200px;
}
.box div {
  background-color: rgb(96 139 168 / 0.2);
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
  padding: 20px;
}
.box > *:first-child {
  align-self: stretch;
}
.box .selected {
  align-self: center;
}
```

Aligning content on the cross axis with the <code>align-content</code> property

So far, we have focused on aligning items or individual items inside the area defined by a flex container containing a single line of flex items. When flex items are allowed to wrap across multiple lines, the `align-content` property can be used to control the distribution of space between the lines, also known as **packing flex lines**.

For `align-content` to have an effect, the cross axis dimension (the height in this case) of the flex container must be greater than needed to display the items. It then works on all the items as a set. The `align-content` values dictate what happens with the extra available space and the alignment of the entire set of items within it.

The `align-content` property takes the following values:

- `align-content: flex-start`
- `align-content: flex-end`
- `align-content: start`
- `align-content: end`
- `align-content: center`
- `align-content: space-between`
- `align-content: space-around`
- `align-content: space-evenly`
- `align-content: stretch`
- `align-content: normal` (behaves as `stretch`)
- `align-content: baseline`
- `align-content: first baseline`
- `align-content: last baseline`

In the live example below, the flex container has a height of `400 pixels`, which is more than needed to display our items. The value of `align-content` is `space-between`, which means that the available space is shared out *between* the flex lines, which are placed flush with the start and end of the container on the cross axis.

Try out the other values to see how the `align-content` property works.

```
<div class="box">
  <div>One</div>
  <div>Two</div>
  <div>Three</div>
  <div>Four</div>
  <div>Five</div>
  <div>Six</div>
  <div>Seven</div>
  <div>Eight</div>
</div>
```

```
.box {
  width: 450px;
  border: 2px dotted rgb(96 139 168);
  display: flex;
  flex-wrap: wrap;
  height: 300px;
  align-content: space-between;
}

.box > * {
  padding: 20px;
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
  background-color: rgb(96 139 168 / 0.2);
  flex: 1 1 100px;
}

.box div {
  background-color: rgb(96 139 168 / 0.2);
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
  padding: 20px;
}
```

Once again we can switch our `flex-direction` to `column` in order to see how this property behaves when we are working by column. As before, we need enough space in the cross axis to have some free space after displaying all of the items.

```
<div class="box">
  <div>One</div>
  <div>Two</div>
  <div>Three</div>
  <div>Four</div>
  <div>Five</div>
  <div>Six</div>
  <div>Seven</div>
  <div>Eight</div>
</div>
```

```
.box {
  display: flex;
  flex-wrap: wrap;
  flex-direction: column;
  width: 400px;
  height: 300px;
  align-content: space-between;
  border: 2px dotted rgb(96 139 168);
}

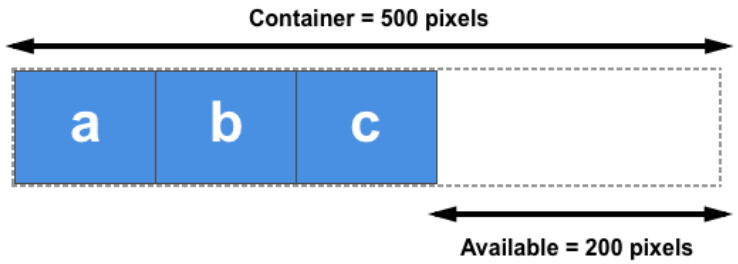
.box > * {
  padding: 20px;
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
  background-color: rgb(96 139 168 / 0.2);
  flex: 1 1 100px;
}

.box div {
  background-color: rgb(96 139 168 / 0.2);
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
  padding: 20px;
}
```

Aligning content on the main axis

Now that we have seen how alignment works on the cross axis, we can take a look at the main axis. Here we only have one property available to us — `justify-content`. This is because we are only dealing with items as a group on the main axis. With `justify-content` we control what happens with available space, should there be more space than is needed to display the items.

In our initial example with `display: flex` on the container, the items display as a row and all line up at the start of the container. This is due to the initial value of `justify-content` being `normal`, which behaves as `start`. Any available space is placed at the end of the items.



The `baseline` values aren't relevant in this dimension. Otherwise, the `justify-content` property accepts the same values as `align-content`.

- `justify-content: flex-start`
- `justify-content: flex-end`
- `justify-content: start`
- `justify-content: end`
- `justify-content: left`
- `justify-content: right`
- `justify-content: center`
- `justify-content: space-between`
- `justify-content: space-around`
- `justify-content: space-evenly`
- `justify-content: stretch` (behaves as start)
- `justify-content: normal` (behaves as stretch, which behaves as start)

In the example below, the value of `justify-content` is `space-between`. The available space after displaying the items is distributed between the items. The left and right item line up flush with the start and end.

```
<div class="box">
  <div>One</div>
  <div>Two</div>
  <div>Three</div>
  <div>Four</div>
</div>
```

```
.box {
  display: flex;
  justify-content: space-between;
  border: 2px dotted rgb(96 139 168);
}

.box > * {
  padding: 20px;
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
  background-color: rgb(96 139 168 / 0.2);
}
```

If the main axis is in the block direction because `flex-direction` is set to `column`, then `justify-content` will distribute space between items in that dimension as long as there is space in the flex container to distribute.

```
<div class="box">
  <div>One</div>
  <div>Two</div>
  <div>Three</div>
  <div>Four</div>
</div>
```

```
.box {
  display: flex;
  flex-direction: column;
  justify-content: space-between;
  height: 300px;
  border: 2px dotted rgb(96 139 168);
}

.box > * {
  padding: 20px;
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
  background-color: rgb(96 139 168 / 0.2);
}
```

Alignment and writing modes

Remember that with all of these alignment methods, the values of `start` and `end` are writing mode-aware. If the value of `justify-content` is `start` and the writing mode is left-to-right, as in English, the items will align starting at the left side of the container.

However if the writing mode is right-to-left as in Arabic, the items will line up starting at the right side of the container.

The live example below has the `direction` property set to `rtl` to force a right-to-left flow for our items. You can remove this, or change the values of `justify-content` to see how flexbox behaves when the start of the inline direction is on the right.

```
<div class="box">
  <div>One</div>
  <div>Two</div>
  <div>Three</div>
  <div>Four</div>
</div>
```

```
.box {
  direction: rtl;
  display: flex;
  justify-content: flex-end;
  border: 2px dotted rgb(96 139 168);
}

.box > * {
  padding: 20px;
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
  background-color: rgb(96 139 168 / 0.2);
}
```

Alignment and <code>flex-direction</code>

The direction of `flex-start` of the line will also change if you change the `flex-direction` property — for example, using `row-reverse` instead of `row`. The directions of `start` and `end` are unaffected by `flex-direction` changes.

In this next example, `flex-direction: row-reverse` and `justify-content: flex-end` define the direction and location of the items within the flex container. In a left to right language, the items line up on the left. Try changing `flex-direction: row-reverse` to `flex-direction: row`. You will see that the items now move to the right-hand side, and the visual order of the items is reversed.

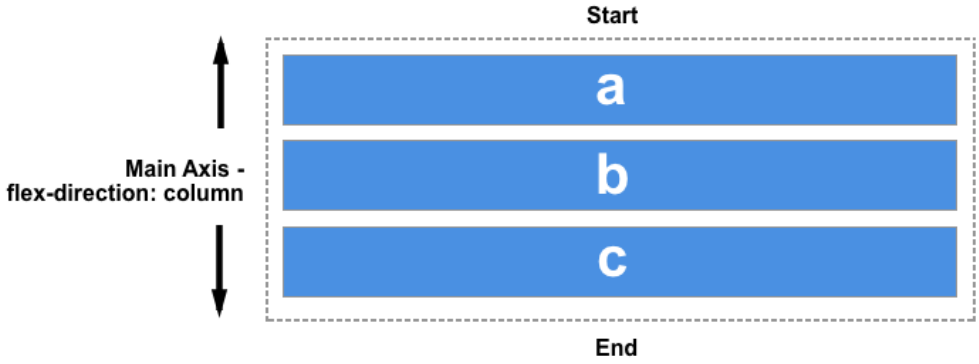
```
<div class="box">
  <div>One</div>
  <div>Two</div>
  <div>Three</div>
  <div>Four</div>
</div>
```

```
.box {
  display: flex;
  flex-direction: row-reverse;
  justify-content: flex-end;
  border: 2px dotted rgb(96 139 168);
}

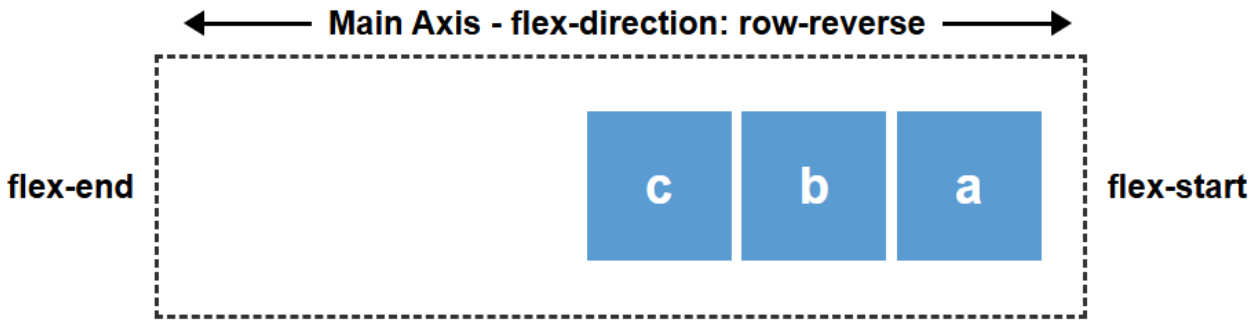
.box > * {
  padding: 20px;
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
  background-color: rgb(96 139 168 / 0.2);
}
```

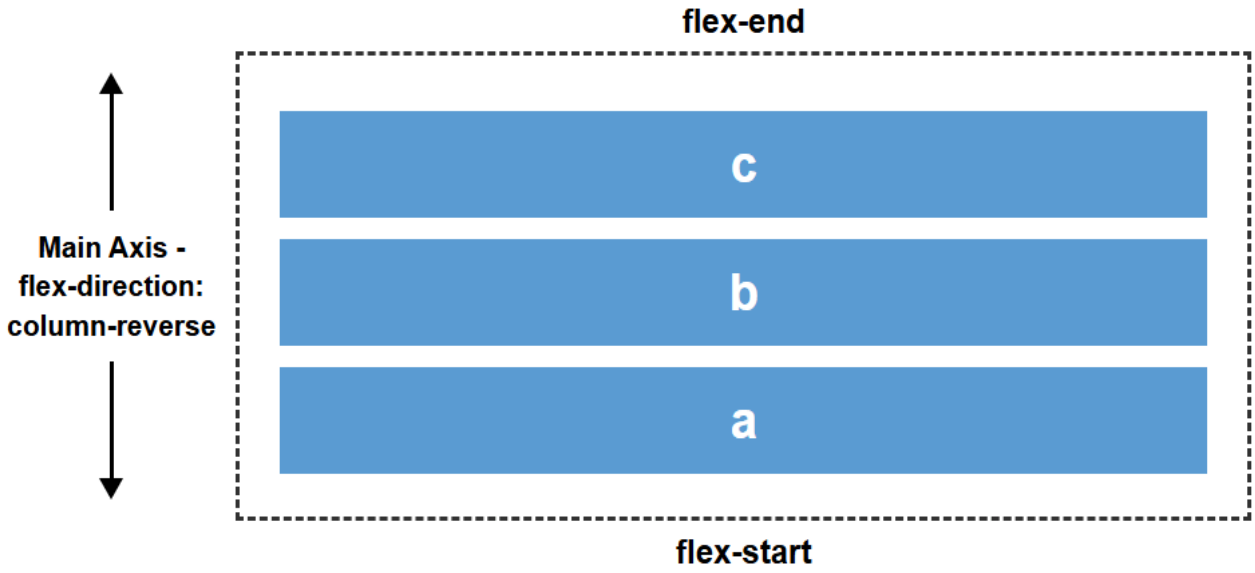
While this may all seem a little confusing, the rule to remember is that unless you do something to change it, flex items lay themselves out in the direction that words are laid out in the language of your document along the inline, row axis. `flex-start` will be where the beginning of a sentence of text would start.

You can switch them to display in the block direction for the language of your document by selecting `flex-direction: column`. Then, `start` and `flex-start` will be where the top of your first paragraph of text would start.



If you change `flex-direction` to one of the reverse values, they will lay themselves out from the end axis and in the reverse order to the way words are written in the language of your document. Then, `flex-start` will change to the end of that axis — so to the location where your lines would wrap if working in rows, or at the end of your last paragraph of text in the block direction.





Using auto margins for main axis alignment

We don't have a `justify-items` or `justify-self` property available to us on the main axis as our items are treated as a group on that axis. However it is possible to do some individual alignment in order to separate an item or a group of items from others by using auto margins along with flexbox.

A common pattern is a navigation bar where some key items are aligned to the right, with the main group on the left. You might think that this should be a use case for a `justify-self` property. However, consider the image below. As an example, take the following image with three items on one side and two on the other. If `justify-self` were to work on flex items and was set on item *d*, it would also change the alignment of item *e* that follows, which may or may not be what is intended.

Instead, the *d* item can be pushed over using CSS margins.

In this live example, item 4 is separated from the first three items by setting `margin-left` to `auto`, which consumes all the space it can in its axis. This is how centering a block with `margin` auto left and right works. Each side tries to take as much space as it can, and so the block is pushed into the middle.

In this live example, the flex items are arranged in a row with the basic flex values, and the class `push`, set on the fourth item, applies `margin-left: auto` to that item. Try removing the class on the fourth item or adding the class to a different item to see how it works.

```
<div class="box">
  <div>One</div>
  <div>Two</div>
  <div>Three</div>
  <div class="push">Four</div>
  <div>Five</div>
</div>
```

```
.box {
  display: flex;
  border: 2px dotted rgb(96 139 168);
}

.box > * {
  padding: 20px;
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
  background-color: rgb(96 139 168 / 0.2);
}
.push {
  margin-left: auto;
}
```

Creating gaps between items

To create a gap between flex items, use the `gap`, `column-gap`, and `row-gap` properties. The `column-gap` property creates gaps between items in a row. The `row-gap` property creates gaps between flex lines when you have `flex-wrap` set to `wrap`.

The `gap` property is a shorthand that sets both `row-gap` and `column-gap`. The gaps between flex items or flex lines depend on the direction. If the `flex-direction` property creates rows, the first value defines the gap between flex lines, and the second value defines the gap between items within each line. With columns (when `flex-direction` is set to `column` or `column-reverse`), the first value defines the gap between flex items, and the second value defines the gaps between flex lines.

```
<div class="box">
  <div>One</div>
  <div>Two</div>
  <div>Three</div>
  <div>Four</div>
  <div>Five</div>
  <div>Six</div>
</div>
```

```
.box {
  display: flex;
  flex-wrap: wrap;
  row-gap: 10px;
  column-gap: 2em;
  border: 2px dotted rgb(96 139 168);
}

.box > * {
  flex: 1;
  padding: 20px;
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
  background-color: rgb(96 139 168 / 0.2);
}
```

Basic concepts of flexbox

The flexible box layout module (usually referred to as flexbox) is a one-dimensional layout model for distributing space between items and includes numerous alignment capabilities. This article gives an outline of the main features of flexbox, which we will explore in more detail in the rest of these guides.

When we describe flexbox as being one-dimensional we are describing the fact that flexbox deals with layout in one dimension at a time — either as a row or as a column. This can be contrasted with the two-dimensional model of CSS Grid Layout, which controls columns and rows together.

The two axes of flexbox

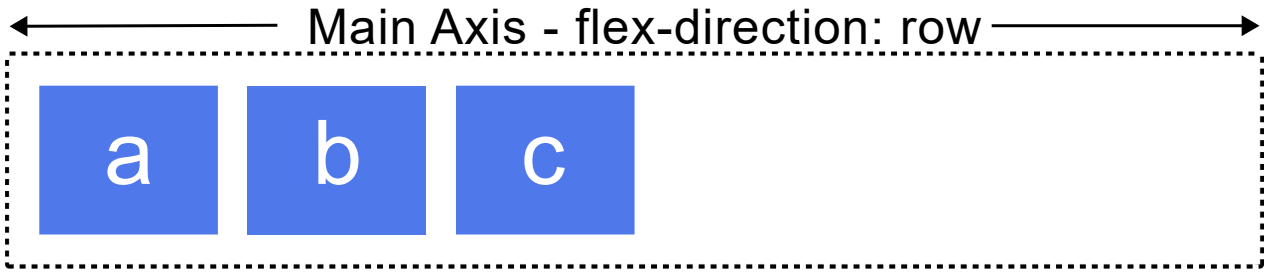
When working with flexbox you need to think in terms of two axes — the *main axis* and the *cross axis*. The main axis is defined by the `flex-direction` property, and the cross axis runs perpendicular to it. Everything we do with flexbox refers back to these axes, so it is worth understanding how they work from the outset.

The main axis

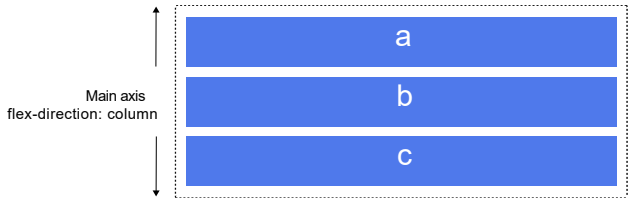
The main axis is defined by `flex-direction`, which has four possible values:

- `row`
- `row-reverse`
- `column`
- `column-reverse`

Should you choose `row` or `row-reverse`, your main axis will run along the row in the **inline direction**.



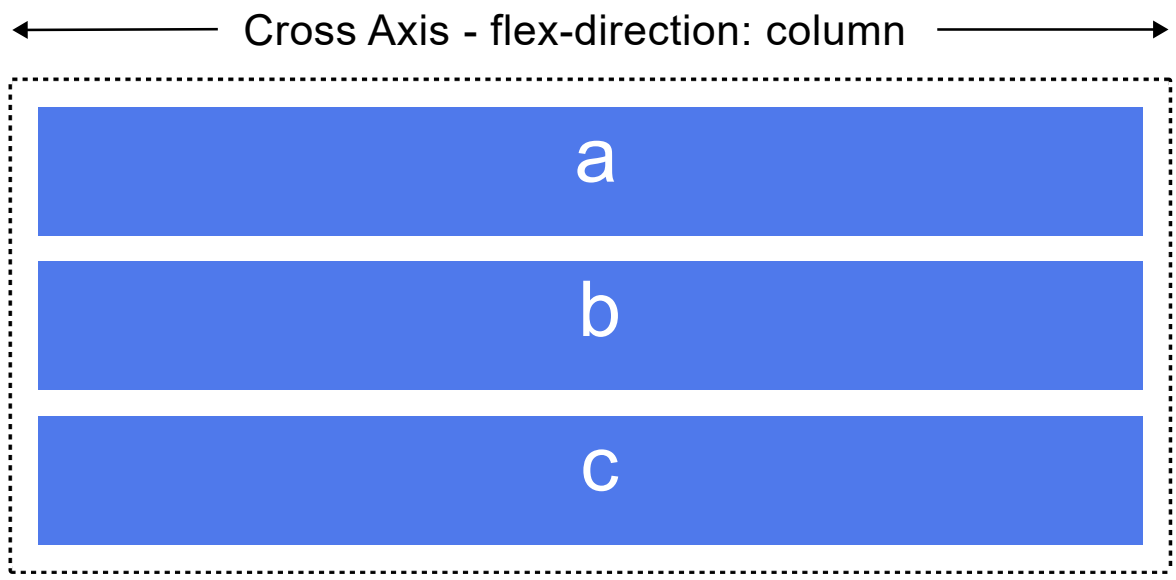
Choose `column` or `column-reverse` and your main axis will run in the **block direction**, from the top of the page to the bottom.



The cross axis

The cross axis runs perpendicular to the main axis. Therefore, if your `flex-direction` (main axis) is set to `row` or `row-reverse` the cross axis runs down the columns.

If your main axis is `column` or `column-reverse` then the cross axis runs along the rows.

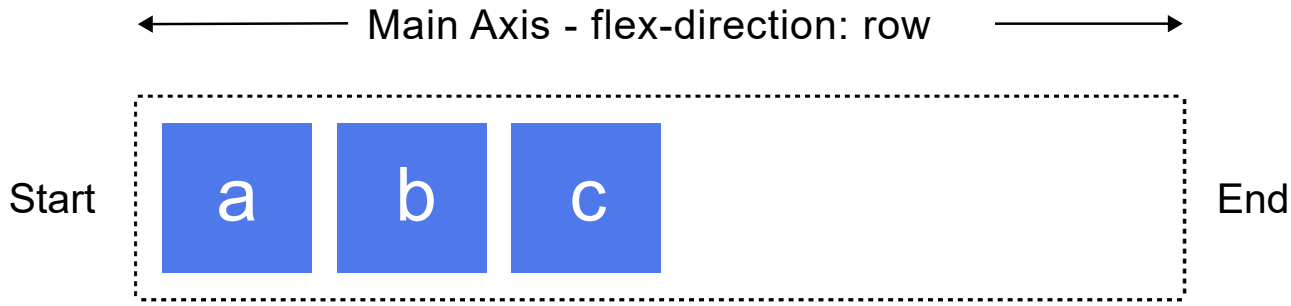


Start and end lines

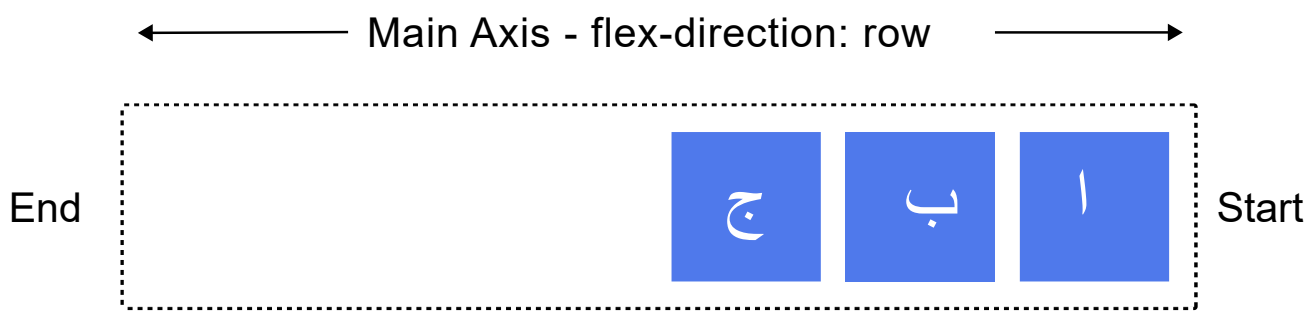
Another vital area of understanding is how flexbox makes no assumption about the writing mode of the document. Flexbox doesn't just assume that all lines of text start at the top left of a document and run towards the right-hand side, with new lines appearing one under the other. Rather, it supports all writing modes, like other logical properties and values.

You can read more about the relationship between flexbox and writing modes in a later article; however, the following description should help explain why we do not talk about left and right and top and bottom when we describe the direction that our flex items flow in.

If the `flex-direction` is `row` and I am working in English, then the start edge of the main axis will be on the left, the end edge on the right.



If I were to work in Arabic, then the start edge of my main axis would be on the right and the end edge on the left.



In both cases the start edge of the cross-axis is at the top of the flex container and the end edge at the bottom, as both languages have a horizontal writing mode.

After a while, thinking about start and end rather than left and right becomes natural, and will be useful to you when dealing with other layout methods such as CSS Grid Layout which follow the same patterns.

The flex container

An area of a document that is laid out using flexbox is called a **flex container**. To create a flex container, set the area's `display` property to `flex`. When we do this, the direct children of that container become **flex items**. You can explicitly control whether the container itself is displayed inline or in block formatting context using `inline flex` or `inline-flex` for inline flex containers or `block flex` or `flex` for block level flex containers.

Initial values

As with all properties in CSS, some initial values are defined, so the contents of a new flex container will behave in the following way:

- Items display in a row (the `flex-direction` property's default value is `row`).
- The items start from the start edge of the main axis.
- The items do not stretch on the main dimension but can shrink (a flex-item's `flex-grow` property's default value is `0` and its `flex-shrink` property's default value is `1`).
- The items will stretch to fill the size of the cross-axis (the `align-items` property's default value is `stretch`).
- The flex-item's `flex-basis` property's default value is `auto`. This means that, in each case, it will be equal to the flex item `width` in horizontal writing mode, and the flex item `height` in vertical writing mode. If the corresponding `width`/`height` is also set to `auto`, the `flex-basis` `content` value is used instead.
- All the items will be in a single row (the `flex-wrap` property's default value is `nowrap`), overflowing their container if their combined `width`/`height` exceeds the containing element `width`/`height`.

The result of this is that your items will all line up in a row, using the size of the content as their size in the main axis. If there are more items than can fit in the container, they will not wrap but will instead overflow. If some items are taller than others, all items will stretch along the full length of the cross-axis.

You can see in the live sample below how this looks. Click "Play" to open the example in the MDN Playground and edit the items or add new items to try out the initial behavior of flexbox:

```
<div class="box">
  <div>One</div>
  <div>Two</div>
  <div>Three <br />has <br />extra <br />text</div>
</div>
```

```
.box > * {
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
  background-color: rgb(96 139 168 / 0.2);
}

.box {
  border: 2px dotted rgb(96 139 168);
  display: flex;
}
```

Changing flex-direction

Adding the `flex-direction` property to the flex container allows us to change the direction in which our flex items display. Setting `flex-direction: row-reverse` will keep the items displaying along the row, however the start and end lines are switched.

If we change `flex-direction` to `column` the main axis switches and our items now display in a column. Set `column-reverse` and the start and end lines are again switched.

The live sample below has `flex-direction` set to `row-reverse`. Try the other values — `row`, `column` and `column-reverse` — to see what happens to the content.

```
<div class="box">
  <div>One</div>
  <div>Two</div>
  <div>Three</div>
</div>
```

```
.box > * {
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
  background-color: rgb(96 139 168 / 0.2);
}

.box {
```

```
  border: 2px dotted rgb(96 139 168);
  display: flex;
  flex-direction: row-reverse;
}
```

Multi-line flex containers with flex-wrap

While flexbox is a one dimensional model, it is possible to make flex items wrap across multiple lines. If you do this, you should consider each line as a new flex container. Any space distribution will happen across each line, without reference to the previous or subsequent lines.

To cause wrapping behavior add the property `flex-wrap` with a value of `wrap`. Now, if your items are too large to all display in one line, they will wrap onto another line. The live sample below contains items that have been given a `width`. The total width of the items is too wide for the flex container. As `flex-wrap` is set to `wrap`, the items wrap across multiple lines. If you set it to `nowrap`, which is the initial value, they will shrink to fit the container. They shrink because they are using initial flexbox values, including `flex-shrink: 1`, that allows items to shrink. Using `nowrap` would cause an overflow if the items were not able to shrink, or could not shrink small enough to fit.

```
<div class="box">
  <div>One</div>
  <div>Two</div>
  <div>Three</div>
</div>
```

```
.box > * {
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
  background-color: rgb(96 139 168 / 0.2);
  width: 200px;
}

.box {
  width: 500px;
  border: 2px dotted rgb(96 139 168);
  display: flex;
  flex-wrap: wrap;
}
```

Find out more about wrapping flex items in the guide Mastering wrapping of flex items.

The flex-flow shorthand

You can combine the two properties `flex-direction` and `flex-wrap` into the `flex-flow` shorthand.

In the live sample below, try changing the first value to one of the allowable values for `flex-direction` - `row`, `row-reverse`, `column` or `column-reverse`, and also change the second to `wrap` and `nowrap`.

```
<div class="box">
  <div>One</div>
  <div>Two</div>
  <div>Three</div>
</div>
```

```
.box > * {
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
  background-color: rgb(96 139 168 / 0.2);
  width: 200px;
}

.box {
  width: 500px;
  border: 2px dotted rgb(96 139 168);
  display: flex;
  flex-flow: row wrap;
}
```

Properties applied to flex items

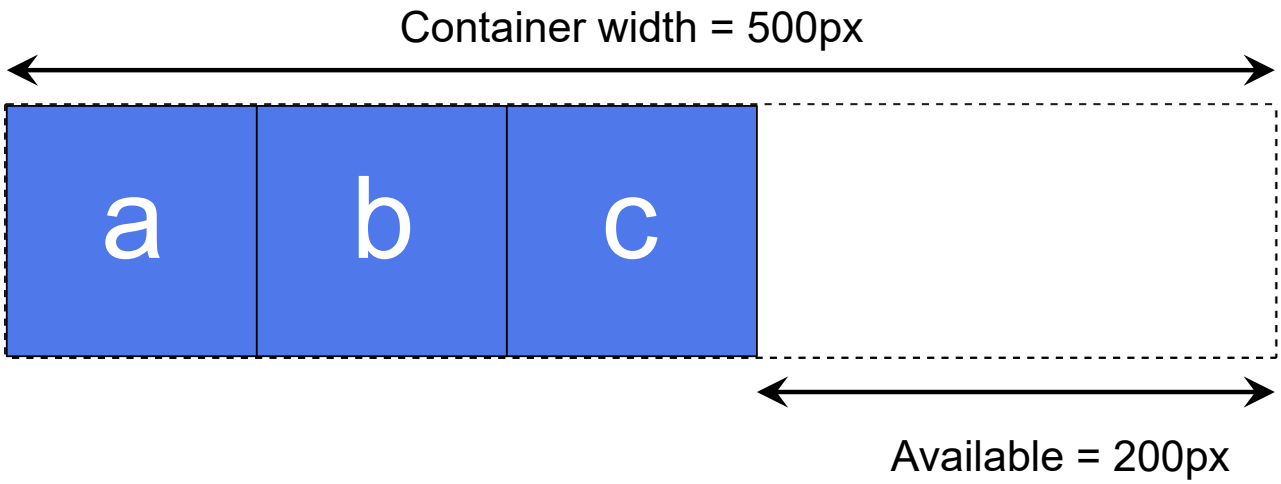
To control the inline-size of each flex item, we target them directly via three properties:

- `flex-grow`
- `flex-shrink`
- `flex-basis`

We will take a brief look at these properties below, but if you want more comprehensive information, take a look at the Controlling ratios of flex items on the main axis guide.

Before we can make sense of these properties we need to consider the concept of **available space**. What we are doing when we change the value of these flex properties is to change the way that available space is distributed among our items. This concept of available space is also important when we come to look at aligning items.

If we have three 100 pixel-wide items in a container which is 500 pixels wide, then the space we need to lay out our items is 300 pixels. This leaves 200 pixels of available space. If we don't change the initial values then flexbox will put that space after the last item.



If we instead would like the items to grow and fill the space, then we need to have a method of distributing the leftover space between the items. The `flex` properties that we apply to the items themselves, enable dictating how that available space should be distributed among the sibling flex items.

The flex-basis property

The `flex-basis` is what defines the size of that item in terms of the space it leaves as available space. The initial value of this property is `auto` — in this case the browser looks to see if the item has a size. In the example above, all of the items have a width of 100 pixels. This is used as the `flex-basis`.

If the items don't have a size then the content's size is used as the flex-basis. This is why when we just declare `display: flex` on the parent to create flex items, the items all move into a row and take only as much space as they need to display their contents.

The flex-grow property

With the `flex-grow` property set to a positive integer, if there is available space, the flex item can grow along the main axis from its `flex-basis`. Whether the item stretches to take up all the available space on that axis, or just a portion of the available space depends on if the other items are allowed to grow too and the value of their `flex-grow` properties.

Each item with a positive value consumes a portion of any available space based on their `flex-grow` value. If we gave all of our items in the example above a `flex-grow` value of 1 then the available space in the flex container would be equally shared between our items and they would stretch to fill the container on the main axis. If we give our first item a `flex-grow` value of 2, and the other items a value of 1 each, there are a total of 4 parts; 2 parts of the available space will be given to the first item (100px out of 200px in the case of the example above) and 1 part each the other two (50px each out of the 200px total).

The flex-shrink property

Where the `flex-grow` property deals with adding space in the main axis, the `flex-shrink` property controls how it is taken away. If we do not have enough space in the container to lay out our items, and `flex-shrink` is set to a positive integer, then the item can become smaller than the `flex-basis`. As with `flex-grow`, different values can be assigned in order to cause one item to shrink faster than others — an item with a higher value set for `flex-shrink` will shrink faster than its siblings that have lower values.

An item can shrink down to its `min-content` size. This minimum size is taken into account while working out the actual amount of shrinkage that will happen, which means that `flex-shrink` has the potential to appear less consistent than `flex-grow` in behavior. We'll therefore take a more detailed look at how this algorithm works in the article Controlling ratios of items along the main axis.

> **Note:** These values for `flex-grow` and `flex-shrink` are proportions. Typically if we had all of our items set to `flex: 1 1 200px` and then wanted one item to grow at twice the rate, we would set that item to `flex: 2 1 200px`. However you could also use `flex: 10 1 200px` and `flex: 20 1 200px` if you wanted.

Shorthand values for the flex properties

You will very rarely see the `flex-grow`, `flex-shrink`, and `flex-basis` properties used individually; instead they are combined into the `flex` shorthand. The `flex` shorthand allows you to set the three values in this order — `flex-grow`, `flex-shrink`, `flex-basis`.

The live sample below allows you to test out the different values of the flex shorthand; remember that the first value is `flex-grow`. Giving this a positive value means the item can grow. The second is `flex-shrink` — with a positive value the items can shrink, but only if their total values overflow the main axis. The final value is `flex-basis`; this is the value the items are using as their base value to grow and shrink from.

```
<div class="box">
  <div class="one">One</div>
  <div class="two">Two</div>
  <div class="three">Three</div>
</div>
```

```
.box > * {
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
  background-color: rgb(96 139 168 / 0.2);
}

.box {
  border: 2px dotted rgb(96 139 168);
  display: flex;
}

.one {
  flex: 1 1 auto;
}

.two {
  flex: 1 1 auto;
}
```

```
.three {
  flex: 1 1 auto;
}
```

There are also some predefined shorthand values which cover most of the use cases. You will often see these used in tutorials, and in many cases these are all you will need to use. The predefined values are as follows:

- `flex: initial`
- `flex: auto`
- `flex: none`
- `flex: <positive-number>`

The `initial` value is a CSS-wide keyword that represents the initial value for a property. Setting `flex: initial` resets the item to the initial values of the three longhand properties, which is the same as `flex: 0 1 auto`. The initial value of `flex-grow` is `0`, so items will not grow larger than their `flex-basis` size. The initial value of `flex-shrink` is `1`, so items can shrink if they need to rather than overflowing. The initial value of `flex-basis` is `auto`. Items will either use any size set on the item in the main dimension, or they will get their size from the content size.

Using `flex: auto` is the same as using `flex: 1 1 auto`; this is similar to `flex: initial`, except that the items can grow and fill the container as well as shrink if needed.

Using `flex: none` will create fully inflexible flex items. It is as if you wrote `flex: 0 0 auto`. The items cannot grow or shrink and will be laid out using flexbox with a `flex-basis` of `auto`.

The shorthand you often see in tutorials is `flex: 1` or `flex: 2` and so on. This is the same as writing `flex: 1 1 0` or `flex: 2 1 0` and so on, respectively. The items get minimum size due to `flex-basis: 0` and then proportionally grow to fill the available space. In this case, the `flex-shrink` value of `1` is redundant because the items start with minimum size — they're not given any size that could cause them to overflow the flex container.

Try these shorthand values in the live sample below.

```
<div class="box">
  <div class="one">One</div>
  <div class="two">Two</div>
  <div class="three">Three</div>
</div>
```

```
.box > * {
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
  background-color: rgb(96 139 168 / 0.2);
}

.box {
  border: 2px dotted rgb(96 139 168);
  display: flex;
}

.one {
  flex: 1;
}

.two {
  flex: 1;
}

.three {
  flex: 1;
}
```

Alignment, justification and distribution of free space between items

A key feature of flexbox is the ability to align and justify items on the main- and cross-axes, and to distribute space between flex items. Note that these properties are set on the flex container, not on the items themselves.

align-items

The `align-items` property aligns all the flex items on the cross axis.

The initial value for this property is `stretch` and is why flex items stretch to the height of the flex container by default (or the width if `flex-direction` is set to `column` or `column-reverse`). This height may come from the tallest item in the container or the size set on the flex container itself.

You could instead set `align-items` to `flex-start`, or simply `start`, in order to make the items line up at the start of the flex container, `flex-end`, or just `end`, to align them to the end, or `center` to align them in the center. Try this in the live sample — I have given the flex container a height in order that you can see how the items can be moved around inside the container. See what happens if you set the value of align-items to:

- `stretch`
- `flex-start`
- `flex-end`
- `start`
- `end`
- `center`
- `baseline`
- `last baseline`

```
<div class="box">
  <div>One</div>
  <div>Two</div>
  <div>Three <br />has <br />extra <br />text</div>
</div>
```

```
.box > * {
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
  background-color: rgb(96 139 168 / 0.2);
}

.box {
  width: 500px;
  height: 130px;
  border: 2px dotted rgb(96 139 168);
```

```
  display: flex;
  align-items: flex-start;
}
```

The `align-items` is set on the flex container and impacts all the flex items. If you want to align a flex item differently from others, you can set the `align-self` on the flex item.

justify-content

The `justify-content` property is used to align the items on the main axis, the direction in which `flex-direction` has set the flow. The initial value is `flex-start` which will line the items up at the start edge of the container, but you could also set the value to `flex-end` to line them up at the end, or `center` to line them up in the center.

You can also use the value `space-between` to take all the spare space after the items have been laid out, and share it out evenly between the items so there will be an equal amount of space between each item. To cause an equal amount of space on the right and left (or top and bottom for columns) of each item use the value `space-around`. With `space-around`, items have a half-size space on either end. Or, to cause items to have equal space around them use the value `space-evenly`. With `space-evenly`, items have a full-size space on either end.

Try the following values of `justify-content` in the live sample:

- `start`
- `end`
- `left`
- `right`
- `normal`
- `flex-start`
- `flex-end`
- `center`
- `space-around`
- `space-between`
- `space-evenly`
- `stretch`

```
<div class="box">
  <div>One</div>
  <div>Two</div>
  <div>Three</div>
</div>
```

```
.box > * {
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
  background-color: rgb(96 139 168 / 0.2);
}

.box {
  border: 2px dotted rgb(96 139 168);
  display: flex;
  justify-content: flex-start;
}
```

The article Aligning items in a flex container explores these properties in more depth, in order to have a better understanding of how they work. These basic examples, however, are useful in the majority of use cases.

justify-items

The `justify-items` property is ignored in flexbox layouts.

place-items and place-content

The `place-items` property is a shorthand property for `align-items` and `justify-items`. If set on a flex container, it will set the alignment but not the justification, as `justify-items` is ignored in flexbox.

There is another shorthand property, `place-content`, that defines the `align-content` and `justify-content` properties. The `align-content` property only affects flex containers that wrap, and is discussed in Aligning items in a flex container.

Next steps

After reading this article you should have an understanding of the basic features of flexbox. In the next article, we will look at how this specification relates to other parts of CSS.

Controlling ratios of flex items along the main axis

In this guide, we explore the three properties that control the size and flexibility of flex items along the main axis: `flex-grow`, `flex-shrink`, and `flex-basis`. Fully understanding how these properties work with growing and shrinking items is the key to mastering CSS flexible box layout.

A first look

Our three properties control the following aspects of a flex item's flexibility:

- `flex-grow`: How much of the positive free space does this item get?
- `flex-shrink`: How much negative free space can be removed from this item?
- `flex-basis`: What is the size of the item before growing and shrinking happens?

The properties are usually expressed using the shorthand `flex` property. The following code would set the `flex-grow` property to `2`, `flex-shrink` to `1` and `flex-basis` to `auto`.

```
.item {
  flex: 2 1 auto;
}
```

Important concepts when working on the main axis

To understand the `flex` properties, it is helpful to know the *natural size* of flex items before any growing or shrinking takes place. Additionally, it is important to understand the concept of *free space*, which is the difference between the combined natural size of all the flex items along the main axis and the size of the main axis itself.

Flex item sizing

To determine how much space is available to lay out flex items, the browser needs to know how big the item is to start with. How is this calculated for items that don't have a width or a height applied using an absolute length unit?

In CSS, the `min-content` and `max-content` keywords can be used in place of a `<length>` unit. Generally, `min-content` is the smallest size an element can be while still fitting the longest word, and `max-content` is the size the element would need to be to fit all the content without wrapping.

The example below contains two paragraph elements with different strings of text. The first paragraph has a width of `min-content`. Notice that the text has used all of the soft wrapping opportunities available to it, becoming as small as possible without overflowing. This is the `min-content` size of that string. Essentially, the longest word in the string is dictating the size.

The second paragraph, with a value of `max-content`, does the opposite. It grows as large as it needs to be to fit the content without taking soft-wrapping opportunities. It will overflow the box it is in if that container is too narrow.

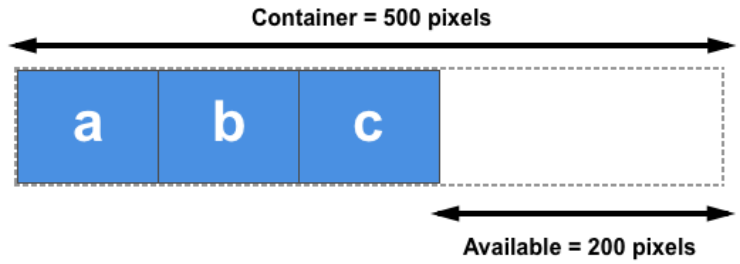
```
<p class="min-content">
  I am sized with min-content and so I will take all of the soft-wrapping
  opportunities.
</p>
<p class="max-content">
  I am sized with max-content and so I will take none of the soft-wrapping
  opportunities.
</p>
```

```
.min-content {
  width: min-content;
  border: 2px dotted rgb(96 139 168);
}
.max-content {
  width: max-content;
  border: 2px dotted rgb(96 139 168);
}
```

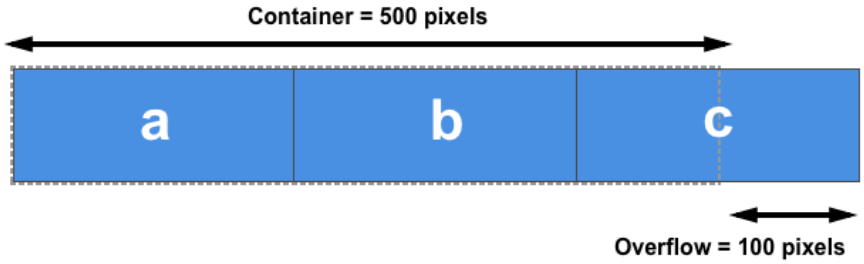
Remember this behavior and what effects `min-content` and `max-content` have as we explore `flex-grow` and `flex-shrink` later in this article.

Positive and negative free space

We also need to understand the concept of **positive and negative free space**. When a flex container has *positive free space*, it has more space than required to display the flex items inside the container. For example, a `500px`-wide container, with `flex-direction` set to `row` and containing three `100px`-wide flex items has `200px` of positive free space. This positive free space can be distributed between the items if filling the container is desired.



A flex container has *negative free space* when the combined value of the natural sizes of the flex items is larger than the available space in the flex container. If the three flex items in the `500px`-wide container example above are each `200px` wide instead of `100px`, their combined natural width is `600px`, resulting in `100px` of negative free space. This space can be removed from the items to make them fit the container, or the items will overflow.



We need to understand this distribution of positive free space and removal of negative free space to learn about the property components of the `flex` shorthand.

In the following examples, the `flex-direction` is set to `row`, so the size of items will be determined by their width. We will be calculating the positive and negative free space by comparing the total width of all the items with the container's width. You could also try out each example with `flex-direction: column`. The main axis would then be the column, and you would then compare the height of the items and their container to calculate the positive and negative free space.

The <code>flex-basis</code> property

The `flex-basis` property specifies the initial size of a flex item before any distribution of the positive or negative free space happens. The initial value for this property is `auto`. This property accepts the same values as the `width` and `height` properties, and it also accepts the `content` keyword.

If `flex-basis` is set to `auto`, the initial size of the item is the `<length-percentage>` size of the main size, if any was set. For example, if the item has `width: 200px` set, then `200px` would be the `flex-basis` for this item. Percentage values are relative to the flex container's inner main size. If `width: 50%` were set, the `flex-basis` for this item would be half of the container's content-box width. If no such size is set, meaning the item is auto-sized, then `auto` resolves to the size of its content (see the `min-` and `max-content` sizing discussion above), meaning the `flex-basis` is the item's `max-content` size.

This example contains three inflexible flex items, with both `flex-grow` and `flex-shrink` set to `0`. The first item, which has an explicit width of `150px`, takes a `flex-basis` of `150px`, whereas the other two items have no width set and so are sized according to their content width or `max-content`.

```
<div class="box">
  <div>One</div>
  <div>Two</div>
  <div>Three</div>
</div>
```

```
.box > * {
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
  background-color: rgb(96 139 168 / 0.2);
  flex: 0 0 auto;
```

```
}

.box {
  width: 500px;
  border: 2px dotted rgb(96 139 168);
  display: flex;
}

.box :first-child {
  width: 150px;
}
```

In addition to the `auto` keyword and any other valid `width` value, you can use the `content` keyword as the `flex-basis`. This results in the `flex-basis` being based on the content size, even if there is a `width` set on the item. This creates the same effect as removing any width set and using `auto` as the `flex-basis`. While similar to setting `max-content`, the `content` value enables any `aspect-ratio` to be calculated based on the cross-axis size.

To completely ignore the size of the flex item during space distribution, set `flex-basis` to `0` and set a non-zero `flex-grow` value. Let's learn `flex-grow` before looking at this value in action.

The <code>flex-grow</code> property

The `flex-grow` property specifies the **flex grow factor**, which determines how much a flex item will grow relative to the other flex items in the flex container when positive free space is distributed.

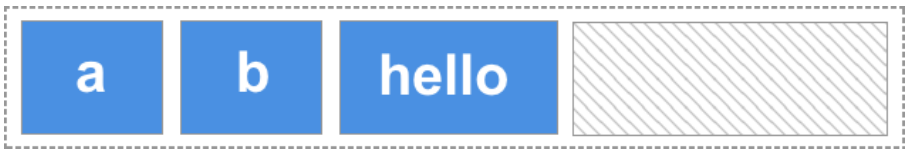
If all items have the same `flex-grow` factor, the positive free space will be distributed evenly among them. For this scenario, common practice is to set `flex-grow: 1`, but you could give them any value, such as `88`, `100`, or `1.2`; it is a ratio. If the factor is the same for all the flex items in the container and there is positive free space, that space will be distributed equally.

Combining <code>flex-grow</code> and <code>flex-basis</code>

Things can get confusing in terms of how `flex-grow` and `flex-basis` interact. Let's consider the case of three flex items of differing content lengths and the following `flex` rules applied to them:

```
.class {
  flex: 1 1 auto;
}
```

In this case, the `flex-basis` value is `auto` and the items don't have a width set, so they are auto-sized. This means the `flex-basis` used is the `max-content` size of each item. After laying out the items, there is some positive free space in the flex container, which is shown in the image below as the hatched area; the hatched area is the positive free space that will be distributed between the three items based on their `flex-grow` factors:



We are working with a `flex-basis` equal to the content size. This means the available space to distribute is subtracted from the total available space (the width of the flex container), and the remaining space is then shared equally between the three items. The biggest item remains the largest because it started from a bigger size, even though it has the same amount of spare space as the others:

To create three equally-sized items, even if the original elements have different sizes, set the `flex-basis` component to `0`:

```
.class {
  flex: 1 1 0;
}
```

Here, for the purpose of space distribution calculation, we are setting the size of each item to `0`. This means all the space is available for distribution. Since all the items have the same `flex-grow` factor, they each get an equal amount of space. This results in three equal-width flex items.

Try changing the `flex-grow` factor from 1 to 0 in this live example to see the different behavior:

```
<div class="box">
  <div>One</div>
  <div>Two</div>
  <div>Three has more content</div>
</div>
```

```
.box > * {
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
  background-color: rgb(96 139 168 / 0.2);
  flex: 1 1 0;
}

.box {
  width: 400px;
  border: 2px dotted rgb(96 139 168);
  display: flex;
}
```

Giving items different flex-grow factors

Using `flex-grow` and `flex-basis` together enables us to control individual item sizes by setting different `flex-grow` factors. If we keep the `flex-basis` at `0` so that all the space can be distributed, we can create differently sized flex items by assigning each item a different `flex-grow` factor.

In the example below, we use `1` as the `flex-grow` factor for the first two items and double it to `2` for the third item. With `flex-basis: 0` set on all the items, the available space is distributed as follows:

1. The `flex-grow` factor values of all the sibling flex items are added together (the total is 4 in this case).
2. The positive free space in the flex container is divided by this total value.
3. The free space is distributed according to the individual values. In this case, the first item gets one part, the second one part, and the third two parts. This means that the third item is twice the size of the first and second items.

```
<div class="box">
  <div class="one">One</div>
  <div class="two">Two</div>
  <div class="three">Three</div>
</div>
```

```
.box > * {
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
  background-color: rgb(96 139 168 / 0.2);
  flex: 1 1 0;
}

.box {
  border: 2px dotted rgb(96 139 168);
  display: flex;
}

.one {
  flex: 1 1 0;
}

.two {
  flex: 1 1 0;
}

.three {
  flex: 2 1 0;
}
```

Remember that you can use any positive value here. It is the ratio between the items that matters. You can use large numbers or decimals; it's up to you. To test this, change the `flex-grow` values in the above example to `.25`, `.25`, and `.50`. You should see the same result.

The <code>flex-shrink</code> property

The `flex-shrink` property specifies the **flex shrink factor**, which determines how much the flex item will shrink relative to the rest of the flex items in the flex container when negative free space is distributed.

This property deals with situations where the combined `flex-basis` value of the flex items is too large to fit in the flex container and would otherwise overflow. As long as an item's `flex-shrink` is a positive value, the item will shrink to not overflow the container.

While `flex-grow` is used to add available space to items that can grow, `flex-shrink` is used to remove space to ensure items fit in their container without overflowing.

In this example, there are three `200px`-wide flex items in a `500px`-wide container. With `flex-shrink` set to `0`, the items are not allowed to shrink, causing them to overflow the container.

```
<div class="box">
  <div>One</div>
  <div>Two</div>
  <div>Three has more content</div>
</div>
```

```
.box > * {
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
  background-color: rgb(96 139 168 / 0.2);
  flex: 0 0 auto;
  width: 200px;
}

.box {
  width: 500px;
  border: 2px dotted rgb(96 139 168);
  display: flex;
}
```

Change the `flex-shrink` value to `1`; each item will shrink by the same amount, fitting all the items into the container. The negative free space has been proportionally removed from each item, making each flex item smaller than its initial width.

Combining <code>flex-shrink</code> and <code>flex-basis</code>

It may appear that `flex-shrink` works in the same way as `flex-grow`, by shrinking rather than growing elements. However, there are some important differences to note.

The concept of flex base size affects how negative space is distributed across flex items. The flex shrink factor is multiplied by the flex base size when distributing negative space. This distributes negative space in proportion to how much the item is able to shrink. So, for example, a small item won't shrink to zero before a larger item has been noticeably reduced.

Small items will not shrink to less than their `min-content` size, which is the smallest size the element can be if it used all the available soft wrapping opportunities.

This example demonstrates `min-content` flooring, with the `flex-basis` resolving to the size of the content. If you change the width on the flex container, such as increasing it to `700px`, and then reduce the flex item width, you can see that the first two items will wrap. However, they will never become smaller than their `min-content` size. When the container gets small, the space is only removed from the third item when shrunken further.

```
<div class="box">
  <div>Item One</div>
  <div>Item Two</div>
  <div>Item Three has more content and so has a larger size</div>
</div>
```

```
.box > * {
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
  background-color: rgb(96 139 168 / 0.2);
  flex: 1 1 auto;
}

.box {
  border: 2px dotted rgb(96 139 168);
  width: 500px;
  display: flex;
}
```

In practice, this shrinking behavior provides reasonable results. It prevents content from disappearing completely and from becoming smaller than its minimum content size. The above rules are sensible for content that needs to shrink to fit its container.

Giving items different <code>flex-shrink</code> factors

In the same way as `flex-grow`, you can give flex items different `flex-shrink` factors. This can help change the default behavior if, for example, you want an item to shrink more or less rapidly than its siblings or to not shrink at all.

In this example, the first item has a `flex-shrink` factor of `1`, the second item `0` (so it won't shrink at all), and the third item `4`, making a total of `5` shrink factors. The third item, therefore, shrinks approximately four times more rapidly than the first, but neither will shrink below their `min-content` width. Play around with the different values: as with `flex-grow`, you can use decimals or larger numbers here as well.

```
<div class="box">
  <div class="one">One</div>
  <div class="two">Two</div>
  <div class="three">Three</div>
</div>
```

```
.box > * {
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
  background-color: rgb(96 139 168 / 0.2);
  width: 200px;
}

.box {
  display: flex;
  width: 500px;
  border: 2px dotted rgb(96 139 168);
}

.one {
  flex: 1 1 auto;
}

.two {
  flex: 1 0 auto;
}

.three {
  flex: 2 4 auto;
}
```

Mastering sizing of flex items

To understand how flex item sizing works, you need to consider the factors below, which we've discussed in these guides:

What determines the base size of an item?

- Is `flex-basis` set to `auto`, and does the item have a width set? If so, the size will be based on that width.
- Is `flex-basis` set to `auto`, but the item doesn't have a width set? If so, the size will be based on the item's content size.
- Is `flex-basis` a length or a percentage, but not zero? If so, this will be the size of the item (floored at `min-content`).
- Is `flex-basis` set to `0`? If so, the item's size will not be taken into consideration for the space-sharing calculation.

Is there available space?

Items can grow only if there is positive free space, and they won't shrink unless there is negative free space.

- If we add up the widths of all the items (or heights if working in a column), is that total **less** than the total width (or height) of the container? If so, there will be positive free space, and `flex-grow` will come into play.
- If we add up the widths of all the items (or heights if working in a column), is that total **more** than the total width (or height) of the container? If so, there will be negative free space, and `flex-shrink` will come into play.

What are the other ways to distribute space?

If you do not want space added to the items, remember that you can manage free space between or around items using the alignment properties described in the guide for aligning items in a flex container. The `justify-content` property will enable the distribution of free space between or around items. You can also use auto margins on flex items to absorb space and create gaps between items.

With all these flex properties available to you, you will find that most layout tasks are possible, although it might take a little bit of experimentation at first.

Ordering flex items

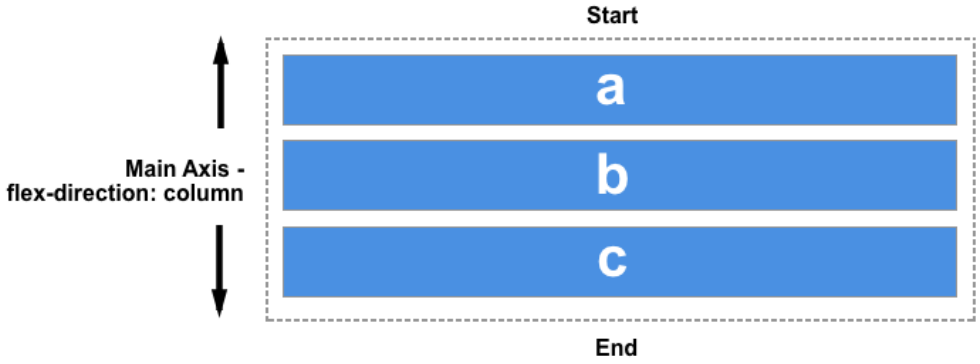
Layout methods such as flexbox and grid enable controlling the order of content. In this article, we will take a look at ways in which you can change the visual order of your content when using flexbox. We will also consider how reordering items impacts accessibility.

Reverse the display of the items

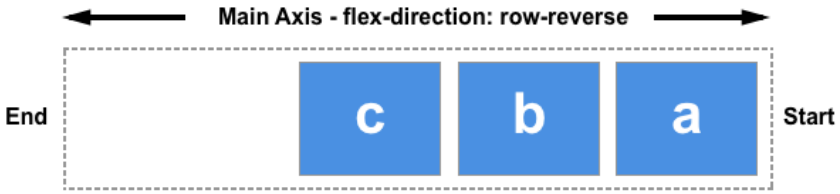
The `flex-direction` property can take one of four values:

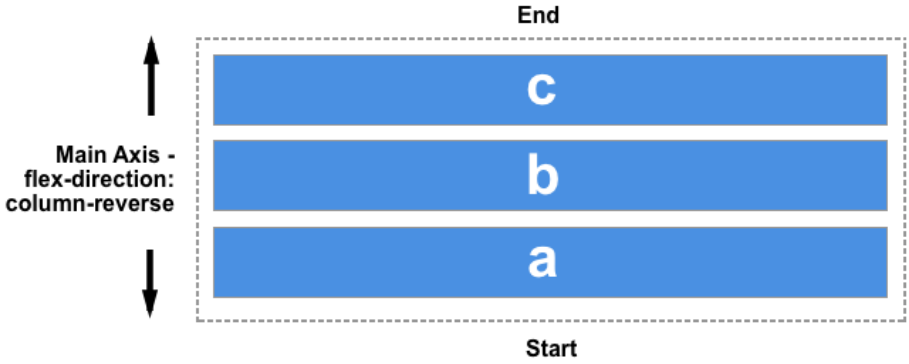
- `row`
- `column`
- `row-reverse`
- `column-reverse`

The first two values keep the items in the same order that they appear in the document source order and display them sequentially from the start line.

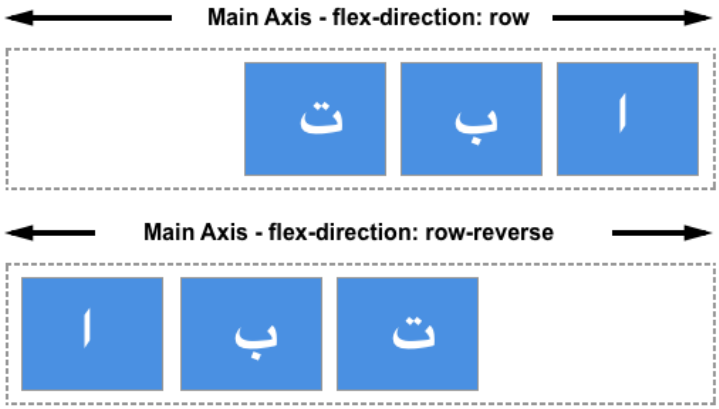


The second two values reverse the items by switching the start and end lines.





Remember that the start line relates to writing modes. The row-related examples above demonstrate how `row` and `row-reverse` work in a left-to-right language such as English. If you are working in a right-to-left language like Arabic then `row` would start on the right, `row-reverse` on the left.



This can seem like an easy way to display things in reverse order. However, you should be mindful that the items are only *visually* displayed in reverse order. The reordering capabilities of flex layout affect only the visual rendering. The tabbing order and speech order follow the order of the source code. This means that only the visual presentation changes; the source order remains the same, providing a different user experience for non-CSS UAs (think Siri or Alexa) and assistive technology users. If you change the order of a navigation bar, the tabbing order is still the document source order, not your visual order, which can be cognitively confusing.

If you are using a reverse value, or otherwise reordering your items, you should consider whether you should really be changing the logical order in the source.

The flexible box layout specification warns us not to use reordering as a way of fixing source issues:

> "Authors *must not* use order or the *-reverse values of `flex-flow`/`flex-direction` as a substitute for correct source ordering, as that can ruin the accessibility of the document."

As you tab from link to link in the live example below, the focus style is highlighted, demonstrating that changing the order of flex-items with `flex-direction` does not change the tabbing order, which will continue to follow the source code order.

```
<div class="box">
  <div><a href="#">One</a></div>
  <div><a href="#">Two</a></div>
  <div><a href="#">Three</a></div>
</div>
```

```
.box > * {
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
  background-color: rgb(96 139 168 / 0.2);
  padding: 10px;
}

.box > * a:focus {
  background-color: yellow;
  color: black;
}

.box {
  border: 2px dotted rgb(96 139 168);
  display: flex;
  flex-direction: row-reverse;
}
```

In the same way that changing the value of `flex-direction` does not change the tabbing order, changing this value does not change paint order. It is a visual reversal of the items only.

The order property

In addition to reversing the order in which flex items are visually displayed, you can target individual items and change where they appear in the visual order with the `order` property.

The `order` property is designed to lay the items out in *ordinal groups*. This means items are assigned an integer that represents their group. The items are then placed in the visual order according to that integer, lowest values first. If more than one item has the same integer value, then within that group the items are laid out as per source order.

As an example, five flex items are assigned `order` values as follows:

- Source item 1: `order: 2`
- Source item 2: `order: 3`
- Source item 3: `order: 1`
- Source item 4: `order: 3`
- Source item 5: `order: 1`

These items would be displayed on the page in the following order:

- Source item 3: `order: 1`
- Source item 5: `order: 1`
- Source item 1: `order: 2`
- Source item 2: `order: 3`
- Source item 4: `order: 3`

Play around with the values in this live example below and see how that changes the order. Also, try changing `flex-direction` to `row-reverse` and see what happens — the start line is switched so the ordering begins from the opposite side.

```
<div class="box">
  <div><a href="#">1</a></div>
  <div><a href="#">2</a></div>
  <div><a href="#">3</a></div>
  <div><a href="#">4</a></div>
  <div><a href="#">5</a></div>
</div>
```

```
.box > * {
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
  background-color: rgb(96 139 168 / 0.2);
  padding: 10px;
}

.box {
  border: 2px dotted rgb(96 139 168);
  display: flex;
  flex-direction: row;
}
.box :nth-child(1) {
  order: 2;
}
.box :nth-child(2) {
  order: 3;
}
.box :nth-child(3) {
  order: 1;
}
.box :nth-child(4) {
  order: 3;
}
.box :nth-child(5) {
  order: 1;
}
```

Flex items have a default `order` value of `0`. Therefore, items with an integer value greater than `0` will be displayed after any items that have not been given an explicit `order` value.

You can also use negative values with `order`, which can be quite useful. If you want to make one item display first and leave the order of all other items unchanged, you can give that item order of `-1`. As this is lower than `0`, the item will always be displayed first.

In the live code example below, the items are laid out using flexbox. By changing which item has the class `active` assigned to it in the HTML, you can change which item displays first and therefore becomes full width at the top of the layout, with the other items displaying below it.

```
<div class="box">
  <div><a href="#">1</a></div>
  <div><a href="#">2</a></div>
  <div class="active"><a href="#">3</a></div>
  <div><a href="#">4</a></div>
  <div><a href="#">5</a></div>
</div>
```

```
* {
  box-sizing: border-box;
}

.box > * {
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
  background-color: rgb(96 139 168 / 0.2);
  padding: 10px;
}

.box {
  width: 500px;
  border: 2px dotted rgb(96 139 168);
  display: flex;
  flex-wrap: wrap;
  flex-direction: row;
}

.active {
  order: -1;
  flex: 1 0 100%;
}
```

The items are displayed in *order-modified document order* meaning the value of the `order` property is taken into account before the items are displayed.

`Order` also changes the paint order of the items; items with a lower value for `order` are painted first and items with a higher value for `order` painted afterwards.

The order property and accessibility

Use of the `order` property has the same implications for accessibility as changing the direction with `flex-direction`. Using `order` changes the order in which items are painted, and the order in which they appear visually. It does not change the sequential navigation order of the items. Therefore, if a user is using a keyboard to tab through the content on the page, they could find themselves jumping around your content in a very confusing way.

By tabbing around any of the live examples on this page, you can see how `order` is potentially creating a strange experience for anyone not using a pointing device like a mouse. To read more about this disconnect of visual order and logical order and some of the potential problems it raises for accessibility, see the following resources.

- Flexbox and the keyboard navigation disconnect via tink.uk (2016)

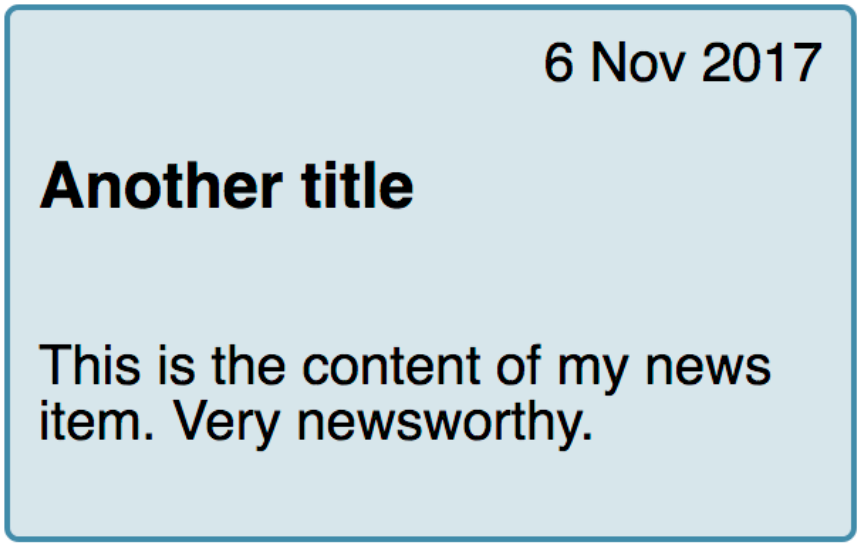
- The Responsive Order Conflict for Keyboard Focus via alastairc.uk (2017)

Use cases for <code>order</code>

There are some use cases for which the fact that the logical and therefore reading order of flex items is separate from the visual order, is helpful. Used carefully, the `order` property can allow for some useful common patterns to be easily implemented.

You might have a design, perhaps a card that will display a news item. The heading of the news item is the key thing to highlight and would be the element that a user might jump to if they were tabbing between headings to find the content they wanted to read. The card also has a date; the finished design we want to create is something like this.



Visually, the date appears above the heading, in the source. However, if the card was read out by a screen reader I would prefer that the title was announced first and then the publication date. We can accomplish this with the `order` property.

The card is our flex container, with `flex-direction` set to `column`. We give the date an `order` of `-1`, placing it above the heading.

```
<div class="wrapper">
  <div class="card">
    <h3>News item title</h3>
    <div class="date">1 Nov 2017</div>
    <p>This is the content of my news item. Very newsworthy.</p>
  </div>
  <div class="card">
    <h3>Another title</h3>
```

```
    <div class="date">6 Nov 2017</div>
    <p>This is the content of my news item. Very newsworthy.</p>
  </div>
</div>
```

```
body {
  font-family: sans-serif;
}

.wrapper {
  display: flex;
  flex: 1 1 200px;
  gap: 1em;
}

.card {
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
  background-color: rgb(96 139 168 / 0.2);
  padding: 1em;
  display: flex;
  flex-direction: column;
}

.date {
  order: -1;
  text-align: right;
}
```

These small tweaks are the sort of cases where the `order` property makes sense. Keep the logical order the same as the reading and tab order of the document, and maintain that in the most accessible and structured fashion. Then use `order` for purely visual design tweaks. Don't reorder items that receive keyboard focus. Ensure you always test your content using only a keyboard rather than a mouse or a touchscreen; this will reveal if your development choices make it more complex to navigate the content.

Relationship of flexbox to other layout methods

In this article, we will take a look at how flexbox fits in with all the other CSS modules. We'll find out which specifications you also need to take notice of if you want to learn flexbox, and find out why flexbox is different to some other modules.

The box alignment module

Many people first look at flexbox when they want to properly align flex items inside a flex container. Flexbox provides access to properties that allow the alignment of items on their cross axis and justification of items on the main axis.

Flexbox was originally defined in its own flexible box layout module, but the properties and values that are common to other layout methods are defined in the CSS box alignment module. This module details how alignment, justification, gaps, and gutters work in all layout systems — not just flexbox. When a feature is defined in both specifications, note that the box alignment module supersedes the flexible box layout module.

Writing Modes

In the Basic concepts of flexbox article, it is noted that flexbox is **writing mode aware**. Writing modes are fully detailed in the CSS writing modes module, which details how CSS supports the different writing modes that exist internationally. We need to be aware of how this will impact our flex layouts as the writing mode changes the direction that blocks are laid out in our document. Understanding **block** and **inline** directions is key to new layout methods.

It is worth noting that we might want to change the writing mode of our document for reasons other than publishing content in a language that uses a different writing mode. The CSS writing modes module defines how text can be written horizontally, left-to-right and right-to-left, and vertically, top-to-bottom. This is important for internationalization and translations, but these feature can also be used for creative designs.

The writing modes

The writing modes specification defines the following values of the `writing-mode` property, which serve to change the direction that blocks are laid out on the page, to match the direction that blocks lay out when content is formatted in that particular writing mode. You can change the live example below to these modes in order to see what happens to the flex layout.

- `horizontal-tb`
- `vertical-rl`
- `vertical-lr`
- `sideways-rl`
- `sideways-lr`

```
<div class="box">
  <div>One</div>
  <div>Two</div>
  <div>Three</div>
</div>
```

```
.box > * {
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
  background-color: rgb(96 139 168 / 0.2);
}

.box {
  width: 500px;
  border: 2px dotted rgb(96 139 168);
  display: flex;
  writing-mode: horizontal-tb;
}
```

Note that you would not normally use CSS and the `writing-mode` property to change an entire document to another writing mode. This would be done via HTML, by adding a `dir` and `lang` attribute to the `<html>` element to indicate the document language and default text direction. This would mean that the document would display correctly even if CSS did not load.

Flexbox and other layout methods

Some properties were designed assuming that content is laid out using the standard block layout system, and don't apply in the context of flex layout. An element set to `display: flex` behaves in most ways like any other block-level container that establishes a containing block. Floats will not intrude, and the containers' margins will not collapse.

With regard to flex items, if an item was floated or cleared and then becomes a flex item due to the parent having `display: flex` applied, the floating and clearing will no longer happen, and the item will not be taken out of normal flow in the way that floats are. If you have used the `vertical-align` property, as used with `inline-block` or table layout for alignment, this will no longer affect the item and you can use the alignment properties of flexbox instead.

In this next live example the child elements have been floated, and then their container has had `display: flex` added. If you remove `display: flex`, you should see that the `.box` element collapses as we have no clearing applied. This demonstrates that the float is happening. Re-apply `display: flex` and the collapsing does not happen. This is because the items no longer have a float applied, as they have been transformed into flex items.

```
<div class="box">
  <div>One</div>
  <div>Two</div>
  <div>Three</div>
</div>
```

```
.box {
  width: 500px;
  border: 2px dotted rgb(96 139 168);
  display: flex;
}

.box > * {
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
  background-color: rgb(96 139 168 / 0.2);
  float: left;
}
```

Flexbox and grid layout

CSS grid layout and flexbox share many properties and values. For divergent properties, if a flex item becomes a grid item, any `flex` values assigned to the child elements, such as `flex-end`, will be ignored. As noted above, values defined in the box alignment module that work across both layout methods supersede those defined in flexbox only.

Flex and grid — what's the difference?

A common question is to ask what the difference is between flexbox and CSS grid layout — why do we have two specifications that sometimes appear to be doing the same thing?

The most straightforward answer to this question is defined in the specifications themselves. Flexbox is a one-dimensional layout method whereas grid layout is a two-dimensional layout method. The example below has a flex layout. As already described in the Basic concepts article, flex items can be allowed to wrap but, once they do, each line behaves as if it were a flex container of its own. When space is distributed, flexbox does not look at the placement of items in other rows and tries to line things up with each other.

```
<div class="box">
  <div>One</div>
  <div>Two</div>
  <div>Three</div>
  <div>Four</div>
  <div>Five</div>
  <div>Six</div>
  <div>Seven</div>
</div>
```

```
.box {
  border: 2px dotted rgb(96 139 168);
  display: flex;
  flex-wrap: wrap;
  padding: 1em;
}

.box > * {
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
  background-color: rgb(96 139 168 / 0.2);
  padding: 1em;
  flex: 1 1 200px;
}
```

If we create a very similar layout using grid, we can control the layout in both rows and columns.

```
<div class="box">
  <div>One</div>
  <div>Two</div>
  <div>Three</div>
  <div>Four</div>
  <div>Five</div>
  <div>Six</div>
  <div>Seven</div>
</div>
```

```
.box {
  border: 2px dotted rgb(96 139 168);
  padding: 1em;
  display: grid;
  grid-template-columns: repeat(auto-fill, minmax(200px, auto));
}

.box > * {
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
  padding: 1em;
  background-color: rgb(96 139 168 / 0.2);
}
```

These examples point to another key difference between these layout methods. In grid layout, you do the majority of sizing specification on the container, setting up tracks and then placing items into them. In flexbox, while you create a flex container and set the direction at that level, any control over item sizing needs to happen on the items themselves.

In some cases, you could use either layout method. As you become confident with both, you will find each one is better suited to specific layout needs, and you'll end up with both methods in your CSS. There is rarely a right or wrong answer.

As a general rule, if you are setting widths on flex items to make items in one row of a wrapped flex container line up with the items above them, you should instead opt for a two-dimensional grid layout.

There are no set rules like "you should use flexbox for small components and grid layout for larger ones." A tiny component can be two dimensional, and a large layout can be represented better with layout in one dimension. Try things out — you have a choice of layout methods, so take advantage of it.

For more comparisons of grid and flexbox see the article Relationship of grid layout to other layout methods. This article details many of the ways that grid layout differs from flex layout and demonstrates some of the extra functionality you get when using grid layout such as layering of items on the grid. This may also help you decide which layout method to use.

Flexbox and display: contents

The `contents` value of the `display` property is described in the spec as follows:

> "The element itself does not generate any boxes, but its children and pseudo-elements still generate boxes as normal. For the purposes of box generation and layout, the element must be treated as if it had been replaced with its children and pseudo-elements in the document tree."

This value of `display` controls box generation, and whether the element should generate a box that we can style and see on the page, or whether instead the box it would normally create should be removed and the child elements essentially moved up to participate in whatever layout method the parent would have been part of. This is easier to see with an example.

In the following live example, we have a flex container containing three flex items. One has two elements nested inside it, which would not ordinarily participate in flex layout. Flex layout only applies to the direct children of a flex container.

By adding `display: contents` to the wrapper around the nested elements, you can see that the item has disappeared from the layout, allowing the two sub-children to be laid out as if they were direct children of the flex container. You can try removing the `display: contents` line to see it return.

Note that this only removes the box from the layout; the sub-children don't become direct children in any other way. We used a direct child selector to add the background and borders to the flex items; it has not been applied to our nested children. They have been laid out as flex items, but as they are not direct children they do not get the other styling.

As the box is removed, you cannot then use it to — for example — add a background color behind the nested sub children. If you remove `display: contents` in this live example you will see that the direct child we are removing has an orange background color. This also disappears when the box disappears.

```
<div class="box">
  <div>One</div>
  <div>Two</div>
  <div class="nested">
    <div>Sub-item 1</div>
    <div>Sub-item 2</div>
  </div>
</div>
```

```
.box > * {
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
  padding: 1em;
  background-color: rgb(96 139 168 / 0.2);
}

.box {
  border: 2px dotted rgb(96 139 168);
  padding: 1em;
  display: flex;
}

.nested {
  background-color: orange;
  display: contents;
}
```

> **Warning:** Some browsers incorrectly remove some elements with `display: contents` from the accessibility tree (but descendants will remain), removing those elements' semantics while maintaining their child content. This means the element itself may not be announced by screen readers. See `display: contents` and `display: contents` considered harmful.

Typical use cases of flexbox

In this guide, we will take a look at some of the common use cases for flexbox — those places where flexbox makes more sense than another layout method.

Why choose flexbox?

Flexbox is generally the right CSS layout solution when you want to lay out a collection of items in one dimension or control the spacing between items. In this guide, we'll look at some of the typical use cases of flexbox.

Navigation

A common pattern for navigation is to have a list of items displayed as a horizontal bar. It's probably the most common of flexbox examples, and could be considered an ideal flexbox use case.

When we have a set of items that we want to display horizontally, we may well end up with additional space. We need to decide what to do with that space, and have a couple of options. We either display the space outside of the items — therefore spacing them out with white space between or around them — or we absorb the extra space inside the items and therefore need a method of allowing the items to grow and take up this space.

Space distributed outside the items

To distribute the space between or around the items, we use the alignment properties in flexbox, and the `justify-content` property. You can read more about this property in Aligning items in a flex container, which deals with aligning items on the main axis.

In this example, we display the items at their natural size and use `justify-content: space-between` to space the items equally. You can change how the space is distributed using the `space-around` or `space-evenly` values. You could also use `start` to put the space at the end of the items, `end` to place it before them, or `center` to center the navigation items.

```
<nav>
  <ul>
    <li><a href="#">Page 1</a></li>
    <li><a href="#">Page 2</a></li>
    <li><a href="#">Page 3 is longer</a></li>
    <li><a href="#">Page 4</a></li>
```

```
  </ul>
</nav>
```

```
nav {
  border: 2px solid #eeeeee;
}

nav a {
  text-decoration: none;
  color: black;
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
  background-color: rgb(96 139 168 / 0.2);
  padding: 10px;
  display: block;
}

nav ul {
  list-style: none;
  margin: 0;
  padding: 0;
  display: flex;
  justify-content: space-between;
}
```

Space distributed within the items

A different pattern for navigation would be to distribute the available space within the items themselves, rather than create space between them. The `flex` properties allow items to grow and shrink in proportion to one another as described in Controlling ratios of flex items along the main axis.

If you wanted to respect the size property of your navigation items but have the available space shared out equally among them, you might use `flex: auto`, which is the shorthand for `flex: 1 1 auto` — all items grow and shrink from a flex-basis of `auto`. This would mean that the longer item would have more space because it started from a larger size, even though the same amount of available space is assigned to it as the others.

In the live example below try changing `flex: auto` to `flex: 1`. This shorthand for `flex: 1 1 0` causes all of the items to become the same width, as they are working from a `flex-basis` of `0`, allowing all of the space to be distributed evenly.

```
<nav>
  <ul>
    <li><a href="#">Page 1</a></li>
    <li><a href="#">Page 2</a></li>
    <li><a href="#">Page 3 is longer</a></li>
    <li><a href="#">Page 4</a></li>
  </ul>
</nav>
```

```
nav {
  border: 2px solid #eeeeee;
}
nav ul {
  list-style: none;
  margin: 0;
  padding: 0;
  display: flex;
}

nav a {
  text-decoration: none;
  color: black;
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
  background-color: rgb(96 139 168 / 0.2);
  padding: 10px;
  display: block;
}

nav li {
  flex: auto;
}
```

Split navigation

Another way to align items on the main axis is to use auto margins. This enables the design pattern of a navigation bar where one group of items are aligned left and another group aligned right. Here we are using the auto margins technique described in Using auto margins for main axis alignment.

The items are aligned on the main axis with `normal`, which behaves as `start`, as this is the initial behavior of flexbox. The `gap` property creates gaps between items. And we are aligning the last item to the right by giving it a `margin-left` value of `auto`. You can move the class from one item to another to change where the split happens.

```
<nav>
  <ul>
    <li><a href="#">Page 1</a></li>
    <li><a href="#">Page 2</a></li>
    <li><a href="#">Page 3 is longer</a></li>
    <li class="push-right"><a href="#">Page 4</a></li>
  </ul>
</nav>
```

```
nav {
  border: 2px solid #eeeeee;
}

nav a {
  text-decoration: none;
  color: black;
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
  background-color: rgb(96 139 168 / 0.2);
  padding: 10px;
  display: block;
```

```
}

nav ul {
  list-style: none;
  margin: 0;
  padding: 0;
  display: flex;
  gap: 20px;
}

.push-right {
  margin-left: auto;
}
```

Center item

A long-standing joke among developers is that the hardest problem in web design is vertical centering. Vertically centering content is very straightforward with flexbox alignment properties, as the following live example shows.

Click **"Play"** and try changing the alignment, for example aligning the item to the start with `start` or end with `end`:

```
<div class="box">
  <div></div>
</div>
```

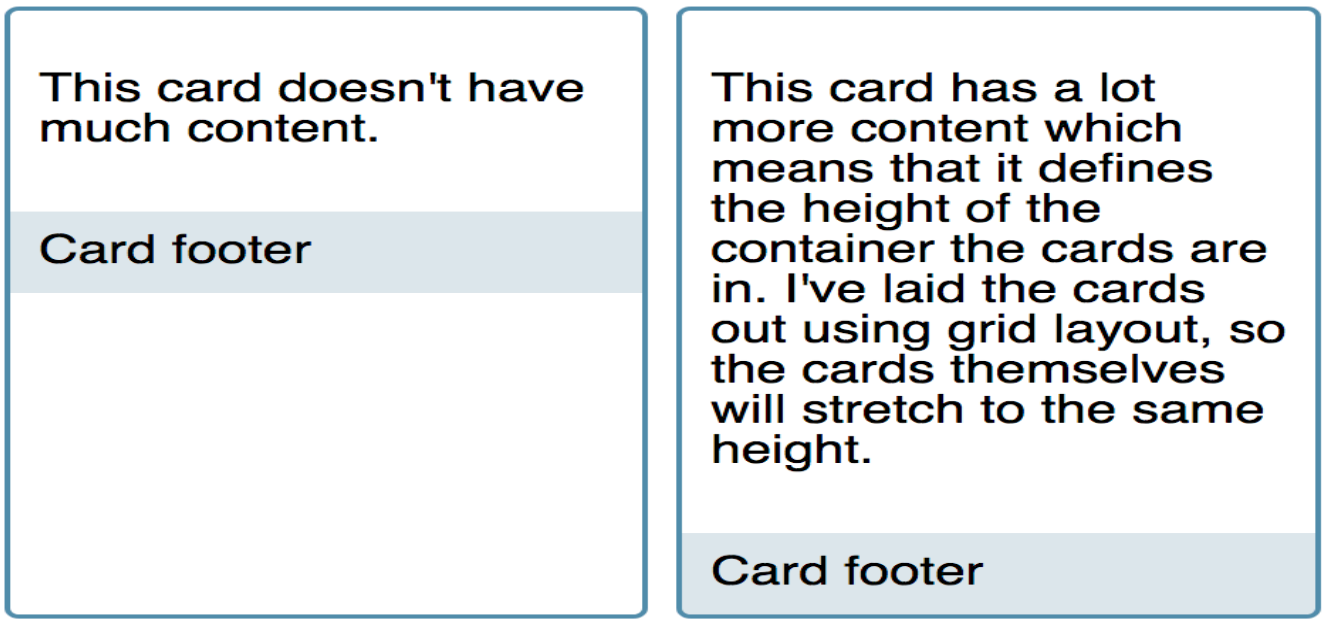
```
.box {
  height: 300px;
  border: 2px dotted rgb(96 139 168);
  display: flex;
  align-items: center;
  justify-content: center;
}

.box div {
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
  background-color: rgb(96 139 168 / 0.2);
  width: 100px;
  height: 100px;
}
```

With CSS box alignment properties, you can vertically center an element inside another without flexbox. In the example above, try removing the flex properties from the box and adding `align-content: center`. Then add `margin: auto` to the element you want to horizontally center.

Card layout pushing footer down

Whether you use flexbox or grid to lay out a list of card components, these layout methods only work on direct children of the flex or grid component. This means that if you have variable amounts of content, the card will stretch to the height of the grid area or flex container. Any content inside uses regular block layout, meaning that on a card with less content the footer will rise up to the bottom of the content rather than stick to the bottom of the card.



Flexbox solves this. We make the card a flex container, with `flex-direction: column`. We then set the content area to `flex: 1`, which is the shorthand for `flex: 1 1 0` — the item can grow and shrink from a flex basis of `0`. As this is the only item that can grow, it takes up all available space in the flex container and pushes the footer to the bottom. If you remove the `flex` property from the live example you will see the footer moves up to sit directly under the content.

```
<div class="cards">
  <div class="card">
    <div class="content">
      <p>This card doesn't have much content.</p>
    </div>
    <footer>Card footer</footer>
  </div>
  <div class="card">
    <div class="content">
      <p>
        This card has a lot more content which means that it defines the height
        of the container the cards are in. I've laid the cards out using grid
```

```
        layout, so the cards themselves will stretch to the same height.
      </p>
    </div>
    <footer>Card footer</footer>
  </div>
</div>
```

```
body {
  font-family: sans-serif;
}
.cards {
  display: grid;
  grid-template-columns: repeat(auto-fill, minmax(200px, 1fr));
  grid-gap: 10px;
}

.card {
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
  display: flex;
  flex-direction: column;
}

.card .content {
  padding: 10px;
  flex: 1 1 auto;
}

.card footer {
  background-color: rgb(96 139 168 / 0.2);
  padding: 10px;
}
```

Media objects

The media object — an image or other media element with some descriptive text side-by-side — is a common pattern in web design. Media objects should be able to be flipped — moving the image from one side to the other.

This pattern is used for comments and other places where images are placed next to their descriptions. We can use flexbox to allow the part of the media object containing the image to take its sizing information from the image with the content of the media object flexing to take up the remaining space.

In this example, the media object is aligned to `flex-start` and the `.content` is set to grow, with the grow factor set to `1`. These properties are the same as those used for our column layout card pattern above.

```
<div class="media">
  <div class="image">
    <img
      alt="A colorful balloon against a blue sky"
      src="https://mdn.github.io/shared-assets/images/examples/balloon.jpg" />
  </div>
  <div class="content">
    This is the content of my media object. Items directly inside the flex
    container will be aligned to flex-start.
  </div>
</div>
```

```
img {
  max-width: 100%;
  display: block;
}

.media {
  border: 2px dotted rgb(96 139 168);
  display: flex;
  align-items: flex-start;
}

.media .content {
  flex: 1;
  padding: 10px;
}
```

Some things that you might want to try in this live example relate to the different ways you might want to constrain the media object in your design.

To prevent the image from growing too large, you should add a `max-width` to the image. As that side of the media object uses the initial values of flexbox, it can shrink, but not grow, and uses a `flex-basis` of auto. Any `width` or `max-width` applied to the image will become the `flex-basis`.

```
.image img {
  max-width: 100px;
}
```

You could also allow both sides to grow and shrink in proportion. If you set both sides to `flex: 1`, they will grow and shrink from a `flex-basis` of `0`, so you will end up with two equal-sized columns. You could either take the content as a guide and set both to `flex: auto`, in which case they would grow and shrink from the size of the content or any size applied directly to the flex items such as a `width` on the image.

```
.media .content {
  flex: 1;
  padding: 10px;
}

.image {
  flex: 1;
}
```

You could also give each side different `flex-grow` factors, for example setting the side with the image to `flex: 1` and the content side to `flex: 3`. This will mean they use a `flex-basis` of `0` but distribute that space at different rates according to the `flex-grow` factor you have assigned. The flex properties we use to do this are described in detail in the guide Controlling ratios of flex items along the main axis.

```
.media .content {
  flex: 3;
  padding: 10px;
}
```

```
.image {
  flex: 1;
}
```

Flipping the media object

To switch the display of the media object and have the image on the right and content on the left, we set the `flex-direction` property to `row-reverse`.

In this example, we added a `flipped` class next to the `media` class. Remove the class from the HTML to see how the display changes.

```
<div class="media flipped">
  <div class="image">
    <img
      alt="A colorful balloon against a blue sky"
      src="https://mdn.github.io/shared-assets/images/examples/balloon.jpg" />
  </div>
  <div class="content">
    This is the content of my media object. Items directly inside the flex
    container will be aligned to flex-start.
  </div>
</div>
```

```
img {
  max-width: 100%;
  display: block;
}

.media {
  border: 2px dotted rgb(96 139 168);
  display: flex;
  align-items: flex-start;
}

.flipped {
  flex-direction: row-reverse;
}

.media .content {
  flex: 1;
  padding: 10px;
}
```

Form controls

Flexbox is particularly useful when it comes to styling form controls. Forms have several small elements that we typically want to align with each other. A common pattern is to have a `<label>` and `<input>` pair combined with a `<button>`, perhaps for a search form or a newsletter sign-up form where you want your visitor to enter their email address.

Flexbox makes this type of layout achievable with just a few declarations. The `<label>`, `<input>` and `<button>` are contained in a wrapper that is set to `display: flex`. The flex properties allow the `<input>` field to grow, while the button and label do not grow. The text input field will grow and shrink depending on the space available.

```
<div class="wrapper">
  <label for="text">Label</label>
  <input id="text" type="text" />
  <button type="button">Send</button>
</div>
```

```
* {
  font: 1.1em sans-serif;
}

.wrapper {
  display: flex;
  border: 1px solid rgb(96 139 168);
}
.wrapper > * {
  padding: 10px;
  border: none;
  color: white;
}
.wrapper > input[type="text"] {
  background-color: rgb(96 139 168 / 0.5);
  border-right: 1px solid rgb(96 139 168);
  flex: 1 1 auto;
}
.wrapper button {
  background-color: rgb(96 139 168);
  color: white;
}
.wrapper label {
  background-color: #666666;
}
```

Patterns like this can make it easier to create a library of form elements for your design, which easily accommodate additional elements being added. You are taking advantage of the flexibility of flexbox by mixing items that do not grow with those that do.

Conclusion

While exploring the above patterns, you have hopefully started to see how you can think through the best way to use flexbox to achieve the result that you want. Quite often you have more than one choice. Mix items that cannot stretch with those that can, use the content to inform the size, or allow flexbox to share out space in proportion. It's up to you.

Think about the best way to present the content that you have and then see how flexbox or other layout methods can help you achieve it.

Mastering wrapping of flex items

Flexbox was designed as a single-dimensional layout tool — it deals with laying out items as a row or column — but not both at once. It is, however, possible to wrap flex items onto new lines, creating new rows if `flex-direction` is `row` and new columns if `flex-direction` is `column`. This guide explains flexbox wrapping, what it is designed for, and what situations require CSS grid layout rather than flexbox.

Making things wrap

The initial value of the `flex-wrap` property is `nowrap`. This means if a set of flex items is too wide for their flex container, they will overflow it. To make them wrap once they are too wide, add the `flex-wrap` property with a value of `wrap`, or use the shorthand `flex-flow` with values of `row wrap` or `column wrap`. Items will then wrap onto new lines when they overflow their container.

In this example, there are ten flex items with a `flex-basis` of `160px` that can grow and shrink. Once there is not enough space to place another 160 pixel item in a row, a new flex line is created. New lines are created as needed until all of the items are placed. As the items can grow, they will expand to fill each row completely. If there is only one item on the final line it will stretch to fill the entire line.

```
<div class="box">
  <div>One</div>
  <div>Two</div>
  <div>Three</div>
  <div>Four</div>
  <div>Five</div>
  <div>Six</div>
  <div>Seven</div>
  <div>Eight</div>
  <div>Nine</div>
  <div>Ten</div>
</div>
```

```
.box {
  width: 500px;
  border: 2px dotted rgb(96 139 168);
  display: flex;
  flex-wrap: wrap;
}

.box > * {
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
  background-color: rgb(96 139 168 / 0.2);
  flex: 1 1 160px;
}
```

The same thing happens with flex columns. To wrap and create new columns, the container needs to have a height. In the case of columns, items stretch vertically to fill each column completely.

```
<div class="box">
  <div>One</div>
  <div>Two</div>
  <div>Three</div>
  <div>Four</div>
  <div>Five</div>
  <div>Six</div>
  <div>Seven</div>
  <div>Eight</div>
  <div>Nine</div>
  <div>Ten</div>
</div>
```

```
.box {
  border: 2px dotted rgb(96 139 168);
  height: 300px;
  display: flex;
  flex-direction: column;
  flex-wrap: wrap;
}
.box > * {
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
  background-color: rgb(96 139 168 / 0.2);
  flex: 1 1 80px;
}
```

Wrapping and flex-direction

Wrapping works as you might expect when combined with `flex-direction`. If `flex-direction` is set to `row-reverse` then the items will start from the end edge of the container and lay themselves out in reverse ordered lines.

```
<div class="box">
  <div>One</div>
  <div>Two</div>
  <div>Three</div>
  <div>Four</div>
  <div>Five</div>
  <div>Six</div>
  <div>Seven</div>
  <div>Eight</div>
  <div>Nine</div>
  <div>Ten</div>
</div>
```

```
.box {
  border: 2px dotted rgb(96 139 168);
  display: flex;
  flex-wrap: wrap;
  flex-direction: row-reverse;
  width: 500px;
}
.box > * {
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
  background-color: rgb(96 139 168 / 0.2);
  flex: 1 1 160px;
}
```

Note that the reversing is only happening in the inline, row direction. We start on the right then go onto the second line and again start from the right. We aren't reversing in both directions, starting from the bottom coming up the container!

Balanced wrapping

One potential issue with flexbox wrapping is that, by default, the flex items are not distributed evenly across the lines. In the previous example, we have three items on the first three lines, but only one on the last line. We can distribute the flex items more evenly across the four flex lines by including the `balance` keyword within the `flex-wrap` value, alongside the `wrap` or `wrap-reverse` keyword.

This example uses the same HTML as the previous example, and nearly the same CSS, except that the `flex-wrap` value has been changed from `wrap` to `wrap balance`.

```
<div class="box">
  <div>One</div>
  <div>Two</div>
  <div>Three</div>
  <div>Four</div>
  <div>Five</div>
  <div>Six</div>
  <div>Seven</div>
  <div>Eight</div>
  <div>Nine</div>
  <div>Ten</div>
</div>
```

```
.box {
  border: 2px dotted rgb(96 139 168);
  display: flex;
  flex-wrap: wrap balance;
  flex-direction: row-reverse;
  width: 500px;
}
.box > * {
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
  background-color: rgb(96 139 168 / 0.2);
  flex: 1 1 160px;
}
```

```
@supports not (flex-wrap: balance) {
  body::before {
    content: "Your browser does not support flex-wrap: balance.";
    background-color: wheat;
    text-align: center;
    padding: 1rem 0;

    z-index: 1;
    position: fixed;
    inset: 40% 0 auto;
  }
}
```

```
flex-wrap: wrap balance;
```

This line could also have been written as just `flex-wrap: balance`. If `balance` is specified as the only keyword in the `flex-wrap` value, the other keyword defaults to `wrap`. We wrote it out explicitly so it is clearer what is going on. Note that including the `balance` keyword with the `nowrap` value is invalid, and the declaration will be ignored.

The updated rendering looks like so:

Note how the items are now distributed more evenly, or "balanced," with two lines of three items and two lines of two items.

If you want to distribute your balanced flex items across a greater number of lines, you can do so using the `flex-line-count` property. This specifies a minimum number of lines. If we add the following to the previous example:

```
.box {
  border: 2px dotted rgb(96 139 168);
  display: flex;
  flex-wrap: wrap balance;
  flex-line-count: 5;
  flex-direction: row-reverse;
  width: 500px;
}
.box > * {
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
  background-color: rgb(96 139 168 / 0.2);
  flex: 1 1 160px;
}
```

```
flex-line-count: 5;
```

We end up with the following:

We now have five lines of two flex items.

The `flex-line-count` property has no effect on flex-containers that do not have the `balance` keyword included in their `flex-wrap` property values.

Single-dimensional layout explained

As we have seen from the above examples if our items are allowed to grow and shrink, when there are fewer items in the last row or column then those items grow to fill the available space.

There are no flexbox features to tell items in one row to line up with items in the row above — each flex line acts like a new flex container. It deals with space distribution across the main axis. If there is only one item, and that item is allowed to grow, it will fill the axis just as if you had a single item flex container. If you want layout in two dimensions then you probably want grid layout.

This example demonstrates the difference, using CSS grid layout to create a layout with as many columns of at least `160px` as will fit, distributing the extra space between all columns. We use the same HTML as the flexbox wrapped row example above but set `display: grid` on it. Instead of the `flex` shorthand, which has no effect outside of flexbox, we set the item's minimum width and ability to grow directly on the container with `grid-template-columns`. With CSS grid, the last item stays in its grid cell; grid items don't stretch when there are fewer of them in the last row.

```
<div class="box">
  <div>One</div>
  <div>Two</div>
  <div>Three</div>
  <div>Four</div>
  <div>Five</div>
```

```
  <div>Six</div>
  <div>Seven</div>
  <div>Eight</div>
  <div>Nine</div>
  <div>Ten</div>
</div>
```

```
.box {
  border: 2px dotted rgb(96 139 168);
  display: grid;
  grid-template-columns: repeat(auto-fill, minmax(160px, 1fr));
  width: 500px;
}

.box > * {
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
  background-color: rgb(96 139 168 / 0.2);
}
```

This is the difference between one and two-dimensional layouts. In a one-dimensional layout method like flexbox, we only control the row or column. In a two-dimensional grid layout, we control both at the same time. If you want the space distribution row by row, use Flexbox. If you don't, use CSS grid.

How do flexbox-based grid systems work?

Flexbox-based layouts can be forced to line up as grid systems, but that is not the intended purpose of flexbox. If you assign percentage widths to flex items — either using `flex-basis` or by adding a width to the item itself and leaving the value of `flex-basis` as `auto` — you can give the impression of a two-dimensional layout.

In this example, `flex-grow` and `flex-shrink` have been set to `0` to make inflexible flex items. The flexibility is controlled via percentages.

```
<div class="box">
  <div>One</div>
  <div>Two</div>
  <div>Three</div>
  <div>Four</div>
  <div>Five</div>
  <div>Six</div>
  <div>Seven</div>
  <div>Eight</div>
  <div>Nine</div>
  <div>Ten</div>
</div>
```

```
* {
  box-sizing: border-box;
}

.box {
  width: 500px;
  border: 2px dotted rgb(96 139 168);
  display: flex;
  flex-wrap: wrap;
}

.box > * {
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
  background-color: rgb(96 139 168 / 0.2);
  flex: 0 0 33.3333%;
}
```

This technique allows you to line up flex items on the cross-axis. However, when you catch yourself adding widths to flex items in this way or adding empty flex items to take up space, it is a good indication you may want to switch to CSS grid layout for that component.

Creating gutters between items

To create gaps or gutters between flex items, use the gap property directly on the flex container to create a fixed space between adjacent flex items. The `gap` property is a shorthand for `row-gap` and `column-gap`. These properties specify the size of the gutters between rows and columns within grid, flex, and multi-column layouts.

The `gap` property is not the only thing that can add space between items. Margins, padding, `justify-content`, and `align-content` can also increase the size of the gutter, affecting the actual size of the gap.

To see how the `gap` property differs from `margin` in both axes, try changing the `gap` value in the container `.box` and adding a `margin` value to the `.box > *` rule in the stylesheet below. Click the "Reset" button to revert to the previous values.

```
<div class="wrapper">
  <div class="box">
    <div>One</div>
    <div>Two</div>
    <div>Three</div>
    <div>Four</div>
    <div>Five</div>
    <div>Six</div>
    <div>Seven</div>
    <div>Eight</div>
    <div>Nine</div>
    <div>Ten</div>
  </div>
</div>
```

```
.wrapper {
  border: 2px dotted rgb(96 139 168);
  width: 500px;
}
.box {
  display: flex;
  flex-wrap: wrap;
  gap: 10px;
}
.box > * {
  flex: 1 1 160px;
```

```
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
  background-color: rgb(96 139 168 / 0.2);
}
```

Collapsed items

The flexbox specification details what should happen if a flex item is collapsed by setting `visibility: collapse` on an item. See the MDN documentation for the `visibility` property. The specification describes the behavior as follows:

> "Specifying `visibility: collapse` on a flex item causes it to become a *collapsed flex item*, producing an effect similar to `visibility: collapse` on a table-row or table-column: the collapsed flex item is removed from rendering entirely, but leaves behind a "strut" that keeps the flex line's cross-size stable. Thus, if a flex container has only one flex line, dynamically collapsing or uncollapsing items may change the flex container's main size, but is guaranteed to have no effect on its cross size and won't cause the rest of the page's layout to "wobble". Flex line wrapping *is* re-done after collapsing, however, so the cross-size of a flex container with multiple lines might or might not change." - Collapsed items

This behavior is useful if you want to target flex items using JavaScript to show and hide content for example. The example in the specification demonstrates one such pattern.

In the following live example, the non-wrapping flex container contains a row with three flex items that are set to flex to equal sizes. The third item has multiple lines of content, growing the container. The default for `align-items` is `normal`; for flex items, `normal` behaves as `stretch`, so all the items stretch by default, filling the container's cross-size height.

The item creating the cross-size is set to `visibility: collapse`, which collapses or hides the flex item, depending on the browser. In either case, the flex container retains a *strut* of the cross-size even though it is not visible. This way, if the item is made visible, the cross-size of the single-line flex container will not change. If you remove `visibility: collapse` from the CSS or change the value to `visible`, you will see the item appear, and the main-size space is redistributed between non-collapsed items, while the cross-size remains unchanged.

> **Note:** Use Firefox for the example below as other common browsers treat `collapse` as `hidden`.

```
<p>
  <label><input type="checkbox" /> Toggle <code>visibility</code> value</label>
</p>
```

```
<div class="box">
  <div>One</div>
  <div>Two</div>
  <div class="collapse">Three <br />has <br />extra <br />text</div>
</div>
```

```
.box {
  border: 2px dotted rgb(96 139 168);
  display: flex;
  width: 600px;
}
.box > * {
  flex: 1 1 200px;
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
  background-color: rgb(96 139 168 / 0.2);
}
.collapse {
  visibility: collapse;
}
```

```
p:has(:checked) + div .collapse {
  visibility: visible;
}
```

The above was a single-line, non-wrapping flex container with a set size of `600px` so whether the item is visible or collapsed, the width is the same. It is important to understand that while the container retains a strut of the collapsed item's cross-size, the main size is not preserved. Multi-line flex containers rewrap their items after removing collapsed items from rendering. The new space that a collapsed item leaves in the main direction may cause non-collapsed items to be placed in a different line than if the item were not collapsed. Because each line is laid out like an independent single-line flex container and its composition may change after collapsing, its cross-axis size may change too.

The following example shows this behavior. The third flex item is collapsed, so it occupies zero space along the main axis (the inline-size is 0). When collapsed, its strut is on the first row after the fourth item, with the first row being tall enough to fit the three lines of text that the third item would have had. Then, if you uncollapse the item (e.g., by removing the `collapse` class), there is no longer enough horizontal space for the fifth item on the first row, and it moves to the second. This causes the second row to grow to fit the two lines of text of its new member, and the last flex item is pushed onto a new row. With a taller second line and a new third line, the flex container is much taller than it was before.

> **Note:** Use Firefox for the example below as other common browsers treat `collapse` as `hidden`.

```
<p>
  <label><input type="checkbox" /> Toggle <code>visibility</code> value</label>
</p>
```

```
<div class="box">
  <div>One</div>
  <div>Two is the width of this sentence.</div>
  <div class="collapse">Three <br />is <br />five <br />lines <br />tall.</div>
  <div>Four</div>
  <div>Five<br />Five</div>
  <div>Six</div>
  <div>Seven</div>
  <div>Eight</div>
  <div>Nine</div>
  <div>Ten</div>
  <div>Eleven is longer</div>
</div>
```

```
.box {
  border: 2px dotted rgb(96 139 168);
  width: 500px;
  display: flex;
  flex-wrap: wrap;
}
.box > * {
  padding: 10px;
  border: 2px solid rgb(96 139 168);
```

```
  border-radius: 5px;
  background-color: rgb(96 139 168 / 0.2);
  flex: 1 1 auto;
  min-width: 50px;
}
.collapse {
  visibility: collapse;
}
```

```
p:has(:checked) + div .collapse {
  visibility: visible;
}
```

If this causes a problem for your layout, it may require a rethinking of the structure, for example, putting each row into a separate flex container so that they can't shift rows.

Using <code>visibility: hidden</code> and <code>display: none</code>

In the previous live examples, try using `visibility: hidden` or `display: none` instead of `visibility: collapse`. Using `visibility: hidden`, the item is made invisible, but the box is kept in the formatting structure, so it still behaves as if it were part of the layout. When you use `display: none`, the item is completely removed from the formatting structure. Not only is it invisible but the structure is removed as well. This means counters ignore it and things like transitions do not run.

CSS font loading

The **CSS font loading** module describes events and interfaces used for dynamically loading font resources.

Reference

Interfaces

- `fontFace` interface
  - `FontFace()` constructor
  - `fontFace.family` property
  - `fontFace.style` property
  - `fontFace.weight` property
  - `fontFace.stretch` property
  - `fontFace.unicodeRange` property
  - `fontFace.variant` property
  - `fontFace.featureSettings` property
  - `fontFace.variationSettings` property
  - `fontFace.display` property
  - `fontFace.ascentOverride` property
  - `fontFace.descentOverride` property
  - `fontFace.lineGapOverride` property
  - `fontFace.load()` method (returns a promise)
- `fontFaceSet` interface
- `fontFaceSetLoadEvent` event

CSS fonts

The **CSS fonts** module defines font-related properties and how font resources are loaded. It lets you define the style of a font, such as its family, size and weight, and the glyph variants to use when multiple are available for a single character.

A font is a resource file containing the visual representation of characters, mapping character codes to glyphs that represent letters, numbers, punctuation and even emojis of a typeface. A font family is a group of fonts that share common design styles and font properties, with each member of the group providing different ways of displaying the glyphs, varying by stroke weight, slant, or relative width, among other attributes. A font typically represents a single style of a typeface, such as Helvetica that is Bold and Italic. A font family is the complete set of styles. Including such a font in a document or design is done by defining a separate `@font-face` declaration for each font resource.

The properties, at-rules, and descriptors of the CSS fonts module enable the downloading of multiple variations of a font. They also define the font file to use for a particular font characteristic, along with fallback instructions in case a resource fails to load. The CSS font selection mechanism describes the process of matching a given set of CSS font properties to a single font face.

The CSS fonts module also supports variable fonts. Unlike regular fonts, where each style is implemented as a separate font file, variable fonts can contain all styles within a single file. By using a single `@font-face` declaration, you can import a variable font that includes all the styles. Depending on the font, this can include a multitude of font variants. Variable fonts are a part of the OpenType font specification.

Guides

Learn: Fundamental text and font styling

> This beginner's learning article covers the basic fundamentals of text and font styling. It covers how to set the font weight, family, and style by using the `font` shorthand and how to align text and manage line and letter spacing.

Learn: Web fonts

> This beginner's learning article explains how to use custom fonts on your web page to allow for more varied and custom text styling.

OpenType font features

> Font features or variants refer to different glyphs or character styles contained within an OpenType font. These include things like ligatures (special glyphs that combine characters like 'fi' or 'ffl'), kerning (adjustments to the spacing between specific letterform pairings), fractions, numeral styles, and a number of others. These are all referred to as OpenType Features, and are made available to use on the web via specific properties and a low-level control property — `font-feature-settings`. This article provides you with all you need to know about using OpenType font features in CSS.

Web Open Font Format (WOFF)

> WOFF uses a compressed version of the same table-based `sfnt` structure used by TrueType, OpenType, and Open Font Format, but adds metadata and private-use data structures, including predefined fields allowing foundries and vendors to provide license information if desired.

Variable fonts

> This article will help you get started with using variable fonts.

Improving font performance

> This article, part of the CSS performance guide, discusses font loading, loading only the required glyphs, and defining font display behavior with the `font-display` descriptor.

OpenType font features

Font features or variants refer to different glyphs or character styles contained within an OpenType font. These include things like ligatures (special glyphs that combine characters like 'fi' or 'ffl'), kerning (adjustments to the spacing between specific letterform pairings), fractions, numeral styles, and several others. These are all referred to as OpenType Features, and are made available to use on the web via specific properties and low-level control properties — `font-feature-settings`. This article provides you with all you need to know about using OpenType font features in CSS.

Some fonts will have one or more of these features enabled by default (kerning and default ligatures are common examples), while others are left to the designer or developer to choose to enable in specific scenarios.

In addition to broad feature sets like ligatures or lining figures (numerals that line up evenly as opposed to 'oldstyle', which look more like lower-case letters), there are also very specific ones such as stylistic sets (which might include several specific variants of glyphs meant to be used together), alternates (which might be one or more variants of the letter 'a'), or even language-specific alterations for East Asian languages. In the latter case, these alterations are actually necessary to properly express the language, so they go beyond the more stylistic preference of most other OpenType features.

> **Warning:** There are many CSS attributes defined to leverage font features, but unfortunately many are not fully implemented. They are all defined and shown here, but many will only work using the lower-level `font-feature-settings` property. It's possible to write CSS to work both ways but this can become cumbersome. The issue with using `font-feature-settings` for everything is that every time you want to change one of the individual features, you have to redefine the entire string (similar to manipulating variable fonts with `font-variation-settings`).

Discovering availability of features in fonts

This is sometimes the trickiest thing to work out if you don't have any documentation that came with the fonts (many type designers and foundries will provide sample pages and CSS just for this very reason). But there are some sites that make it easier to figure out. You can visit wakamaifondue.com, drop your font file on the circle where instructed, and in a few moments you'll have a full report on all the capabilities and features of your font. Axis-praxis.org also offers a similar capability, with the ability to click on the features to turn them on or off in a given text block.

Why you would use them?

Given that these features take a bit of work to discover and use, it may seem a fair question to ask why one would bother to use them. The answer lies in the specific features that will make a site more useful, readable, and polished:

- **Ligatures** like 'ff' or 'fi' make letter spacing and reading more even and smooth.
- **Fractions** can make home improvement and recipe sites much easier to read and understand.
- **Numerals** within paragraphs of text set as 'oldstyle' sit more comfortably between lower-case letters, and likewise setting them as 'tabular numbers' will make them line up better when setting a list of costs in a table say. 'lining' figures on the other hand sit more uniformly on their own or in front of capitalized words.

While none of these features individually will render a site useless due to their absence, each of them in turn can make a site easier to use and more memorable for its attention to detail.

> OpenType features are like secret compartments in fonts. Unlock them and you'll find ways to make fonts look and behave differently in subtle and dramatic ways. Not all OpenType features are appropriate to use all of the time, but some features are critical for great typography. -- *Tim Brown, Head of Typography at Adobe.*

Sometimes it's substance, not just style

There are some cases — like with `font-variant-east-asian` — that OpenType features are directly tied to using different forms of certain glyphs, which can impact meaning and readability. In cases such as these, it's more than just a nicety, but rather an integral part of the content itself.

The font features

There are a number of different features to consider. They are grouped and explained here according to the main attributes and options covered in the W3C specifications.

> **Note:** The examples below show the properties and some example combinations, along with the lower-level syntax equivalents. They may not match exactly due to browser implementation inconsistencies, but in many cases, the first example will match the second. The typefaces shown are Playfair Display, Source Serif Pro, IBM Plex Serif, Dancing Script, and Kokoro (all available and free to use, most are on Google Fonts and other services).

Kerning

Associated CSS property: `font-kerning`

This refers to the spacing between specific glyph pairings. This is generally on by default (as recommended by the OpenType specification). It should be noted that if `letter-spacing` is also set on your text, that is applied after kerning. Click "Play" in the code blocks below to edit the example in the MDN Playground:

```
<fieldset>
  <legend>Using <code>font-kerning</code> property</legend>
  <div class="container container1">
    <p>Puffy Pangolins</p>
  </div>
  <input type="checkbox" name="checkbox1" id="checkbox1" value="on" checked />
  <label for="checkbox1">Kerning active</label>
</fieldset>

<fieldset>
  <legend>Using <code>font-feature-settings</code> property</legend>
  <div class="container container2">
    <p>Puffy Pangolins</p>
  </div>
  <input type="checkbox" name="checkbox2" id="checkbox2" value="on" checked />
  <label for="checkbox2">Kerning active</label>
</fieldset>
```

```
@font-face {
  font-family: "Plex Serif";
  font-weight: normal;
  font-style: normal;
  font-stretch: normal;
  src:
    url("https://mdn.github.io/shared-assets/fonts/plex/IBMPlexSerif-Regular.woff")
      format("woff"),
    url("https://mdn.github.io/shared-assets/fonts/plex/IBMPlexSerif-Regular.woff2")
      format("woff2");
}

body {
  font:
    1.2em "Plex Serif",
    "Times New Roman",
    serif;
  margin: 1rem;
}

fieldset {
  margin-bottom: 1rem;
}

label {
  user-select: none;
}

.container > p {
  font-size: 4rem;
  margin: 1.5rem 0;
}
```

```
/* kerning: auto|normal|none */
.container1 * {
  font-kerning: normal;
}
.inactive.container1 * {
  font-kerning: none;
}

/* 'kern' 1|0 (on or off) */
.container2 * {
  font-feature-settings: "kern" 1;
}
.inactive.container2 * {
  font-feature-settings: "kern" 0;
}
```

```
const checkBox1 = document.getElementById("checkbox1");
const checkBox2 = document.getElementById("checkbox2");
const container1 = document.querySelector(".container1");
const container2 = document.querySelector(".container2");

const toggleInactive = (checkBox, container) => {
  if (checkBox.checked) {
    container.classList.remove("inactive");
  } else {
    container.classList.add("inactive");
  }
};

checkBox1.addEventListener("change", () => {
  toggleInactive(checkBox1, container1);
});

checkBox2.addEventListener("change", () => {
  toggleInactive(checkBox2, container2);
});
```

Alternates

Associated CSS property: `font-variant-alternates`

Fonts can supply a number of different alternatives for various glyphs, such as different styles of lower case 'a' or more or less elaborate swashes in a script typeface. This property can activate an entire set of alternates or just a specific one, depending on the values supplied. The example below is showing several different aspects of working with alternate characters. Fonts with alternate glyphs can make them available across the board or individually in separate stylistic sets, or even individual characters. In this example you can see two different typefaces, and the introduction of the `@font-feature-values` at-rule. This is used to define shortcuts or named options that can be defined per font family. This way you can create a named option that applies to only a single font, or one that is shared and can be applied more generally. Click "Play" in the code blocks below to edit the example in the MDN Playground:

```
<fieldset>
  <legend>Using <code>font-variant-alternates</code> property</legend>
  <div class="container container1">
    <p><span class="script">My</span> Perfidious pangram</p>
  </div>
  <input type="checkbox" name="checkbox1" id="checkbox1" value="on" checked />
  <label for="checkbox1">Alternates active</label>
</fieldset>

<fieldset>
  <legend>Using <code>font-feature-settings</code> property</legend>
  <div class="container container2">
    <p><span class="script">My</span> Perfidious pangram</p>
  </div>
  <input type="checkbox" name="checkbox2" id="checkbox2" value="on" checked />
  <label for="checkbox2">Alternates active</label>
</fieldset>
```

```
@font-face {
  font-family: "Plex Serif";
  font-weight: normal;
  font-style: normal;
  font-stretch: normal;
  src:
    url("https://mdn.github.io/shared-assets/fonts/plex/IBMPlexSerif-Regular.woff")
      format("woff"),
    url("https://mdn.github.io/shared-assets/fonts/plex/IBMPlexSerif-Regular.woff2")
      format("woff2");
}

@font-face {
  font-family: "Dancing Script";
  font-weight: normal;
  font-style: normal;
  font-stretch: normal;
  src:
    url("https://mdn.github.io/shared-assets/fonts/dancing-script/dancing-script-regular.woff")
      format("woff"),
    url("https://mdn.github.io/shared-assets/fonts/dancing-script/dancing-script-regular.woff2")
      format("woff2");
}

body {
  font:
    1.2em "Plex Serif",
    "Times New Roman",
    serif;
  margin: 1rem;
}

.script {
  font-family: "Dancing Script", serif;
}

fieldset {
  margin-bottom: 1rem;
}

label {
  user-select: none;
}

.container > * {
  font-size: 4rem;
  margin: 1.5rem 0;
}
```

```
@font-feature-values "Plex Serif" {
  @styleset {
```

```
    alt-a: 1;
    alt-g: 2;
  }
  @stylistic {
    alternates: 1;
  }
}

@font-feature-values "Dancing Script" {
  @stylistic {
    alternates: 1;
  }
}

.container1 * {
  font-variant-alternates: styleset(alt-a);
}
.container1 .script {
  font-variant-alternates: stylistic(alternates);
}
.inactive.container1 * {
  font-variant-alternates: normal;
}

.container2 * {
  font-feature-settings: "ss01";
}
.container2 .script {
  font-feature-settings: "salt";
}
.inactive.container2 * {
  font-feature-settings:
    "ss01" 0,
    "salt" 0;
}
```

```
const checkBox1 = document.getElementById("checkbox1");
const checkBox2 = document.getElementById("checkbox2");
const container1 = document.querySelector(".container1");
const container2 = document.querySelector(".container2");

const toggleInactive = (checkBox, container) => {
  if (checkBox.checked) {
    container.classList.remove("inactive");
  } else {
    container.classList.add("inactive");
  }
};

checkBox1.addEventListener("change", () => {
  toggleInactive(checkBox1, container1);
});

checkBox2.addEventListener("change", () => {
  toggleInactive(checkBox2, container2);
});
```

In this case, `@stylistic(alternates)` will show all the alternate characters for either font. Applying this to just the word 'My' alters the way the 'M' renders, and applying `@styleset(alt-a)` only changes the lower case 'a'.

Try changing the line

```
font-variant-alternates: styleset(alt-a);
```

to

```
font-variant-alternates: styleset(alt-g);
```

and notice that the lower case 'a' reverts to its regular form and the lower case 'g's changes instead.

Ligatures

Associated CSS property: `font-variant-ligatures`

Ligatures are glyphs that replace two or more separate glyphs in order to represent them more smoothly (from a spacing or aesthetic perspective). Some of the most common are letters like 'fi', 'fl', or 'ffl' — but there are many other possibilities. There are the most frequent ones (referred to as common ligatures), and there are also more specialized categories like 'discretionary ligatures', 'historical ligatures', and 'contextual alternates'. While these last ones are not technically ligatures, they are generally similar in that they replace specific combinations of letters when they appear together.

While more common in script typefaces, in the below example they are used to create arrows. Click "Play" in the code blocks below to edit the example in the MDN Playground:

```
<fieldset>
  <legend>Using <code>font-variant-ligatures</code> property</legend>
  <div class="container container1">
    <p>Puffy Perfect -^ &lt;-&gt;</p>
  </div>
  <input type="checkbox" name="checkbox1" id="checkbox1" value="on" checked />
  <label for="checkbox1">Ligatures active</label>
</fieldset>

<fieldset>
  <legend>Using <code>font-feature-settings</code> property</legend>
  <div class="container container2">
    <p>Puffy Perfect -^ &lt;-&gt;</p>
  </div>
  <input type="checkbox" name="checkbox2" id="checkbox2" value="on" checked />
  <label for="checkbox2">Ligatures active</label>
</fieldset>
```

```
@font-face {
  font-family: "Playfair Display";
```

```
  font-weight: normal;
  font-style: normal;
  font-stretch: normal;
  src:
    url("https://mdn.github.io/shared-assets/fonts/playfair-display/playfair-display-regular.woff")
      format("woff"),
    url("https://mdn.github.io/shared-assets/fonts/playfair-display/playfair-display-regular.woff2")
      format("woff2");
}

body {
  font:
    1.2em "Playfair Display",
    "Times New Roman",
    serif;
  margin: 1rem;
}

fieldset {
  margin-bottom: 1rem;
}

label {
  user-select: none;
}

.container > p {
  font-size: 4rem;
  margin: 1.5rem 0;
}
```

```
.container1 * {
  font-variant-ligatures: common-ligatures discretionary-ligatures contextual;
}
.inactive.container1 * {
  font-variant-ligatures: none;
}

/* 'liga', 'dlig', 'hlig', 'calt' */
.container2 * {
  font-feature-settings: "dlig", "liga", "calt";
}
.inactive.container2 * {
  font-feature-settings:
    "dlig" 0,
    "liga" 0,
    "calt" 0;
}
```

```
const checkBox1 = document.getElementById("checkbox1");
const checkBox2 = document.getElementById("checkbox2");
const container1 = document.querySelector(".container1");
const container2 = document.querySelector(".container2");

const toggleInactive = (checkBox, container) => {
  if (checkBox.checked) {
    container.classList.remove("inactive");
  } else {
    container.classList.add("inactive");
  }
};

checkBox1.addEventListener("change", () => {
  toggleInactive(checkBox1, container1);
});

checkBox2.addEventListener("change", () => {
  toggleInactive(checkBox2, container2);
});
```

Position

Associated CSS property: `font-variant-position`

Position variants are used to enable typographic superscript and subscript glyphs. These are designed to work with the surrounding text without altering the baseline or line spacing. This is especially useful with the `<sub>` or `<sup>` elements. Click "Play" in the code blocks below to edit the example in the MDN Playground:

```
<fieldset>
  <legend>Using <code>font-variant-position</code> property</legend>
  <div class="container container1">
    <p>Ups<span class="super">1</span> and downs<span class="sub">2</span></p>
  </div>
  <input type="checkbox" name="checkbox1" id="checkbox1" value="on" checked />
  <label for="checkbox1">Position active</label>
</fieldset>

<fieldset>
  <legend>Using <code>font-feature-settings</code> property</legend>
  <div class="container container2">
    <p>Ups<span class="super">1</span> and downs<span class="sub">2</span></p>
  </div>
  <input type="checkbox" name="checkbox2" id="checkbox2" value="on" checked />
  <label for="checkbox2">Position active</label>
</fieldset>
```

```
@font-face {
  font-family: "Playfair Display";
  font-weight: normal;
  font-style: normal;
  font-stretch: normal;
  src:
```

```
    url("https://mdn.github.io/shared-assets/fonts/playfair-display/playfair-display-regular.woff")
      format("woff"),
    url("https://mdn.github.io/shared-assets/fonts/playfair-display/playfair-display-regular.woff2")
      format("woff2");
}

body {
  font:
    1.2em "Playfair Display",
    "Times New Roman",
    serif;
  margin: 1rem;
}

fieldset {
  margin-bottom: 1rem;
}

label {
  user-select: none;
}

.container > p {
  font-size: 4rem;
  margin: 1.5rem 0;
}
```

```
/* position: normal|sub|super */
.container1 .super {
  font-variant-position: super;
}
.container1 .sub {
  font-variant-position: sub;
}
.inactive.container1 * {
  font-variant-position: normal;
}

/* 'subs', 'sups' */
.container2 .super {
  font-feature-settings: "sups";
}
.container2 .sub {
  font-feature-settings: "subs";
}
.inactive.container2 * {
  font-feature-settings:
    "sups" 0,
    "subs" 0;
}
```

```
const checkBox1 = document.getElementById("checkbox1");
const checkBox2 = document.getElementById("checkbox2");
const container1 = document.querySelector(".container1");
const container2 = document.querySelector(".container2");

const toggleInactive = (checkBox, container) => {
  if (checkBox.checked) {
    container.classList.remove("inactive");
  } else {
    container.classList.add("inactive");
  }
};

checkBox1.addEventListener("change", () => {
  toggleInactive(checkBox1, container1);
});

checkBox2.addEventListener("change", () => {
  toggleInactive(checkBox2, container2);
});
```

Capitals

Associated CSS property: `font-variant-caps`

One of the more common use cases for OpenType features is proper small caps. These are capital letters sized to fit better among lower case letters and are generally used for acronyms and abbreviations. Click "Play" in the code blocks below to edit the example in the MDN Playground:

```
<fieldset>
  <legend>Using <code>font-variant-caps</code> property</legend>
  <div class="container container1">
    <p>
      <span class="small-caps">Small Caps</span> and
      <span class="all-small-caps">All Small Caps</span>
    </p>
  </div>
  <input type="checkbox" name="checkbox1" id="checkbox1" value="on" checked />
  <label for="checkbox1">Caps active</label>
</fieldset>

<fieldset>
  <legend>Using <code>font-feature-settings</code> property</legend>
  <div class="container container2">
    <p>
      <span class="small-caps">Small Caps</span> and
      <span class="all-small-caps">All Small Caps</span>
    </p>
  </div>
  <input type="checkbox" name="checkbox2" id="checkbox2" value="on" checked />
```

```
  <label for="checkbox2">Caps active</label>
</fieldset>
```

```
@font-face {
  font-family: "Playfair Display";
  font-weight: normal;
  font-style: normal;
  font-stretch: normal;
  src:
    url("https://mdn.github.io/shared-assets/fonts/playfair-display/playfair-display-regular.woff")
      format("woff"),
    url("https://mdn.github.io/shared-assets/fonts/playfair-display/playfair-display-regular.woff2")
      format("woff2");
}

body {
  font:
    1.2em "Playfair Display",
    "Times New Roman",
    serif;
  margin: 1rem;
}

fieldset {
  margin-bottom: 1rem;
}

label {
  user-select: none;
}

.container > p {
  font-size: 4rem;
  margin: 1.5rem 0;
}
```

```
/* position: normal | small-caps | all-small-caps | petite-caps | all-petite-caps | unicase | titling-caps */
.container1 .small-caps {
  font-variant-caps: small-caps;
}
.container1 .all-small-caps {
  font-variant-caps: all-small-caps;
}
.inactive.container1 * {
  font-variant-caps: normal;
}

/* 'smcp', 'c2sc' */
.container2 .small-caps {
  font-feature-settings: "smcp" 1;
}
.container2 .all-small-caps {
  font-feature-settings:
    "c2sc" 1,
    "smcp" 1;
}
.inactive.container2 * {
  font-feature-settings:
    "smcp" 0,
    "c2sc" 0;
}
```

```
const checkBox1 = document.getElementById("checkbox1");
const checkBox2 = document.getElementById("checkbox2");
const container1 = document.querySelector(".container1");
const container2 = document.querySelector(".container2");

const toggleInactive = (checkBox, container) => {
  if (checkBox.checked) {
    container.classList.remove("inactive");
  } else {
    container.classList.add("inactive");
  }
};

checkBox1.addEventListener("change", () => {
  toggleInactive(checkBox1, container1);
});

checkBox2.addEventListener("change", () => {
  toggleInactive(checkBox2, container2);
});
```

Numerals

Associated CSS property: `font-variant-numeric`

There are several different styles of numerals commonly included in fonts:

- 'Lining' figures are all the same height and on the same baseline.
- 'Oldstyle' figures are mixed height and designed to have the appearance of ascenders and descenders like other lower case letters. These are designed to be used inline with a copy so the numerals visually blend with the surrounding glyphs in a similar fashion to small caps.

There is also the notion of spacing. Proportional spacing is the normal setting, whereas tabular spacing lines up numerals evenly regardless of character width, making it more appropriate for lining up tables of numbers in financial tables.

There are two types of fractions supported through this property:

- Diagonal slashed fractions.
- Vertically stacked fractions.

Ordinals are also supported (such as '1st' or '3rd'), as is a slashed zero if present in the font.

Lining and old-style figures

Click "Play" in the code blocks below to edit the example in the MDN Playground:

```
<fieldset>
  <legend>Using <code>font-variant-numeric</code> property</legend>
  <div class="container container1">
    <p>
      <span class="lining">6,142</span> or <span class="oldstyle">6,142</span>
    </p>
  </div>
  <input type="checkbox" name="checkbox1" id="checkbox1" value="on" checked />
  <label for="checkbox1">Numeric active</label>
</fieldset>

<fieldset>
  <legend>Using <code>font-feature-settings</code> property</legend>
  <div class="container container2">
    <p>
      <span class="lining">6,142</span> or <span class="oldstyle">6,142</span>
    </p>
  </div>
  <input type="checkbox" name="checkbox2" id="checkbox2" value="on" checked />
  <label for="checkbox2">Numeric active</label>
</fieldset>
```

```
@font-face {
  font-family: "Source Serif";
  font-weight: normal;
  font-style: normal;
  font-stretch: normal;
  src:
    url("https://mdn.github.io/shared-assets/fonts/source-serif/SourceSerifPro-Regular.ttf.woff")
      format("woff"),
    url("https://mdn.github.io/shared-assets/fonts/source-serif/SourceSerifPro-Regular.ttf.woff2")
      format("woff2");
}

body {
  font:
    1.2em "Source Serif",
    "Times New Roman",
    serif;
  margin: 20px;
  padding: 0;
}

fieldset {
  margin-bottom: 1rem;
}

label {
  user-select: none;
}

.container > p {
  font-size: 4rem;
  margin: 1.5rem 0;
}
```

```
.container1 .lining {
  font-variant-numeric: lining-nums;
}
.container1 .oldstyle {
  font-variant-numeric: oldstyle-nums;
}
.inactive.container1 * {
  font-variant-numeric: normal;
}

.container2 .lining {
  font-feature-settings: "lnum" 1;
}
.container2 .oldstyle {
  font-feature-settings: "onum" 1;
}
.inactive.container2 * {
  font-feature-settings:
    "lnum" 0,
    "onum" 0;
}
```

```
const checkBox1 = document.getElementById("checkbox1");
const checkBox2 = document.getElementById("checkbox2");
const container1 = document.querySelector(".container1");
const container2 = document.querySelector(".container2");

const toggleInactive = (checkBox, container) => {
  if (checkBox.checked) {
    container.classList.remove("inactive");
  } else {
    container.classList.add("inactive");
  }
};

checkBox1.addEventListener("change", () => {
  toggleInactive(checkBox1, container1);
});

checkBox2.addEventListener("change", () => {
```

```
  toggleInactive(checkBox2, container2);
});
```

Fractions, ordinals, and slashed zero

Click "Play" in the code blocks below to edit the example in the MDN Playground:

```
<fieldset>
  <legend>Using <code>font-variant-numeric</code> property</legend>
  <div class="container container1">
    <p>
      <span class="diagonal-fractions">3/16</span>, or
      <span class="ordinal">1st</span> of <span class="zero">0</span>
    </p>
  </div>
  <input type="checkbox" name="checkbox1" id="checkbox1" value="on" checked />
  <label for="checkbox1">Numeric active</label>
</fieldset>

  user-select: none;
}

.container > p {
  font-size: 4rem;
  margin: 1.5rem 0;
}
```

```
.container1 * {
  font-variant-east-asian: normal;
}
.inactive.container1 * {
  font-variant-east-asian: jis78;
}

.container2 * {
  font-feature-settings: "jp78" 0;
}
.inactive.container2 * {
  font-feature-settings: "jp78";
}
```

```
const checkBox1 = document.getElementById("checkbox1");
const checkBox2 = document.getElementById("checkbox2");
const container1 = document.querySelector(".container1");
const container2 = document.querySelector(".container2");

const toggleInactive = (checkBox, container) => {
  if (checkBox.checked) {
    container.classList.remove("inactive");
  } else {
    container.classList.add("inactive");
  }
};

checkBox1.addEventListener("change", () => {
  toggleInactive(checkBox1, container1);
});
```

```
checkBox2.addEventListener("change", () => {
  toggleInactive(checkBox2, container2);
});
```

> **Note:** These glyphs were copied out of a font sample and are not intended as prose.

Font variant shorthand

The `font-variant` property is the shorthand syntax for defining all of the above. Setting a value of `normal` resets all properties to their initial value. Setting a value of `none` sets `font-variant-ligatures` to none and all other properties to their initial value. Meaning that if kerning is on by default, it will still be on even with a value of `none` being supplied here. Click "Play" in the code blocks below to edit the example in the MDN Playground:

```
<fieldset>
  <legend>Using <code>font-variant</code> property</legend>
  <div class="container container1">
    <p>Spiffy Plastic -> 3/4 time</p>
  </div>
  <input type="checkbox" name="checkbox1" id="checkbox1" value="on" checked />
  <label for="checkbox1">Features active</label>
</fieldset>

<fieldset>
  <legend>Using <code>font-feature-settings</code> property</legend>
  <div class="container container2">
    <p>Spiffy Plastic -> 3/4 time</p>
  </div>
  <input type="checkbox" name="checkbox2" id="checkbox2" value="on" checked />
  <label for="checkbox2">Features active</label>
</fieldset>
```

```
@font-face {
  font-family: "Playfair Display";
  font-weight: normal;
  font-style: normal;
  font-stretch: normal;
  src:
    url("https://mdn.github.io/shared-assets/fonts/playfair-display/playfair-display-regular.woff")
      format("woff"),
    url("https://mdn.github.io/shared-assets/fonts/playfair-display/playfair-display-regular.woff2")
      format("woff2");
}

body {
  font:
    1.2em "Playfair Display",
    "Times New Roman",
    serif;
  margin: 20px;
  padding: 0;
}

fieldset {
  margin-bottom: 1rem;
}

label {
  user-select: none;
}

.container > p {
  font-size: 4rem;
  margin: 1.5rem 0;
}
```

```
.container1 * {
  font-variant: common-ligatures discretionary-ligatures contextual
    diagonal-fractions;
}
.inactive.container1 * {
  font-variant: none;
}

.container2 * {
  font-feature-settings: "dlig", "liga", "calt", "frac";
}
.inactive.container2 * {
  font-feature-settings:
    "dlig" 0,
    "liga" 0,
    "calt" 0,
    "frac" 0;
}
```

```
const checkBox1 = document.getElementById("checkbox1");
const checkBox2 = document.getElementById("checkbox2");
const container1 = document.querySelector(".container1");
const container2 = document.querySelector(".container2");

const toggleInactive = (checkBox, container) => {
  if (checkBox.checked) {
    container.classList.remove("inactive");
  } else {
    container.classList.add("inactive");
  }
};

checkBox1.addEventListener("change", () => {
  toggleInactive(checkBox1, container1);
});
```

```
checkBox2.addEventListener("change", () => {
  toggleInactive(checkBox2, container2);
});
```

Font feature settings

`font-feature-settings` is the 'low-level syntax' that allows explicit access to every named available OpenType feature. This gives a lot of control but has some disadvantages in how it impacts inheritance and — as mentioned above — if you wish to change one setting, you have to redeclare the entire string (unless you're using CSS custom properties to set the values). Because of this, it's best to use the standard properties shown above wherever possible.

There are a huge number of possible features. You can see examples of a number of them above, and there are several resources available for finding more of them.

The general syntax looks like this:

```
.small-caps {
  font-feature-settings: "smcp", "c2sc";
}
```

According to the specification you can either supply just the 4-character feature code or supply a 1 following the code (for enabling that feature) or a 0 (zero) to disable it. This is helpful if you have a feature like ligatures enabled by default but you would like to turn them off like so:

```
.no-ligatures {
  font-feature-settings:
    "liga" 0,
    "dlig" 0;
}
```

More on font-feature-settings codes

- 'The Complete CSS Demo for OpenType Features' (can't vouch for the truth of the name, but it's pretty big)
- A list of OpenType features on Wikipedia

Using CSS feature detection for implementation

Since not all properties are evenly implemented, it's good practice to set up your CSS using feature detection to utilize the correct properties, with `font-feature-settings` as the fallback.

For example, small caps can be set several ways, but if you want to ensure that no matter what the underlying capitalization is that you end up with everything in small caps, it requires 2 settings with `font-feature-settings` versus a single property value using `font-variant-caps`.

```
.small-caps {
  font-feature-settings: "smcp", "c2sc";
}

@supports (font-variant-caps: all-small-caps) {
  .small-caps {
    font-feature-settings: normal;
    font-variant-caps: all-small-caps;
  }
}
```

Variable fonts

Variable fonts are an evolution of the OpenType font specification that enables many different variations of a typeface to be incorporated into a single file, rather than having a separate font file for every width, weight, or style. They let you access all the variations contained in a given font file via CSS and a single `@font-face` reference. This article will give you all you need to know to get you started using variable fonts.

> **Note:** To use variable fonts on your operating system, you need to make sure that it is up to date. For example, Linux OSes need the latest Linux FreeType version, and macOS prior to High Sierra (10.13) does not support variable fonts. If your operating system is not up to date, you will not be able to use variable fonts in web pages or the Firefox Developer Tools.

Variable Fonts: what they are, and how they differ

To better understand what's different about variable fonts, it is worth reviewing what non-variable ones are like and how they compare.

Standard (or Static) fonts

In the past, a typeface would be produced as several individual fonts, and each font would represent one specific width/weight/style combination. So you would have separate files for 'Roboto Regular', 'Roboto Bold', and 'Roboto Bold Italic' — meaning that you could end up with 20 or 30 different font files to represent a complete typeface (it could be several times that for a large typeface that has different widths as well).

In such a scenario, to use a typeface for typical use on a site for body copy you would need at least four files: regular, italic, bold, and bold italic. If you wanted to add more weights, like a lighter one for captions or a heavier one for extra emphasis, that would mean several more files. This results in more HTTP requests, and more data being downloaded (usually around 20k or more per file).

Variable fonts

With a variable font, all of those permutations can be contained in a single file. That file would be larger than a single font, but in most cases smaller or about the same size as the 4 you might load for body copy. The advantage in choosing the variable font is that you have access to the entire range of weights, widths, and styles available, rather than being constrained to only the few that you previously would have loaded separately.

This allows for common typographic techniques such as setting different size headings in different weights for better readability at each size or using a slightly narrower width for data-dense displays. For comparison, it is typical in a typographic system for a magazine to use 10–15 or more different weight and width combinations throughout the publication — giving a much wider range of styles than currently typical on the web (or indeed practical for performance reasons alone).

A note about font families, weights, and variants

You might notice that we have been talking about having a specific font file for every weight and style (i.e., bold and italic and bold italic), rather than relying upon the browser to synthesize them. The reason for this is that most typefaces have very specific designs for bolder weights and italics that often include completely different characters (lower-case 'a' and 'g's are often quite different in italics, for example). To most accurately reflect the typeface design and avoid differences between browsers and how they may or may not synthesize the different styles, it's more accurate to load the specific font files where needed when using a non-variable font.

You may also find that some variable fonts come split into two files: one for uprights and all their variations, and one containing the italic variations. This is sometimes done to reduce the overall file size in cases where the italics aren't needed or used. In all cases, it is still possible to link them with a common `font-family` name so you can call them using the same `font-family` and appropriate `font-style`.

Introducing the 'variation axis'

The heart of the new variable fonts format is the concept of an **axis of variation** describing the allowable range of that particular aspect of the typeface design. So the 'weight axis' describes how light or how bold the letterforms can be; the 'width axis' describes how narrow or how wide they can be; the 'italic axis' describes if italic letterforms are present and can be turned on or off accordingly, etc. Note that an axis can be a range or a binary choice. Weight might range from 1–999, whereas italic might be 0 or 1 (off or on).

As defined in the specification, there are two kinds of axes: **registered** and **custom**:

- Registered axes are those that are most frequently encountered, and common enough that the authors of the specification felt it was worth standardizing. The five currently registered axes are weight, width, slant, italic, and optical size. The W3C has undertaken to map them to existing CSS attributes, and in one case introduced a new one, which you'll see below.
- Custom axes are limitless: the typeface designer can define and scope any axis they like and are just required to give it a four-letter **tag** to identify it within the font file format itself. You can use these four-letter tags in CSS to specify a point along that axis of variation, as will be shown in the code examples below.

Registered axes and existing CSS attributes

In this section we'll demonstrate the five registered axes defined with examples and the corresponding CSS. Where possible, both the standard and lower-level syntax are included. The lower-level syntax (`font-variation-settings`) was the first mechanism implemented to test the early implementations of variable font support and is necessary to utilize new or custom axes beyond the five registered ones. However, the W3C's intent was for this syntax not to be used when other attributes are available. Therefore wherever possible, the appropriate property should be used, with the lower-level syntax of `font-variation-settings` only being used to set values or axes not available otherwise.

Notes

1. When using `font-variation-settings` it is important to note that axis names are case-sensitive. The registered axis names must be in lower case, and custom axes must be in upper case. For example:

   ```
   font-variation-settings:
     "wght" 375,
     "GRAD" 88;
   ```

   `wght` (weight) is a registered axis, and `GRAD` (grade) is a custom one.

2. If you have set values using `font-variation-settings` and want to change one of those values, you must redeclare all of them (in the same way as when you set OpenType font features using `font-feature-settings`). You can work around this limitation by using CSS Custom Properties (CSS variables) for the individual values, and modifying the value of an individual custom property. Example code follows at the end of the guide.

Weight

Weight (represented by the `wght` tag) defines the design axis of how thin or thick (light or heavy, in typical typographic terms) the strokes of the letterforms can be. For a long time in CSS there has existed the ability to specify this via the `font-weight` property, which takes numeric values ranging from 100 to 900 in increments of 100, and keywords like `normal` or `bold`, which are aliases for their corresponding numeric values (400 and 700 in this case). These are still applied when dealing with non-variable or variable fonts, but with variable ones, any number from 1 to 1000 is now valid.

It should be noted that at this point there is no way in the `@font-face` declaration to 'map' a specific point on the variation axis of a variable font to the keyword `bold` (or any other keyword). This can generally be resolved fairly easily, but does require an extra step in writing your CSS:

```
font-weight: 375;

font-variation-settings: "wght" 375;
```

Click "Play" in the code blocks below to edit the example in the MDN Playground. Edit the CSS code to play with font-weight values.

```
<div>
  <p class="p1">Weight</p>
  <span>(font-weight: 625)</span>
</div>
<div>
  <p class="p2">Weight</p>
  <span>(font-variation-settings: "wght" 625)</span>
</div>
<div class="adjustable">
  <p class="p3">Weight</p>
  (font-variation-settings: "wght" <span id="angle-text">625</span>)<br />
  <label for="text-axis">Adjust Weight: </label>
  <input
    type="range"
    id="text-axis"
    name="text-axis"
    min="300"
    max="900"
    value="625" />
</div>
```

```
@font-face {
  font-family: "Amstelvar VF";
  src: url("https://mdn.github.io/shared-assets/fonts/variable-fonts/AmstelvarAlpha-VF.woff2")
    format("woff2-variations");
  font-weight: 300 900;
  font-stretch: 35% 100%;
  font-style: normal;
  font-display: swap;
```

```
}

p {
  font:
    1.2em "Amstelvar VF",
    "Georgia",
    serif;
  font-size: 4rem;
  margin: 1rem;
  display: inline-block;
}

.adjustable {
  border: 1px dashed;
  --text-axis: 625;
}
```

```
/* weight range is 300 to 900 */
.p1 {
  font-weight: 625;
}

/* weight range is 300 to 900 */
.p2 {
  font-variation-settings: "wght" 625;
}

/* Adjust with slider & custom property */
.p3 {
  font-variation-settings: "wght" var(--text-axis);
}
```

```
const angle = document.querySelector("#text-axis");
const text = document.querySelector("#angle-text");
const adjustable = document.querySelector(".adjustable");

angle.addEventListener("input", (e) => {
  const angle = e.target.value;
  text.innerText = angle;
  adjustable.style.setProperty("--text-axis", angle);
});
```

Width

Width (represented by the `wdth` tag) defines the design axis of how narrow or wide (condensed or extended, in typographic terms) the letterforms can be. This is typically set in CSS using the `font-stretch` property, with values expressed as a percentage above or below 'normal' (100%), any number greater than 0 is technically valid—though it is far more likely that the range would fall closer to the 100% mark, such as 75%-125%. If a number value supplied is outside the range encoded in the font, the browser should render the font at the closest value allowed.

> **Note:** The % symbol is not used when utilizing `font-variation-settings`.

```
font-stretch: 115%;

font-variation-settings: "wdth" 115;
```

Click "Play" in the code blocks below to edit the example in the MDN Playground. Edit the CSS code to play with font width values.

```
<div>
  <p class="p1">Width</p>
  <span>(font-stretch: 60%)</span>
</div>
<div>
  <p class="p2">Width</p>
  <span>(font-variation-settings: "wdth" 60)</span>
</div>
<div class="adjustable">
  <p class="p3">Width</p>
  (font-variation-settings: "wdth" <span id="angle-text">60</span>)<br />

  <label for="text-axis">Adjust Width: </label>
  <input
    type="range"
    id="text-axis"
    name="text-axis"
    min="55"
    max="100"
    value="60" />
</div>
```

```
@font-face {
  font-family: "Amstelvar VF";
  src: url("https://mdn.github.io/shared-assets/fonts/variable-fonts/AmstelvarAlpha-VF.woff2")
    format("woff2-variations");
  font-weight: 300 900;
  font-stretch: 35% 100%;
  font-style: normal;
  font-display: swap;
}

p {
  font:
    1.2em "Amstelvar VF",
    "Georgia",
    serif;
  font-size: 4rem;
  margin: 1rem;
  display: inline-block;
}
```

```
.adjustable {
  border: 1px dashed;
  --text-axis: 60;
}
```

```
/* width range is 55% to 100% */
.p1 {
  font-stretch: 60%;
}

/* width range is an integer from 55 to 100 */
.p2 {
  font-variation-settings: "wdth" 60;
}

/* Adjust with slider & custom property */
.p3 {
  font-variation-settings: "wdth" var(--text-axis);
}
```

```
const angle = document.querySelector("#text-axis");
const text = document.querySelector("#angle-text");
const adjustable = document.querySelector(".adjustable");

angle.addEventListener("input", (e) => {
  const angle = e.target.value;
  text.innerText = angle;
  adjustable.style.setProperty("--text-axis", angle);
});
```

Italic

The Italic (`ital`) axis can be set in the range `[0-1]`, where `0` specifies "not italic," `0.5` specifies "halfway italic," and `1` specifies "fully italic." Italic designs often include dramatically different letterforms from their upright counterparts, so in the transition from upright to italic, several glyph (or character) substitutions usually occur. Italic and oblique are often used somewhat interchangeably, but in truth are quite different. Oblique is defined in this context with the term `slant` (see the below section), and a typeface would typically have one or the other, but not both.

In CSS, both italic and oblique are applied to text using the `font-style` property. Also note the introduction of `font-synthesis: none;` — which will prevent browsers from accidentally applying the variation axis and a synthesized italic. This can be used to prevent faux-bolding as well.

```
font-style: italic;

font-variation-settings: "ital" 1;

font-synthesis: none;
```

Click "Play" in the code blocks below to edit the example in the MDN Playground. Edit the CSS code to play with font-italics.

```
<div>
  <p class="p1">Italic</p>
  <span>(font-style: italic)</span>
  <p class=".p1-no-synthesis">Italic</p>
  <span>(font-style: italic; font-synthesis: none)</span>
</div>
<div>
  <p class="p2">Italic</p>
  <span>(font-variation-settings: "ital" 1)</span>
</div>
<div class="adjustable">
  <p class="p3">Italic</p>
  (font-variation-settings: "ital" <span id="angle-text">1</span>)<br />

  <label for="slant-angle">Adjust Italic: </label>
  <input
    type="range"
    id="text-axis"
    name="text-axis"
    min="0"
    max="1"
    value="1" />
</div>
```

```
@font-face {
  font-family: "Jost VF";
  src: url("https://mdn.github.io/shared-assets/fonts/variable-fonts/jost-VF.woff2")
    format("woff2-variations");
  font-weight: 300 900;
  font-stretch: 75% 150%;
  font-display: swap;
}

p {
  font:
    1.2em "Jost VF",
    "Helvetica",
    "Arial",
    sans-serif;
  font-size: 4rem;
  margin: 1rem;
  display: inline-block;
}

.adjustable {
  border: 1px dashed;
  --text-axis: 1;
}
```

```
/* font-style: italic, with and without font-synthesis */
.p1 {
  font-style: italic;
```

```
}

.p1-no-synthesis {
  font-style: italic;
  font-synthesis: none;
}

/* italic range is 0 or 1 */
.p2 {
  font-variation-settings: "ital" 1;
  font-synthesis: none;
}

/* Adjust with slider & custom property */
.p3 {
  font-synthesis: none;
  font-variation-settings: "ital" var(--text-axis);
}
```

```
const angle = document.querySelector("#text-axis");
const text = document.querySelector("#angle-text");
const adjustable = document.querySelector(".adjustable");

angle.addEventListener("input", (e) => {
  const angle = e.target.value;
  text.innerText = angle;
  adjustable.style.setProperty("--text-axis", angle);
});
```

Slant

Slant (represented by the `slnt` tag), or as it's often referred to, 'oblique' — is different from true italics in that it changes the angle of the letterforms but doesn't perform any kind of character substitution. It is also variable, in that it is expressed as a numeric range. This allows the font to be varied anywhere along the slant axis. The allowed range is from -90 to 90 degrees.

The two properties that can control the slant are `font-style` and `font-variation-settings`. The following two property declarations are the same:

```
font-style: oblique 14deg;

font-variation-settings: "slnt" -14;
```

Prefer the `font-style` property over the `font-variation-settings` property. The `deg` keyword is not used when using the `font-variation-settings` property. Also, in the case of the `font-variation-settings` property, a positive angle means a counter-clockwise slant.

In the following live example, you can adjust the slant.

```
<div>
  <p class="font-style">Slant</p>
  <span>(font-style: oblique 5deg)</span>
</div>
<div>
  <p class="font-variation">Slant</p>
  <span>(font-variation-settings: 'slnt' -5)</span>
</div>
<div class="adjustable-box">
  <p class="adjustable">Slant</p>
  (font-variation-settings: 'slnt' <span id="angle-text">-5</span>)<br />

  <label for="slant-angle">Adjust Slant: </label>
  <input
    type="range"
    name="range-slider"
    value="5"
    id="slant-angle"
    min="-15"
    max="15" />
</div>
```

```
@font-face {
  font-family: "SlantFont";
  font-style: oblique -15deg 15deg;
  src: url("https://mdn.github.io/shared-assets/fonts/font_with_slant_axis.woff2")
    format("woff2");
}

p {
  font-family: "SlantFont", sans-serif;
  display: inline-block;
  margin: 1rem;
  font-size: 4rem;
}

.adjustable-box {
  border: 1px dashed;
  --text-axis: -5;
}
```

```
.font-style {
  font-style: oblique 5deg;
}

.font-variation {
  font-variation-settings: "slnt" -5;
}

.adjustable {
  font-variation-settings: "slnt" var(--slant-angle);
}
```

```
const angle = document.querySelector("#slant-angle");
const text = document.querySelector("#angle-text");
```

```
const adjustable = document.querySelector(".adjustable");

angle.addEventListener("input", (e) => {
  const angle = -1 * e.target.value;
  text.innerText = angle;
  adjustable.style.setProperty("--slant-angle", angle);
});
```

Optical size

This is something new to digital fonts and CSS, but is a centuries-old technique in designing and creating metal type. Optical sizing refers to the practice of varying the overall stroke thickness of letterforms based on physical size. If the size was very small (such as an equivalent to 10 or 12px), the characters would have an overall thicker stroke, and perhaps other small modifications to ensure that it would reproduce and be readable at a physically smaller size. Conversely, when a much larger size was being used (like 48 or 60px), there might be much greater variation in thick and thin stroke weights, showing the typeface design more in line with the original intent.

While this was originally done to compensate for the ink and paper printing process (very thin lines at small sizes often didn't print, giving the letterforms a broken appearance), it translates well to digital displays when compensating for screen quality and physical size rendering.

Optical size values are generally intended to be automatically applied corresponding to `font-size`, but can also be manipulated using the lower-level `font-variation-settings` syntax.

There is a new attribute, `font-optical-sizing`, created to support variable fonts in CSS. When using `font-optical-sizing`, the only allowed values are `auto` or `none` — so this attribute only allows for turning optical sizing on or off. However when using `font-variation-settings: 'opsz' <num>`, you can supply a numeric value. In most cases you would want to match the `font-size` (the physical size the type is being rendered) with the `opsz` value (which is how optical sizing is intended to be applied when using `auto`). The option to provide a specific value is provided so that should it be necessary to override the default — for legibility, aesthetic, or some other reason — a specific value can be applied.

```
font-optical-sizing: auto;

font-variation-settings: "opsz" 36;
```

Click "Play" in the code blocks below to edit the example in the MDN Playground. Edit the CSS code to play with optical size values.

```
<div>
  <p class="p1">Optical Size</p>
  <span>(font-optical-sizing: none)</span>
</div>
<div>
  <p class="p2">Optical Size</p>
  <span>(font-optical-sizing: auto)</span>
</div>
<div>
  <p class="p3">Optical Size</p>
  <span>(font-variation-settings: "opsz" 64)</span>
</div>

<div class="adjustable">
  <p class="p4">Optical Size</p>
  (font-variation-settings: "opsz" <span id="angle-text">-64</span>)<br />

  <label for="slant-angle">Adjust Optical Sizing: </label>
  <input
    type="range"
    name="text-axis"
    value="64"
    id="text-axis"
    min="8"
    max="144" />
</div>
```

```
@font-face {
  font-family: "Amstelvar VF";
  src: url("https://mdn.github.io/shared-assets/fonts/variable-fonts/AmstelvarAlpha-VF.woff2")
    format("woff2-variations");
  font-weight: 300 900;
  font-stretch: 75% 150%;
  font-style: normal;
  font-display: swap;
}

p {
  font:
    1.2em "Amstelvar VF",
    "Georgia",
    serif;
  font-size: 4rem;
  margin: 1rem;
  display: inline-block;
}

.adjustable {
  border: 1px dashed;
  --text-axis: 64;
}
```

```
.p1 {
  font-optical-sizing: none;
}
/* font-optical-sizing can be auto or none */
.p2 {
  font-optical-sizing: auto;
}

/* optical range is from 8 to 144 */
.p3 {
  font-variation-settings: "opsz" 64;
}

/* Adjust with slider & custom property */
.p4 {
```

```
  font-variation-settings: "opsz" var(--text-axis);
}
```

```
const angle = document.querySelector("#text-axis");
const text = document.querySelector("#angle-text");
const adjustable = document.querySelector(".adjustable");

angle.addEventListener("input", (e) => {
  const angle = e.target.value;
  text.innerText = angle;
  adjustable.style.setProperty("--text-axis", angle);
});
```

Custom axes

Custom axes are just that: they can be any axis of design variation that the typeface designer imagines. There may be some that become fairly common — or even become registered — but only time will tell.

Grade

Grade may become one of the more common custom axes as it has a known history in typeface design. The practice of designing different grades of a typeface was often done in reaction to intended use and printing technique. The term 'grade' refers to the relative weight or density of the typeface design, but differs from traditional 'weight' in that the physical space the text occupies does not change, so changing the text grade doesn't change the overall layout of the text or elements around it. This makes grade a useful axis of variation as it can be varied or animated without causing a reflow of the text itself.

```
font-variation-settings: "GRAD" 88;
```

Click "Play" in the code blocks below to edit the example in the MDN Playground. Edit the CSS code to play with font-grade values.

```
<div>
  <p class="p1">Grade</p>
  <span>(font-variation-settings: 'GRAD' 88)</span>
</div>

<div class="adjustable">
  <p class="p2">Grade</p>
  (font-variation-settings: 'GRAD' <span id="angle-text">88</span>)<br />

  <label for="slant-angle">Adjust Grade: </label>
  <input
    type="range"
    name="text-axis"
    value="88"
    id="text-axis"
    min="88"
    max="150" />
</div>
```

```
@font-face {
  font-family: "Amstelvar VF";
  src: url("https://mdn.github.io/shared-assets/fonts/variable-fonts/AmstelvarAlpha-VF.woff2")
    format("woff2-variations");
  font-weight: 300 900;
  font-stretch: 75% 150%;
  font-style: normal;
  font-display: swap;
}

p {
  font:
    1.2em "Amstelvar VF",
    "Georgia",
    serif;
  font-size: 64px;
  margin: 1rem;
  display: inline-block;
}

.adjustable {
  border: 1px dashed;
  --text-axis: 88;
}
```

```
/* grade range is 88 to 150 */
.p1 {
  font-size: 64px;
  font-variation-settings: "GRAD" 88;
}

/* Adjust with slider & custom property */
.p2 {
  font-size: 64px;
  font-variation-settings: "GRAD" var(--text-axis);
}
```

```
const angle = document.querySelector("#text-axis");
const text = document.querySelector("#angle-text");
const adjustable = document.querySelector(".adjustable");

angle.addEventListener("input", (e) => {
  const angle = e.target.value;
  text.innerText = angle;
  adjustable.style.setProperty("--text-axis", angle);
});
```

Using a variable font: @font-face changes

The syntax for loading variable fonts is very similar to any other web font, with a few notable differences, which are provided via upgrades to the traditional `@font-face` syntax now available in modern browsers.

The basic syntax is the same, but the font technology can be specified, and allowable ranges for descriptors like `font-weight` and `font-stretch` can be supplied, rather than named according to the font file being loaded.

Example for a standard upright (Roman) font

```
@font-face {
  font-family: "MyVariableFontName";
  src: url("path/to/font/file/my-variable-font.woff2")
    format("woff2-variations");
  font-weight: 125 950;
  font-stretch: 75% 125%;

  font-style: normal;
}
```

In this case, the `font-style: normal` declaration indicates that this font file should be used when `font-family` is set to `MyVariableFontName` and `font-style` is set to `normal`. As an alternative, you could use `font-style: oblique 0deg` or `font-style: oblique 0deg 20deg` to indicate that the font has normal upright glyphs (indicated by `0deg`).

Example for a font that contains only italics and no upright characters

```
@font-face {
  font-family: "MyVariableFontName";
  src: url("path/to/font/file/my-variable-font.woff2")
    format("woff2-variations");
  font-weight: 125 950;
  font-stretch: 75% 125%;

  font-style: italic;
}
```

In this case, the `font-style: italic` declaration indicates that this font file should be used when `font-family` is set to `MyVariableFontName` and `font-style` is set to `italic`. As an alternative, you could use `font-style: oblique 14deg` to indicate that the font has italic glyphs.

Example for a font that contains an oblique (slant) axis

```
@font-face {
  font-family: "MyVariableFontName";
  src: url("path/to/font/file/my-variable-font.woff2")
    format("woff2-variations");
  font-weight: 125 950;
  font-stretch: 75% 125%;

  font-style: oblique 0deg 12deg;
}
```

In this case, the `oblique 0deg 12deg` value indicates that this font file should be used when in a style rule the `font-family` property is `MyVariableFontName` and the font-style property is oblique with an angle between zero and 12 degrees inclusive.

> **Note:** Not all browsers have implemented the full syntax for font format, so test carefully. All browsers that support variable fonts will still render them if you set the format to just the file format, rather than format-variations (i.e., `woff2` instead of `woff2-variations`), but it's best to use the proper syntax if possible.

> **Note:** Supplying value ranges for `font-weight`, `font-stretch`, and `font-style` will keep the browser from attempting to render an axis outside that range if you are using the appropriate attribute (i.e., `font-weight` or `font-stretch`), but will not block you from supplying an invalid value via `font-variation-settings`, so use with care.

Working with older browsers

Variable font support can be checked with CSS Feature Queries (see `@supports`), so it's possible to use variable fonts in production and scope the CSS calling the variable fonts inside a feature query block.

```
h1 {
  font-family: some-non-variable-font-family;
}

@supports (font-variation-settings: "wdth" 115) {
  h1 {
    font-family: some-variable-font-family;
  }
}
```

Sample pages

The following example pages show two different ways to structure your CSS. The first uses the standard attributes wherever possible. The second example uses CSS Custom Properties to set values for a `font-variation-settings` string and shows how you can more easily update single variable values by overriding a single variable rather than rewriting the whole string. Note the hover effect on the `h2`, which only alters the grade axis custom property value. Click "Play" in the code blocks below to edit the example in the MDN Playground:

```
<div class="container container1">
  <h1>Moby-Dick</h1>
  <h2>CHAPTER 1. Loomings.</h2>
  <p>
    Call me Ishmael. Some years ago—never mind how long precisely—having little
    or no money in my purse, and nothing particular to interest me on shore, I
    thought I would sail about a little and see the watery part of the world. It
    is a way I have of driving off the spleen and regulating the circulation.
    Whenever I find myself growing grim about the mouth; whenever it is a damp,
    drizzly November in my soul; whenever I find myself involuntarily pausing
    before coffin warehouses, and bringing up the rear of every funeral I meet;
    and especially whenever my hypos get such an upper hand of me, that it
    requires a strong moral principle to prevent me from deliberately stepping
    into the street, and methodically knocking people's hats off then, I account
    it high time to get to sea as soon as I can.
  </p>
</div>
<hr />

Web Open Font Format (WOFF)

WOFF (the **Web Open Font Format**) is a web font format developed by Mozilla in concert with Type Supply, LettError, and other organizations. It uses a compressed version of the same table-based `sfnt` structure used by TrueType, OpenType, and Open Font Format, but adds metadata and private-use data structures, including predefined fields allowing foundries and vendors to provide license information if desired.

There are three main benefits to using WOFF:

1. The font data is compressed, so sites using WOFF will use less bandwidth and will load faster than if they used equivalent uncompressed TrueType or OpenType files.
2. Many font vendors that are unwilling to license their TrueType or OpenType format fonts for use on the web will license WOFF format fonts. This improves availability of fonts to site designers.
3. Both proprietary and free software browser vendors like the WOFF format, so it has the potential of becoming a truly universal, interoperable font format for the web, unlike other current font formats.

There are two versions of WOFF: WOFF and WOFF2. They mostly differ in regard to the compression algorithm used. In `@font-face` they are identified by the `'woff'` and `'woff2'` format descriptor respectively.

Using WOFF

You can use the `@font-face` CSS property to use WOFF fonts for text in web content. It works exactly like OpenType and TrueType format fonts do, except it will likely let your content download more efficiently due to the addition of compression.

Tools for working with WOFF fonts

- Tools for working with WOFF fonts are available. `sfnt2woff` and `woff2sfnt` convert between WOFF and OpenType.

CSS fragmentation

The **CSS fragmentation** module defines how content is displayed when it is broken (fragmented) and flows across multiple pages, regions, or columns. This module defines features for pagination, breaking variable fragment size and orientation, widows and orphans.

This module explains how content breaks across fragmentation containers and how such breaks can be controlled by the author. The generic term for breaking content across containers is *fragmentation*. Fragmentation occurs when an inline box wraps onto multiple lines. This can happen when using layout features such as CSS multi-column layout: For example, when a block spans more than one column inside a column layout container, or spans a page break when printed. Each piece of the rendering for the element is called a *fragment*.

When content is physically printed or displayed as a print preview, there are page breaks. In this paged media, as opposed to continuous media, document content can be split between one or more pages, or fragments. To avoid awkward breaks, such as halfway through a line of text or with a lone word on its own page, browsers can move content that would otherwise fall across the page break in a process is called *pagination*.

CSS gaps

The **CSS gaps** module lets you specify spacing, or "gaps", between items in multi-column, flexbox, and grid layouts. The CSS multi-column layout module originally defined gaps and rules that control the spacing between columns in multi-column containers. This module expands on these visible separators, called *gap decorations*, extending it to grid and flexbox.

While `margin` and `padding` specify visual spacing around individual boxes, the properties in this module enable specifying the spacing between adjacent boxes within a given layout context for layouts that have gutters and gaps, when the spacing is different between sibling boxes as opposed to between the first box, last box, and the container's edge. You can show rules in every gap or in a subset of gaps, defining fully animatable rule widths, colors, and insets.

Gap decorations are painted within a gap as one or more gap decoration segments, with segments occurring between any two adjacent items. When all segments are drawn, column and row rules span the entire height and width of the container. The `rule-visibility-items` property defines whether segments are to be drawn around areas that are not occupied by items. The `rule-break` properties determine if lines break when they intersect a gap, while `rule-inset` defines where segments start and end when rules do break. If they don't break, the `rule-overlap` property defines the painting order of the rules.

Gaps in action

In this example, the 2021 poem from the USA inauguration, *The Hill We Climb*, by Amanda Gorman, is displayed across multiple columns, similar to the way articles are displayed in printed newspapers. If you have JavaScript enabled, controls enable changing the `column-gap`, `column-rule-color`, `column-rule-style` and `column-rule-width` properties, as well as the preferred number of columns and whether the title and a quote should span all of the columns.

```
<article>
  <div class="title">
    <h1>The Hill We Climb</h1>
    <p>&mdash;Amanda Gorman, 2021</p>
  </div>
  <p>
    When day comes, we ask ourselves where can we find light in this never
    ending shade? The loss we carry, a sea we must wade. We braved the belly of
    the beast.
  </p>

  <p>
    We've learned that quiet isn't always peace and the norms and notions of
    what just is, isn't always justice. And yet the dawn is hours before we knew
    it, somehow we do it, somehow we've weathered and witnessed a nation that
    isn't broken but simply unfinished.
  </p>

  <p>
    We, the successors of a country and a time, where a skinny black girl
    descended from slaves and raised by a single mother can dream of becoming
    president, only to find herself reciting for one.
  </p>

  <p>
    And yes, we are far from polished, far from pristine, but that doesn't mean
    we are striving to form a union that is perfect. We are striving to forge
    our union with purpose, to compose a country committed to all cultures,
    colors, characters, and conditions of man. And so we lift our gazes not to
    what stands between us but what stands before us. We close the divide
    because we know to put our future first. We must first put our differences
    aside.
  </p>

  <p>
    We lay down our arms so we can reach out our arms to one another We seek
    harm to none and harmony for all. Let the globe, if nothing else, say this
    is true, that even as we grieved, we grew. That even as we hurt, we hoped.
  </p>

  <p>
    That even as we tired, we tried. That we'll forever be tied together,
    victorious, not because we will never again know defeat, but because we will
    never again sow division.
  </p>

  <p>
    Scripture tells us to envision that everyone shall sit under their own vine
    and fig tree, and no one shall make them afraid.
  </p>

  <p>
    If we’re to live up to our own time, then victory won't lighten the blade
    but in all the bridges we've made, that is the promise to glade, the hill we
    climb if only we dare, it's because being American is more than a pride we
    inherit. It's the past we stepped into and how we repair it.
  </p>

  <blockquote>
    <p>
      We've seen a force that would shatter our nation rather than share it,
      would destroy our country if it meant delaying democracy.
    </p>
  </blockquote>

  <p>
    And this effort very nearly succeeded. But while democracy can be
    periodically delayed, it can never be permanently defeated. In this truth,
    in this faith, we trust. For while we have our eyes on the future, history
    has its eyes on us.
  </p>

  <p>
    This is the era of just redemption. We feared -- at its deception. We did
    not feel prepared to be the heirs of such a terrifying hour, but within it
    we found the power to author a new chapter, to offer hope and laughter to
    ourselves.
  </p>

  <p>
    So, while once we asked, "how could we possibly prevail over catastrophe?",
    now we assert, "how could catastrophe possibly prevail over us?" We will not
    march back to what was, but move to what shall be, a country that is bruised
    but whole, benevolent but bold, fierce and free. We will not be turned
    around or interrupted by intimidation.
  </p>

  <p>
    Because we know our inaction and inertia will be the inheritance of the next
    generation. Our blunders become their burdens. But one thing is certain. If
    we merge mercy with might and might with right, then love becomes our legacy
    and change, our children's birth right.
  </p>

  <p>
    So let us leave behind a country better than one we were left with, every
```

```
    breath from my bronze pounded chest, we will raise this wounded world into a
    wondrous one. We will rise through the gold-limbed hills in the west, we
    will rise from the windswept northeast where our forefathers first realized
    revolution. We will rise from the lake-rimmed cities of the Midwestern
    states.
  </p>

  <p>
    We will rise from the sun-baked South. We will rebuild, reconcile, and
    recover, in every known nook of our nation, in every corner called our
    country, our people diverse and beautiful, will emerge battered and
    beautiful.
  </p>

  <p>When day comes, we step out of the shade, aflame and unafraid.</p>

  <p>
    The new dawn blooms as we free it for there is always light if only we're
    brave enough to see it, if only we're brave enough to be it.

Defining CSS gaps

When creating grid, flexbox, and multi-column layouts using CSS gap properties, you can define and control gaps between columns and rows.

While the `margin` and `padding` properties specify visual spacing around individual boxes, using the properties in the CSS gaps module, you can specify spacing between adjacent boxes in layouts that have gutters and gaps.

This guide explains column and row gaps in different layout types, how to define gaps, and how to use percentages as a `gap` value.

Understanding gaps

While margin and padding can specify spacing around individual boxes, it's sometimes more convenient to specify spacing between adjacent boxes within a given layout. This is particularly true when the spacing between sibling boxes differs from the spacing between the first or last box and the container's edge. The `gap` property, and its `row-gap` and `column-gap` constituent properties, provide this functionality for grid, flexbox, and multi-column layouts.

A *gap* is either a *column gap* or a *row gap*. Their definitions vary by layout type. For all layout types, any gap disappears when it coincides with a fragmentation break.

Grid container gaps

In the context of a grid container, *row gaps* and *column gaps* refer to the gutters between grid rows and grid columns, respectively. The width of the gaps makes the affected grid lines behave as though they acquired thickness: the grid track between two grid lines is the space between the gutters that represent them. By default, the width of the gap is `0` in both directions.

For the purpose of track sizing, each gutter is treated as an extra, empty, fixed-size track of the specified size. A grid item that spans multiple rows or columns also spans the gutters between them.

For example, if `gap: 20px` is set on a 4x4 grid of `100px` by `100px` boxes, the grid would be `460px` by `460px`. While each box is `100px` by `100px`, a grid item that spans two horizontal rows has a height of `220px`. If it spans three, its height is `340px`. If it spans all four, its height is `460px`.

Gutter gaps set the minimum spacing between items: additional spacing may be added by `justify-content` and `align-content` property values, increasing the size of the corresponding gaps.

Gutters appear only between tracks of the implicit grid. If a grid is fragmented between tracks, no gutter spacing is added between those tracks. There is no gutter before the first track or after the last track. If a track is collapsed, it has no gutter.

Flex container gaps

Flex containers are created by setting `display` to `flex` or `inline-flex` on an element containing multiple children. By default, flex items are laid out in a single, non-wrapping row. The default gap between adjacent flex items and, if wrapping, between adjacent columns or rows, is `0`. Whether a flex container with multiple items has columns, rows, or both depends on the flow and wrapping set using the `flex-flow` shorthand.

You can add gaps between adjacent flex items along the main axis. If the `flex-flow` property is set to `row wrap` or `row-reverse wrap`, *column gap* refers to the gutter between adjacent flex items and *row gap* refers to the gutter between flex rows. If `flex-flow` is set to `column wrap` or `column-reverse wrap`, *row gap* refers to the gutter between adjacent flex items and *column gap* refers to the gutter between flex rows.

Multi-column gaps

Multi-col containers are block-level elements with more than one column created by setting the `column-count` to a value greater than `1`. By default, columns are laid out in a single row, with a `1em` wide *column gap* between adjacent columns. The *row gap* is the gutter between rows of column boxes established by setting a `column-height` that requires columns to wrap, creating additional rows.

Using the <code>gap</code> shorthand

The `row-gap` property sets the size of the gap (gutter) between adjacent rows within a container. The `column-gap` property sets the size between a container's columns. Each property value can be specified as a `<length>`, a `<percentage>`, or the keyword `normal`. Percentage values are calculated against the content box size of the container element for that dimension.

The `gap` shorthand defines gaps between both rows and columns and accepts one or two values. The default value is `normal` for both sub-properties. If only one value is declared, it applies to both row and column gaps. If two values are declared, the first sets the `row-gap` value and the second sets the `column-gap`.

The effect of the definition depends on whether the container uses grid, flexbox, or multi-column layout.

You can add visible separators to gaps; these are called gap decorations. If you add decorative rules for gaps between columns, rows, or both, they appear in the middle of their gap but have no effect on the size of the gap, nor do they affect the size of the container. These gap decorations are added to the otherwise "empty space" by using the `rule` shorthand or its constituent properties.

Gaps in grid layouts

In grid containers, the `gap` property defines the size of the gutters between vertical and horizontal tracks. The shorthand property is specified as a value for `<'row-gap'>`, followed optionally by a value for `<'column-gap'>`. If only one value is declared, it applies to both row and column gaps.

In this example, we create a grid container with seven columns:

```
.container {
  display: grid;
  grid-template-columns: repeat(7, 1fr);
}
```

Select different `gap` values to see how they change the spacing between rows and columns:

```
:has([value="a"]:checked) p {
  gap: 2px 10px;
}
:has([value="b"]:checked) p {
  gap: 10px 2px;
}
:has([value="c"]:checked) p {
  gap: 10px;
}
:has([value="d"]:checked) p {
  gap: 2px;
}
```

Gaps in flexbox layouts

In flex containers, the `gap` property defines the space between both flex items and flex lines. Whether the first value sets the gap between flex items or between flex lines depends on the direction in which the flex items are laid out.

Flex items are laid out in rows or columns depending on the value of the `flex-direction` property. If set to `row` or `row-reverse`, the first value defines the gap between flex lines, and the second value defines the gap between adjacent flex items within each line. If only one value is included, it applies to both gaps.

If the `flex-direction` is set to `column` or `column-reverse`, the first value defines the gap between adjacent flex items within a flex line, and the second value defines the gaps between flex lines. Again, if only one value is included, it applies to both gaps.

In this example, we create a flex container and allow the flex items to wrap:

```
.container {
  display: flex;
  flex-wrap: wrap;
  max-width: 300px;
  height: 500px;
}
```

Select different `gap` and `flex-direction` values to see how they change the spacing between flex items and flex lines:

```
i {
  flex: 0 0 18%;
}
i:nth-of-type(2n) {
  flex: 0 0 12%;
}
i:nth-of-type(3n) {
  flex: 0 0 26%;
}
i:nth-of-type(5n) {
  flex: 0 0 20%;
}
i:nth-of-type(7n) {
  flex: 0 0 34%;
}
```

```
:has([value="a"]:checked) p {
  gap: 2px 10px;
}
:has([value="b"]:checked) p {
  gap: 10px 2px;
}
:has([value="c"]:checked) p {
  gap: 10px;
}
:has([value="d"]:checked) p {
  gap: 2px;
}

:has([value="row"]:checked) p {
  flex-direction: row;
}
:has([value="rowR"]:checked) p {
  flex-direction: row-reverse;
}
:has([value="col"]:checked) p {
  flex-direction: column;
}
:has([value="colR"]:checked) p {
  flex-direction: column-reverse;
}
```

```
<fieldset>
  <legend>Select a flex direction:</legend>
  <label
    ><input type="radio" value="row" name="dir" /> flex-direction: row;</label
  >
  <label
    ><input type="radio" value="rowR" name="dir" /> flex-direction:
    row-reverse;</label
  >
  <label
    ><input type="radio" value="col" name="dir" /> flex-direction:
    column;</label
  >
  <label
    ><input type="radio" value="colR" name="dir" /> flex-direction:
    column-reverse;</label
  >
</fieldset>
```

```
<fieldset>
  <legend>Select a layout</legend>
  <label><input type="radio" value="grid" name="dir" checked />Grid</label>
  <label><input type="radio" value="flex" name="dir" />Flexbox</label>
  <label
    ><input type="radio" value="flex2" name="dir" />Flexbox (columns)</label
  >
  <label><input type="radio" value="multicol" name="dir" />Multi-col</label>
</fieldset>
```

Gaps in multi-column layouts

In CSS multi-column layouts, the `gap` property defines the gutter between columns and between rows of columns. The first value defines the gap between rows of column boxes, if multiple rows are established by the `column-height` property. The second value defines the gap between adjacent column boxes.

In this example, we create a multi-col container using the `columns` shorthand property, setting a maximum of seven columns and a minimum column width of `1em`. A column height of `2.35em` enables the creation of additional rows. We also add a thin decorative rule in the middle of the gap using the `rule` property:

```
.container {
  columns: 7 1em / 2.35em;
  width: 450px;
  rule: 1px solid #cccccc;
}
@supports not (column-height: 1em) {
  body::before {
    content: "Your browser does not support the column-height property.";
    background-color: wheat;
    display: block;
    text-align: center;
    padding: 1rem 0;
  }
}
```

By default, there is a `1em` gap between rows and columns. Change this by selecting different `gap` values:

```
:has([value="a"]:checked) p {
  gap: 0.5em 3em;
}
:has([value="b"]:checked) p {
  gap: 3em 0.5em;
}
:has([value="c"]:checked) p {
  gap: 0.5em;
}
:has([value="d"]:checked) p {
  gap: 3em;
}
```

The gutters may appear larger than the specified gap size because the letters don't fill the allotted space. The decorative rule appears in the middle of the gap, either `0.25em` or `1.5em` from the block and inline starts of the column and row's content depending on the setting selected. The extra whitespace is at block- and inline-end, making the gaps look larger than they are.

```
<fieldset>
  <legend>Select a gap value:</legend>
  <label><input type="radio" value="a" name="gap" /> gap: 2px 10px;</label>
  <label><input type="radio" value="b" name="gap" /> gap: 10px 2px;</label>
  <label><input type="radio" value="c" name="gap" /> gap: 10px;</label>
  <label><input type="radio" value="d" name="gap" /> gap: 2px;</label>
</fieldset>
```

```
<fieldset>
  <legend>Select a gap value:</legend>
  <label><input type="radio" value="a" name="gap" /> gap: 0.5em 3em;</label>
  <label><input type="radio" value="b" name="gap" /> gap: 3em 0.5em;</label>
  <label><input type="radio" value="c" name="gap" /> gap: 0.5em;</label>
  <label><input type="radio" value="d" name="gap" /> gap: 3em;</label>
</fieldset>
```

```
<fieldset>
  <legend>Select a gap value:</legend>
  <label><input type="radio" value="a" name="gap" /> gap: 1% 5%;</label>
  <label><input type="radio" value="b" name="gap" /> gap: 5% 1%;</label>
  <label><input type="radio" value="c" name="gap" /> gap: 1%;</label>
  <label><input type="radio" value="d" name="gap" /> gap: 5%;</label>
</fieldset>
```

```
<div>
  <p class="container">
    <i>A</i>
    <i>B</i>
    <i>C</i>
    <i>D</i>
    <i>E</i>
    <i>F</i>
    <i>G</i>
    <i>H</i>
    <i>I</i>
    <i>J</i>
    <i>K</i>
    <i>L</i>
    <i>M</i>
    <i>N</i>
    <i>O</i>
    <i>P</i>
    <i>Q</i>
    <i>R</i>
    <i>S</i>
    <i>T</i>
    <i>U</i>
    <i>V</i>
    <i>W</i>
    <i>X</i>
    <i>Y</i>
    <i>Z</i>
  </p>
</div>
```

```
.container {
  font-size: 2rem;
  font-family: monospace;
  font-weight: bold;
}
i {
  background-color: #cccccc;
  text-align: center;
```

```
}
label {
  display: block;
  font-family: monospace;
  margin: 10px;
}
```

Specifying gap values as percentages

When a container has a fixed size, column and row gaps specified as percentages are calculated relative to the width and height of the container, respectively.

In this example, the size of the container is set. Select different gap sizes as percentage values, and change the layout type to see how the gaps are calculated relative to the container's size. Column gaps of `1%` and `5%` are `3px` and `15px` wide, respectively. Row gaps of `1%` and `5%` are `6px` and `30px` tall, respectively. These gap sizes apply even if the contents overflow the container.

```
.container {
  width: 300px;
  height: 600px;
  background-color: #eeeeee;
  rule: 1px dotted #666666;
}
```

Note that if you set the `gap` property to a single percentage value, the row gap is twice the size of the column gap because the container is twice as tall as it is wide.

```
fieldset {
  width: 44%;
  float: left;
}
p {
  clear: both;
  font-size: 1.25rem;
}

:has([value="a"]:checked) p {
  gap: 1% 5%;
}
:has([value="b"]:checked) p {
  gap: 5% 1%;
}
:has([value="c"]:checked) p {
  gap: 1%;
}
:has([value="d"]:checked) p {
  gap: 5%;
}

:has([value="grid"]:checked) p {
  display: grid;
  grid-template-columns: repeat(5, 1fr);
}
:has([value="flex"]:checked) p {
  display: flex;
  flex-flow: row wrap;
}
:has([value="flex2"]:checked) p {
  display: flex;
  flex-flow: column wrap;
}
:has([value="multicol"]:checked) p {
  columns: 5 2em / 2.35em;
}
```

If we don't have a defined height or width for the container, the behavior of percentage gap values is very different. If the container has a fixed width, percentage gap values are predictable. If the container is auto-sized, percentage gaps could create a circular dependency: the gaps depend on the container's size, but the container's size depends on the gaps. Browsers treat percentage gap values as `auto` (effectively `0`) during intrinsic sizing.

```
.container {
  background-color: #eeeeee;
  rule: 1px dotted #666666;
  height: auto;
  width: auto;
}
```

In the example, the width of the container is constrained by the containing block, while the height is not.

As percentage values are treated as `auto` during intrinsic sizing for gaps in grid layout, the gap is collapsed until the size of the container is determined. This means the size of the container is determined based solely on the dimensions of the content. If the example renders six rows of grid cells, there will be five row gaps, meaning the last row of grid items will overflow the background by either `5%` or `25%`, depending on whether the gap is set to `1%` or `5%`.

In flexbox layouts, the percentage gaps are treated as `0` or ignored during intrinsic sizing. The gap is applied only after sizing. As the container's block size is `auto`, the percentage row gaps resolve against `0`; so `1%` or `5%` of `0` is `0`. Percentage values are effectively ignored - the `row-gap` is `0` for both flexbox and multi-col layouts.

Defining CSS row and column gap rules

When creating grid, flexbox, and multi-column, you can add decorative lines, or *rules*, in the center of the gutters between rows and columns. You can show rules in every gap or a subset of gaps, and fully animate rule widths, colors, and insets. This guide explains how to specify the width, color, and style of these rules.

Overview

The CSS gaps module defines several properties that specify the appearance of lines painted behind content in a grid, flexbox, or multi-col container's gutters, or gaps. These lines don't affect the box model or layout. The size of the gutter is defined by the `gap` property, with the default value being `1em` on multi-column containers and `0` in all other contexts.

If a rule is wider than the gap, the lines are painted behind the content to avoid obscuring it. You should still ensure the color contrast of the content and both the background and the rule are sufficient to ensure legibility.

To learn more about specifying the spacing between adjacent boxes within a given layout context for layouts that have gutters and gaps, see Defining CSS gaps.

All the rule color, line-width, and line-style properties accept a comma-separated list of values, allowing for varying gap decorations within a container.

```
rule-color: blue;
rule-width: 10px, 20px;
rule-style: solid, dashed, solid, dotted;
```

You can use the `repeat()` function within the list to define a set number of repetitions, or to automatically add as many repetitions as needed to provide a value for every line drawn.

```
rule-color: blue, repeat(3, gray, red);
rule-width: 50px, repeat(10, 10px, 20px), 10px;
rule-style: solid, repeat(auto, dashed, dotted), solid;
```

The rule color, line-width, and line-style shorthand properties set the same values for both column and row rules.

The <code>repeat()</code> function

Before introducing the column and row rule properties, it is important to understand the `repeat()` function.

The `repeat()` function can be used to repeat a valid list of CSS values. The first argument specifies how many times to repeat the list of values passed as subsequent arguments. This allows color, line-width, or line-style values to repeat as many times as needed without listing them individually.

The following declarations are equivalent, with both creating a list of eight colors:

```
rule-color: blue, yellow, red, yellow, red, yellow, red, gray;
rule-color: blue, repeat(3, yellow, red), gray;
```

If the number of values exceeds the number of gaps, the excess values are ignored. For example, in a 3x3 grid container, the first row and column rules will be blue and the second yellow. The other color values in the list are unused.

If there are more gaps than values, the list is cycled. In a 10x10 grid container, there are nine gaps in each direction. In this case, the last rules are blue; the first eight row and column rules are each assigned the associated color, then the list cycles, so the ninth row and column rules get the first value in the list.

Here, with only three rows, only two values are used to color the row gaps, while the list is cycled to provide `<color>` values to each of the eleven column rules.

```
div {
  rule-color: blue, repeat(3, yellow, red), gray;
  grid-template-columns: repeat(12, 1fr);
}
```

The `repeat()` function's first parameter is either an `<integer>` of `1` or greater or the keyword `auto`. If the number is invalid (`0`, negative, missing, or a non-integer number), the entire declaration is invalid and ignored. The `auto` keyword within the `repeat()` function creates an *auto-repeater* that fills in values that would otherwise not receive values from other parts of the list, preventing the list from cycling. A property value can include, at most, one `repeat(auto, <value-list>)` auto-repeater.

By setting the following, in a grid that is 3x3 or larger, the `blue` and `gray` rules will each occur exactly once in each direction:

```
rule-color: blue, repeat(auto, yellow, red), gray;
```

In this case, `yellow` and `red` are repeated as many times as needed to fill in values for any rules that are not explicitly specified by other components of the property value. The first rule will always be blue. If there is more than one rule, the last will always be gray. All other rules will cycle between `yellow` and `red`.

```
div {
  rule-color: blue, repeat(auto, yellow, red), gray;
  grid-template-columns: repeat(12, 1fr);
}
```

Line properties

Every visible rule has a color, width, and style. Each of these can be defined as a single value or as a list of values.

Color properties

The `column-rule-color` property specifies the color of lines drawn between columns, the `row-rule-color` property defines the color of lines drawn between rows, and the `rule-color` property sets both the `column-rule-color` and `row-rule-color` to the same value. These properties are all specified as a comma-separated list of values, which can include:

`<color>`

> A valid `<color>` value specifying the color of a line. The default is `currentcolor`.

`<repeat-line-color>`

> A `repeat()` function, with an `<integer>` as the first argument and one or more `<color>` values as subsequent arguments. The `<integer>`, with a value of `1` or more, specifies how many times the list of `<color>` values should be repeated.

`<auto-repeat-line-color>`

> A `repeat()` function, with `auto` as the first argument and one or more `<color>` values as subsequent arguments. This creates an auto-repeater that assigns `<color>` values to gap rules that would otherwise not receive values from the other components of the property value, preventing the property's comma-separated list from cycling. At most, you can include only one `<auto-repeat-line-color>` value in the list.

By using `auto` inside the `repeat()` function as part of the `rule-color` property, we can set the first and last rules to dark and all middle rules to light.

```
div {
  rule-color: black, repeat(auto, lightgray), black;
}
```

If you change the number of columns from `6` to `4` or `8`, the first and last rules in each direction will still be `black` and all the other rules `lightgray`.

The gray horizontal lines are drawn over the black vertical lines. This is because, by default, the row rules are drawn on top of the column rules. This can be changed by setting the `rule-overlap` property to `column-over-row` instead of its default `row-over-column` value.

Width properties

The `column-rule-width` property specifies the width of the lines drawn between columns, the `row-rule-width` property defines the width of the lines drawn between rows, and the `rule-width` property sets both the `column-rule-width` and `row-rule-width` to the same values. These properties are all specified as a comma-separated list of values, which can include:

`<line-width>`

> Defines the width of the line, either as an explicit non-negative `<length>` or the keywords: `thin`, `medium`, or `thick`. The default is `medium`, which generally resolves to `3px`. Custom properties that resolve to a `<line-width>` are also valid.

`<repeat-line-width>`

> A `repeat()` function, with an `<integer>` as the first argument and one or more `<line-width>` values as subsequent arguments. The `<integer>`, with a value of `1` or more, specifies how many times the list of `<line-width>` values should be repeated.

`<auto-repeat-line-width>`

> A `repeat()` function, with `auto` as the first argument and one or more `<line-width>` values as subsequent arguments. This creates an auto-repeater that assigns `<line-width>` values to gap rules that would otherwise not receive values from the other components of the property value, preventing the property's comma-separated list from cycling. At most, you can include only one `<auto-repeat-line-width>` value in the list.

Unlike the `gap` properties, `rule-width` properties don't affect layout. These properties only define rule width. Rules appear in the middle of the gap, have no effect on the size of the gap, and have no impact on the box model. Rules that are wider than the gap are drawn behind the content.

In this example, the `gap` is specified as `20px`. We define varying rule sizes using the `rule-width` property:

```
div {
  rule-width: 10px, repeat(auto, 20px, 30px), 40px;
}
```

The black rules are centered in the gap. This is most noticeable in the first row and column gaps, where the `10px` line is drawn in the middle of the `20px` gap. Rules are drawn behind the content. This is most noticeable when `rule-width` is larger than the `gap`, and the lines show through the semi-opaque grid items.

The grid items all have black text and a semi-transparent, almost white background. Including a `background-color` on your content helps ensure that overflowing rules don't create accessibility issues. For your content to be accessible, there must be sufficient contrast between a background, be it the background color or the rule color, and the text or other important visual information.

Line-style properties

The `column-rule-style` property specifies the style of the lines drawn between columns, the `row-rule-style` property defines the style of the lines drawn between rows, and the `rule-style` sets both the `column-rule-style` and `row-rule-style` to the same value.

These properties are all specified as a comma-separated list of values, which can include:

`<line-style>`

> A keyword — `solid`, `dashed`, `dotted`, `double`, `groove`, `ridge`, `inset`, `outset`, `none`, or `hidden` — which defines the line style of the drawn rule. The default is `none`.

`<repeat-line-style>`

> A `repeat()` function, with an `<integer>` as the first argument and one or more `<line-style>` values as subsequent arguments. The `<integer>`, with a value of `1` or more, specifies how many times the list of `<line-style>` values should be repeated.

`<auto-repeat-line-style>`

> A `repeat()` function, with `auto` as the first argument and one or more `<line-style>` values as subsequent arguments. This creates an auto-repeater that assigns `<line-style>` values to gap rules that would otherwise not receive values from the other components of the property value, preventing the property's comma-separated list from cycling. At most, you can include only one `<auto-repeat-line-style>` value in the list.

As with `border`, the default value is `none`, so a rule must have a `<line-style>` declared with a value other than `hidden` or `none` for it to be painted.

In this example, we assign a list with seven values to the `column-rule-style` property. As the eight-column grid has seven column gaps, each value is used only once. The `row-rule-style` declaration has three values for three row rules, so again, each value is used once.

```
div {
  column-rule-style: solid, dotted, dashed, double, groove, ridge, inset;
  row-rule-style: outset, none, hidden;
}
```

```
div {
  grid-template-columns: repeat(8, 1fr);
}
```

Only the `outset` rules are drawn in the row gutters, as when the `<line-style>` is set to `none` or `hidden`, no line is painted.

Shorthand properties

The `row-rule`, `column-rule`, and `rule` shorthands can be used to declare the colors, line-widths, and line-styles for one or more lines in a single declaration.

These shorthand properties are all specified as a comma-separated list of values, from the following list:

`<gap-rule>`

> Specified as one, two, or three of the values `<line-width>`, `<line-style>`, and `<color>`, in any order. Just like with `border` shorthand values, the `<line-style>` must be included for a line to be painted, as it otherwise defaults to `none`. The default `<line-width>` is `medium` and the default `<color>` is `current-color`.

`<gap-repeat-rule>`

> A `repeat()` function, with an `<integer>` as the first argument and one or more `<gap-rule>` values as subsequent arguments. The `<integer>`, with a value of `1` or more, specifies how many times the list of `<gap-rule>` values should be repeated.

`<auto-repeat-gap-rule>`

> A `repeat()` function, with `auto` as the first argument and one or more `<gap-rule>` values as subsequent arguments. This creates an auto-repeater that assigns `<gap-rule>` values to gap rules that would otherwise not receive values from the other components of the property value, preventing the property's comma-separated list from cycling. At most, you can include only one `<auto-repeat-gap-rule>` value in the list.

The shorthand property declarations are similar to the constituent property values, but each value in the comma-separated list of values is a space-separated list of up to three component values. The `repeat()` function works the same way as with constituent properties, but again, each value is a space-separated list of components.

```
div {
  rule:
    10px solid blue,
    repeat(auto, 20px dashed teal, 5px double orange),
    15px inset rebeccapurple;
}
```

The `rule` shorthand sets both the `column-rule` and `row-rule` to the same value.

```

CSS generated content

The **CSS generated content** module defines how an element's content can be replaced and content can be added to a document with CSS.

Generated content can be used for content replacement, in which case the content of a DOM node is replaced with a CSS `<image>`. The CSS generated content also enables generating language-specific quotes, creating custom list item numbers and bullets, and visually adding content by generating content on select pseudo-elements as anonymous replaced elements.

Generated content in action

```
<div></div>
```

```
body,
div {
  background-repeat: no-repeat;
}
body {
  background-image: linear-gradient(#3a67ab, #e8f6ff 100%);
}
div {
  position: relative;
  width: 400px;
  height: 400px;
  background-image:
```

```
    linear-gradient(
      115deg,
      transparent 48%,
      brown,
      #996600,
      brown,
      transparent 52%
    ),
    linear-gradient(
      60deg,
      transparent 48%,
      brown,
      #996600,
      brown,
      transparent 52%
    ),
    radial-gradient(
      circle 10px at 50% 50%,
      #333333 30%,
      #999999 50%,
      transparent 50%
    ),
    radial-gradient(
      circle 10px at 50% 50%,
      #333333 30%,
      #999999 50%,
      transparent 50%
    ),
    radial-gradient(circle at 50% 50%, white 30%, #eeeeee 50%, transparent 50%),
    radial-gradient(circle at 50% 50%, white 30%, #eeeeee 50%, transparent 50%),
    radial-gradient(circle at 50% 50%, white 30%, #eeeeee 50%, transparent 50%);
  background-size:
    100px 100px,
    100px 100px,
    15px 15px,
    15px 15px,
    200px 200px,
    300px 300px,
    400px 400px;
  background-position:
    95% 120px,
    5% 120px,
    46% 80px,
    54% 80px,
    50% 0,
    50% 90px,
    50% 220px;
}
div::after {
  content: "";
  border: transparent solid 4px;
  border-left: orange 30px solid;
  height: 1px;
  width: 1px;
  position: absolute;
  left: 50%;
  top: 100px;
}

div::before {
  content: "Only one <div>";
  font-size: min(6vh, 2rem);
  justify-content: center;
  display: flex;
  font-family: "Comic Sans", "Papyrus", sans-serif;
}
```

The HTML for this sample is a single, empty `<div>` inside an otherwise empty `<body>`. The snowman was created with CSS images and CSS backgrounds and borders. The carrot nose was added using generated content: an empty box with a wide orange left border added to the `::before` pseudo-element. The text is also generated content: "only one " was generated with the `content` property applied to the `::after` pseudo-element.

Click "Play" in the example above to see or edit the code in the MDN Playground.

Reference

Properties

- `content`
- `quotes`

The CSS generated content module also introduces four at-risk properties: `string-set`, `bookmark-label`, `bookmark-level`, and `bookmark-state`. Currently, no browsers support these features.

Functions

The CSS generated content module introduces six yet-to-be implemented CSS functions including `content()`, `string()`, and `leader()`, and the three `<target>` functions `target-counter()`, `target-counters()`, and `target-text()`.

Data types

- `<content-list>`
- <content-replacement> (see `<image>`)
- `<image>`
- `<counter>`
- `<quote>`
- `<target>`

Guides

"How to" guide for generated content

CSS grid layout

The **CSS grid layout** module excels at dividing a page into major regions or defining the relationship in terms of size, position, and layering between parts of a control built from HTML primitives.

Like tables, grid layout enables an author to align elements into columns and rows. However, many more layouts are either possible or easier with CSS grid than they were with tables. For example, a grid container's child elements could position themselves so they actually overlap and layer, similar to CSS positioned elements.

Grid layout in action

The example shows a three-column track grid with new rows created at a minimum of 100 pixels and a maximum of auto. Items have been placed onto the grid using line-based placement.

```
<div class="wrapper">
  <div class="one">One</div>
  <div class="two">Two</div>
  <div class="three">Three</div>
  <div class="four">Four</div>
  <div class="five">Five</div>
  <div class="six">Six</div>
</div>
```

```
* {
  box-sizing: border-box;
}
.wrapper {
  max-width: 940px;
  margin: 0 auto;
}
.wrapper > div {
  border: 2px solid rgb(233 171 88);
  border-radius: 5px;
  background-color: rgb(233 171 88 / 50%);
  padding: 1em;
  color: #d9480f;
}
.wrapper {
  display: grid;
  grid-template-columns: repeat(3, 1fr);
  gap: 10px;
  grid-auto-rows: minmax(100px, auto);
}
.one {
  grid-column: 1 / 3;
  grid-row: 1;
}
.two {
  grid-column: 2 / 4;
  grid-row: 1 / 3;
}
.three {
  grid-column: 1;
  grid-row: 2 / 5;
}
.four {
  grid-column: 3;
  grid-row: 3;
}
.five {
  grid-column: 2;
  grid-row: 4;
}
.six {
  grid-column: 3;
```

```
  grid-row: 4;
}
```

This sample animation uses `display`, `grid-template-columns`, `grid-template-rows`, and `gap` to create the grid, and `grid-column` and `grid-row` to position items within the grid. To view and edit the HTML and CSS used, click the 'Play' at the top right of the example.

Guides

Basic concepts of grid layout

An overview of the various features provided in the CSS grid layout module.

Relationship of grid layout with other layout methods

How grid layout fits together with other CSS features including flexbox, absolutely positioned elements, and `display: contents`.

Grid layout using line-based placement

Grid lines and how to position items against those lines, including the `grid-area` properties, negative line numbers, spanning multiple cells, and creating grid gutters.

Grid template areas

Placing grid items using named template areas.

Grid layout using named grid lines

Combining names and track sizes; placing grid items by defining named grid lines and template areas.

Auto-placement in grid layout

How grid positions items that don't have any placement properties declared.

Aligning items in CSS grid layout

Aligning, justifying, and centering grid items along the two axes of a grid layout.

Grids, logical values, and writing modes

A look at the interaction between CSS grid layout, box alignment and writing modes, along with CSS logical and physical properties and values.

Grid layout and accessibility

A look at how CSS grid layout can both help and harm accessibility.

Realizing common layouts using grids

A few different layouts demonstrating different techniques you can use when designing with CSS grid layouts, including using `grid-template-areas`, a 12-column flexible grid system, and a product listing using auto-placement.

Subgrid

What subgrid does with use cases and design patterns that subgrid solves.

Grid lanes layout

Details what grid lanes layout is and how to use it.

Box alignment in CSS grid layout

How box alignment works in the context of grid layout.

Defining CSS gaps

Understanding and defining gaps in grid, flexbox, and multi-column layouts, including how percentage values are resolved.

Grid layout and accessibility

HTML is the content layer of a website where we create semantic, well-structured documents. CSS is the presentation layer; we apply CSS to create, among other things, the desired layout for our content. Two-dimensional grid structures are defined using CSS grid layout.

Even though modern HTML and CSS are designed to enable the creation of semantic, accessible content and designs, there are ways to *create* accessibility issues with grids. This article looks at the potential issues that can arise, and how to avoid them.

Re-ordering content in CSS grid layout

We've already seen in these guides that CSS grid layout gives us the power to re-order our page content by positioning items using line-based placement of grid template areas. This placement can be done without considering the item's location in the source. There is also the `order` property, which can change how items auto-place. The `grid-auto-flow` property has a `dense` value, which can take items visually out of the DOM order.

The CSS grid layout specification includes a Reordering and Accessibility section. The introduction to that section details what browsers should do when content is visually reordered using grid layout:

> Grid layout gives authors great powers of rearrangement over the document. However, these are not a substitute for correct ordering of the document source. The `order` property and grid placement do not affect ordering in non-visual media (such as speech). Likewise, rearranging grid items visually does not affect the default traversal order of sequential navigation modes (such as cycling through links, see e.g., `tabindex`).

If you reorder things visually using grid layout, this will not change how the items are ordered if the content is being read out by a screen reader, or other text to speech user agent. In addition, the reordering will not change tab order. This means that someone navigating using the keyboard could be tabbing through links on your site and suddenly find themselves jumping from the top to the bottom of the document due to a reordered item being next in the tab order.

The specification warns authors (the CSSWG term for web developers) not to do this reordering.

> Authors must use `order` and the grid-placement properties only for visual, not logical, reordering of content. Style sheets that use these features to perform logical reordering are non-conforming.

What does this mean for designing with grid layout in practice?

Visual not logical re-ordering

Any time you reorder things with grid layout – or with flexbox – you only perform *visual reordering*. The underlying source is what controls things like text to speech, and the tab order of the document. We can see how this works with an example.

In this example, we have a grid containing five items, each containing a link. The items are placed with line-based placement properties. We've positioned box 1 on the second row of the grid so it visually appears as the fourth item in the list. If we navigate through the links with the tab key, the tab order still begins with box 1, as it comes first in the source.

```
* {
  box-sizing: border-box;
}

.wrapper {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
}

.wrapper > div {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  padding: 1em;
  color: #d9480f;
}
```

```
.wrapper {
  display: grid;
  grid-template-columns: repeat(3, 1fr);
  grid-auto-rows: 100px;
}

.box1 {
  grid-column: 1;
  grid-row: 2;
}
```

```
<div class="wrapper">
  <div class="box box1"><a href="">One</a></div>
  <div class="box box2"><a href="">Two</a></div>
  <div class="box box3"><a href="">Three</a></div>
  <div class="box box4"><a href="">Four</a></div>
  <div class="box box5"><a href="">Five</a></div>
</div>
```

The specification says that in this scenario, if box 1 really makes sense logically in that position, we should go back to our HTML source and make the change there rather than reordering using grid layout. This is what is meant by visual versus logical reordering; logical ordering is important for the meaning and structure of our document and we should make sure that we preserve that structure.

How should we approach accessibility for grid layout?

From the specification we know that we need to ensure our document maintains the logical order of our content. How should we approach our development to make sure that we maintain accessibility for the different users and the ways that they interact with our pages?

Start with a structured and accessible document

> A grid layout should mean we do not need to change our document source in order to get the layout that we want. Therefore the starting point of your page should be a well structured and accessible source document. This is quite often going to give you a good structure for *your smallest screen devices too*. If a user is scrolling through a long document on mobile, the priorities for that user quite often map to what should be a priority in the source.

Create a responsive, and responsible grid

> With a solid document structure defined in your HTML, you can use CSS to add your layout on top. You will likely use media queries to make changes for different screen sizes and devices, including creating additional columns for larger screens. Grid can be very useful here. For example, elements deprioritized in the mobile source order can be moved into a sidebar in a desktop layout. The key here is to keep testing. A good test is to *tab around the document*. Does the order still make sense? Check that you do not end up leaping from the top to the bottom of the layout in a peculiar way. That is a sign that you need to address something about the layout.

Returning to the source

> If at any time in the design process you find yourself using grid to relocate the position of an element, consider whether you should return to your document and make a change to the logical order too. The nice thing about using CSS grid layout is that you should be able to move an item in the source to match the logical order, without needing to make big changes to your layout. The onus is on us as developers to remember to go back to our source and update it to maintain logical order.

Grid and the danger of markup flattening

Another issue to be aware of in CSS grid layout and to a lesser extent in CSS flexbox, is the temptation to *flatten* markup. As we have discovered, for an item to become a grid item it needs to be a direct child of the grid container. Therefore, where you have a `<ul>` element inside a grid container, *that* `ul` becomes a grid item – the child `<li>` elements do not.

The `subgrid` value of `grid-template-columns` and `grid-template-rows` solves this problem. It allows the grid to be inherited by grid items and passed down the tree. Alternatively, setting `display: contents` on a grid item causes the element's children to become grid items. If you set an item to `display: contents`, the box it would normally create disappears and the boxes of the child elements appear as if they have risen up a level.

Starting out with a well-structured document is a very good way to avoid accessibility problems.

Auto-placement in grid layout

CSS grid layout contains rules that control what happens when you create a grid and do not explicitly place some or all of the child items within the grid. When you don't need explicit control over content placement, this "auto-placement" is the simplest way of creating a grid for a set of items.

Default placement

If you don't give the items placement information, they automatically position themselves on the grid, placing one grid item in each grid cell.

```
body {
  font: 1.2em sans-serif;
}
* {
  box-sizing: border-box;
}

.wrapper {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
}

.wrapper > div {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  padding: 1em;
  color: #d9480f;
}
```

```
.wrapper {
  display: grid;
  grid-template-columns: repeat(3, 1fr);
  gap: 10px;
}
```

```
<div class="wrapper">
  <div>One</div>
  <div>Two</div>
  <div>Three</div>
  <div>Four</div>
  <div>Five</div>
</div>
```

Default rules for auto-placement

As you can see with the above example, if you create a grid without placing any items, the child items will lay themselves out, with one grid item in each grid cell in source-code order. The default flow is to arrange items by row. Grid will lay an item out into each cell of the first row. If you have created additional rows using the `grid-template-rows` property, then grid will continue placing items in these rows. If the grid does not have enough rows in the explicit grid to place all of the items new *implicit* rows will be created.

Sizing rows in the implicit grid

The default for automatically created rows in the implicit grid is for them to be *auto-sized*. This means that they will size themselves to contain the content added to them without causing an overflow.

The size of these rows can be controlled using the `grid-auto-rows` property. For example, to make all rows 100px tall, you can use `grid-auto-rows: 100px;`:

```
body {
  font: 1.2em sans-serif;
}
* {
  box-sizing: border-box;
}

.wrapper {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
}

.wrapper > div {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  padding: 1em;
  color: #d9480f;
}
```

```
<div class="wrapper">
  <div>One</div>
  <div>Two</div>
  <div>Three</div>
  <div>Four</div>
  <div>Five</div>
</div>
```

```
.wrapper {
  display: grid;
  grid-template-columns: repeat(3, 1fr);
  gap: 10px;
  grid-auto-rows: 100px;
}
```

Sizing rows using minmax()

The `minmax()` function enables creating rows that have a minimum size, and can grow to fit content as needed when set as the `grid-auto-rows` value. By setting `grid-auto-rows: minmax(100px, auto);` we set each row to be at least 100px tall, while allowing each row to be as tall as needed:

```
body {
  font: 1.2em sans-serif;
}
* {
  box-sizing: border-box;
}
```

```
.wrapper {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
}

.wrapper > div {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  padding: 1em;
  color: #d9480f;
}
```

```
<div class="wrapper">
  <div>One</div>
  <div>Two</div>
  <div>Three</div>
  <div>
    Four <br />This cell <br />Has extra <br />content. <br />Max is auto
    <br />so the row expands.
  </div>
  <div>Five</div>
</div>
```

```
.wrapper {
  display: grid;
  grid-template-columns: repeat(3, 1fr);
  gap: 10px;
  grid-auto-rows: minmax(100px, auto);
}
```

Sizing rows using a track listing

You can also pass in a track listing. This will repeat. The following track listing will create an initial implicit row track as 100 pixels and a second as `200px`. This will continue for as long as content is added to the implicit grid.

```
body {
  font: 1.2em sans-serif;
}
* {
  box-sizing: border-box;
}

.wrapper {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
}

.wrapper > div {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  padding: 1em;
  color: #d9480f;
}
```

```
<div class="wrapper">
  <div>One</div>
  <div>Two</div>
  <div>Three</div>
  <div>Four</div>
  <div>Five</div>
  <div>Six</div>
  <div>Seven</div>
  <div>Eight</div>
</div>
```

```
.wrapper {
  display: grid;
  grid-template-columns: repeat(3, 1fr);
  gap: 10px;
  grid-auto-rows: 100px 200px;
}
```

Auto-placement by column

You can also ask grid to auto-place items by column. Using the property `grid-auto-flow` with a value of `column`. In this case grid will add items in rows that you have defined using `grid-template-rows`. When it fills up a column it will move onto the next explicit column, or create a new column track in the implicit grid. As with implicit row tracks, these column tracks will be auto sized. You can control the size of implicit column tracks with `grid-auto-columns`. This works in the same way as `grid-auto-rows`.

In this example, we have a grid with three 200px high row tracks. We declare `grid-auto-flow: column;` to auto-place by column. With `grid-auto-columns: 300px 100px;`, the columns created will alternate between being `300px` wide and `100px` wide until there are enough column tracks to hold all of the items.

```
.wrapper {
  display: grid;
  grid-template-rows: repeat(3, 200px);
  gap: 10px;
  grid-auto-flow: column;
  grid-auto-columns: 300px 100px;
}
```

```
body {
  font: 1.2em sans-serif;
}
* {
  box-sizing: border-box;
}
```

```
.wrapper {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
}

.wrapper > div {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  padding: 1em;
  color: #d9480f;
}
```

```
<div class="wrapper">
  <div>One</div>
  <div>Two</div>
  <div>Three</div>
  <div>Four</div>
  <div>Five</div>
  <div>Six</div>
  <div>Seven</div>
  <div>Eight</div>
</div>
```

The order of auto placed items

A grid can contain a mixture of item placements. Some of the items may have a specifically defined position on the grid, while others may be auto-placed. If you have a document order that reflects the order in which items sit on the grid, you may not need to write CSS rules to place absolutely everything. The specification contains a long section detailing the Grid item placement algorithm; however, for most of us, we just need to remember a few rules for our items.

Order modified document order

Grid places items that have not been given a grid position in what is described in the specification as "order modified document order". This means that if you have used the `order` property at all, the items will be placed by that order, not their DOM order. Otherwise they will stay by default in the order that they are entered in the document source.

Items with placement properties

The first thing grid will do is place any items that have a position. In the example below I have 12 grid items. Item 2 and item 5 have been placed using line based placement on the grid. You can see how those items are placed and the other items then auto-place in the spaces. The auto-placed items will place themselves before the placed items in DOM order, they don't start after the position of a placed item that comes before them.

```
body {
  font: 1.2em sans-serif;
}
* {
  box-sizing: border-box;
}

.wrapper {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
}

.wrapper > div {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  padding: 1em;
  color: #d9480f;
}
```

```
<div class="wrapper">
  <div>One</div>
  <div>Two</div>
  <div>Three</div>
  <div>Four</div>
  <div>Five</div>
  <div>Six</div>
  <div>Seven</div>
  <div>Eight</div>
  <div>Nine</div>
  <div>Ten</div>
  <div>Eleven</div>
  <div>Twelve</div>
</div>
```

```
.wrapper {
  display: grid;
  grid-template-columns: repeat(4, 1fr);
  grid-auto-rows: 100px;
  gap: 10px;
}
.wrapper div:nth-child(2) {
  grid-column: 3;
  grid-row: 2 / 4;
}
.wrapper div:nth-child(5) {
  grid-column: 1 / 3;
  grid-row: 1 / 3;
}
```

Deal with items that span tracks

You can use placement properties while still taking advantage of auto-placement. In this next example I have added to the layout by setting items 1, 5, and 9 (4n+1) to span two tracks both for rows and columns. I do this with the `grid-column-end` and `grid-row-end` properties and setting the value of this to `span 2`. What this means is that the start line of the item will be set by auto-placement, and the end line will span two tracks.

You can see how this then leaves gaps in the grid, as for the auto-placed items if grid comes across an item that doesn't fit into a track, it will move to the next row until it finds a space the item can fit in.

```
body {
  font: 1.2em sans-serif;
}
* {
  box-sizing: border-box;
}
.wrapper {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
}

.wrapper > div {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  padding: 1em;
  color: #d9480f;
}
```

```
<div class="wrapper">
  <div>One</div>
  <div>Two</div>
  <div>Three</div>
  <div>Four</div>
  <div>Five</div>
  <div>Six</div>
  <div>Seven</div>
  <div>Eight</div>
  <div>Nine</div>
  <div>Ten</div>
  <div>Eleven</div>
  <div>Twelve</div>
</div>
```

```
.wrapper {
  display: grid;
  grid-template-columns: repeat(4, 1fr);
  grid-auto-rows: 100px;
  gap: 10px;
}
.wrapper div:nth-child(4n + 1) {
  grid-column-end: span 2;
  grid-row-end: span 2;
  background-color: #ffa94d;
}
.wrapper div:nth-child(2) {
  grid-column: 3;
  grid-row: 2 / 4;
}
.wrapper div:nth-child(5) {
  grid-column: 1 / 3;
  grid-row: 1 / 3;
}
```

Filling in the gaps

So far, other than items we have specifically placed, grid is always progressing forward and keeping items in DOM order. This is generally what you want, if you are laying out a form for example you wouldn't want the labels and fields to become jumbled up in order to fill in some gap. However sometimes, we are laying things out that don't have a logical order and we would like to create a layout that doesn't have gaps in it.

To do this, add the property `grid-auto-flow` with a value of `dense` to the container. This is the same property you use to change the flow order to `column`, so if you were working in columns you would add both values `grid-auto-flow: column dense`.

Having done this, grid will now backfill the gaps, as it moves through the grid it leaves gaps as before, but then if it finds an item that will fit in a previous gap it will pick it up and take it out of DOM order to place it in the gap. As with any other reordering in grid this does not change the logical order. Tab order for example, will still follow the document order. We will take a look at the potential accessibility issues of grid layout in the Grid layout and accessibility guide, but you should take care when creating this disconnect between the visual order and display order.

```
body {
  font: 1.2em sans-serif;
}
* {
  box-sizing: border-box;
}
.wrapper {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
}

.wrapper > div {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  padding: 1em;
  color: #d9480f;
}
```

```
<div class="wrapper">
  <div>One</div>
  <div>Two</div>
  <div>Three</div>
  <div>Four</div>
  <div>Five</div>
  <div>Six</div>
  <div>Seven</div>
  <div>Eight</div>
  <div>Nine</div>
```

```
  <div>Ten</div>
  <div>Eleven</div>
  <div>Twelve</div>
</div>
```

```
.wrapper div:nth-child(4n + 1) {
  grid-column-end: span 2;
  grid-row-end: span 2;
  background-color: #ffa94d;
}
.wrapper div:nth-child(2) {
  grid-column: 3;
  grid-row: 2 / 4;
}
.wrapper div:nth-child(5) {
  grid-column: 1 / 3;
  grid-row: 1 / 3;
}
.wrapper {
  display: grid;
  grid-template-columns: repeat(4, 1fr);
  grid-auto-rows: 100px;
  gap: 10px;
  grid-auto-flow: dense;
}
```

Anonymous grid items

There is a mention in the specification of anonymous grid items. These are created if you have a string of text inside your grid container, that is not wrapped in any other element. In the example below we have three grid items, assuming you had set the parent with a class of `grid` to `display: grid`. The first is an anonymous item as it has no enclosing markup, this item will always be dealt with via the auto-placement rules. The other two are grid items enclosed in a div, they might be auto-placed or you could place these with a positioning method onto your grid.

```
<div class="grid">
  I am a string and will become an anonymous item
  <div>A grid item</div>
  <div>A grid item</div>
</div>
```

Anonymous items are always auto-placed because there is no way to target them. Therefore if you have some unwrapped text for some reason in your grid, be aware that it might show up somewhere unexpected as it will be auto-placed according to the auto-placement rules.

Use cases for auto-placement

Auto-placement is useful whenever you have a collection of items. That could be items that do not have a logical order such as a gallery of photos, or product listing. In that case you might choose to use the dense packing mode to fill in any holes in your grid. In my image gallery example I have some landscape and some portrait images. I have set landscape images – with a class of `landscape` to span two column tracks. I then use `grid-auto-flow: dense` to create a densely packed grid.

Try removing the line `grid-auto-flow: dense` to see the content reflow to leave gaps in the layout.

```
<ul class="wrapper">
  <li>
    <img
      alt="A colorful hot air balloon against a clear sky"
      src="https://mdn.github.io/shared-assets/images/examples/balloon.jpg" />
  </li>
  <li class="landscape">
    <img
      alt="Three hot air balloons against a clear sky, as seen from the ground"
      src="https://mdn.github.io/shared-assets/images/examples/balloons-small.jpg" />
  </li>
  <li class="landscape">
    <img
      alt="Three hot air balloons against a clear sky, as seen from the ground"
      src="https://mdn.github.io/shared-assets/images/examples/balloons-small.jpg" />
  </li>
  <li class="landscape">
    <img
      alt="Three hot air balloons against a clear sky, as seen from the ground"
      src="https://mdn.github.io/shared-assets/images/examples/balloons-small.jpg" />
  </li>
  <li>
    <img
      alt="A colorful hot air balloon against a clear sky"
      src="https://mdn.github.io/shared-assets/images/examples/balloon.jpg" />
  </li>
  <li>
    <img
      alt="A colorful hot air balloon against a clear sky"
      src="https://mdn.github.io/shared-assets/images/examples/balloon.jpg" />
  </li>
</ul>
```

```
body {
  font: 1.2em sans-serif;
}
* {
  box-sizing: border-box;
}

.wrapper {
  list-style: none;
  margin: 1em auto;
  padding: 0;
  max-width: 800px;
}
.wrapper li {
  border: 1px solid #cccccc;
}

.wrapper li img {
```

```
  display: block;
  object-fit: cover;
  width: 100%;
  height: 100%;
}
```

```
.wrapper {
  display: grid;
  grid-template-columns: repeat(3, minmax(120px, 1fr));
  gap: 10px;
  grid-auto-flow: dense;
}

.wrapper li.landscape {
  grid-column-end: span 2;
}
```

Auto-placement can also help you lay out interface items which do have logical order. An example is the definition list in this next example. Definition lists are an interesting challenge to style as they are flat, there is nothing wrapping the groups of `dt` and `dd` items. In my example I am allowing auto-placement to place the items, however I have classes that start a `dt` in column 1, and `dd` in column 2, this ensure that terms go on one side and definitions on the other - no matter how many of each we have.

```
body {
  font: 1.2em sans-serif;
}
* {
  box-sizing: border-box;
}

.wrapper {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
}
```

```
<div class="wrapper">
  <dl>
    <dt>Mammals</dt>
    <dd>Cat</dd>
    <dd>Dog</dd>
    <dd>Mouse</dd>
    <dt>Birds</dt>
    <dd>Pied Wagtail</dd>
    <dd>Owl</dd>
    <dt>Fish</dt>
    <dd>Guppy</dd>
  </dl>
</div>
```

```
dl {
  display: grid;
  grid-template-columns: auto 1fr;
  max-width: 300px;
  margin: 1em;
  line-height: 1.4;
}
dt {
  grid-column: 1;
  font-weight: bold;
}
dd {
  grid-column: 2;
}
```

What can't we do with auto-placement (yet)?

There are a couple of things that often come up as questions. Currently we can't do things like target every other cell of the grid with our items. A related issue may have already come to mind if you followed the last guide about named lines on the grid. It would be to define a rule that said "auto-place items against the next line named `n`", and grid would then skip other lines. There is an issue raised about this on the CSSWG GitHub repository, and you would be welcome to add your own use cases to this.

It may be that you come up with your own use cases for auto-placement or any other part of grid layout. If you do, raise them as issues or add to an existing issue that could solve your use case. This will help to make future versions of the specification better.

Basic concepts of grid layout

CSS grid layout introduces a two-dimensional grid system to CSS. Grids can be used to lay out major page areas or small user interface elements. This guide introduces the CSS grid layout and the terminology that is part of the CSS grid layout specification. The features shown in this overview will then be explained in greater detail in the other guides in this series.

What is a grid?

A grid is a set of intersecting horizontal and vertical lines defining rows and columns. Elements can be placed onto the grid within these column and row lines. CSS grid layout has the following features:

Fixed and flexible track sizes

You can create a grid with fixed track sizes – using pixels for example. This sets the grid to the specified pixel which fits to the layout you desire. You can also create a grid using flexible sizes with percentages or with the `fr` unit designed for this purpose.

Item placement

You can place items into a precise location on the grid using line numbers, names or by targeting an area of the grid. Grid also contains an algorithm to control the placement of items not given an explicit position on the grid.

Creation of additional tracks to hold content

You can define an explicit grid with grid layout. The features defined by the grid layout module provide the flexibility to add additional rows and columns when needed. Features such as adding "as many columns that will fit into a container" are included.

Alignment control

CSS grid layout and CSS box alignment features enable us to control how the items align once placed into a grid area, and how the entire grid is aligned.

Control of overlapping content

More than one item can be placed into a grid cell or area and they can partially overlap each other. This layering may then be controlled with the `z-index` property.

Grid is a powerful layout method that, when combined with other parts of CSS such as flexbox, can help you create layouts that are responsive, flexible, and accessible. It all starts by creating a grid in your **grid container**.

Grid container

We create a *grid container* by declaring `display: grid` or `display: inline-grid` on an element. As soon as we do this, all *direct children* of that element become *grid items*.

In this example, we have a containing div with a class of `wrapper`. Nested inside are five child elements.

```
<div class="wrapper">
  <div>One</div>
  <div>Two</div>
  <div>Three</div>
  <div>Four</div>
  <div>Five</div>
</div>
```

We make the `.wrapper` a grid container using `display: grid;`.

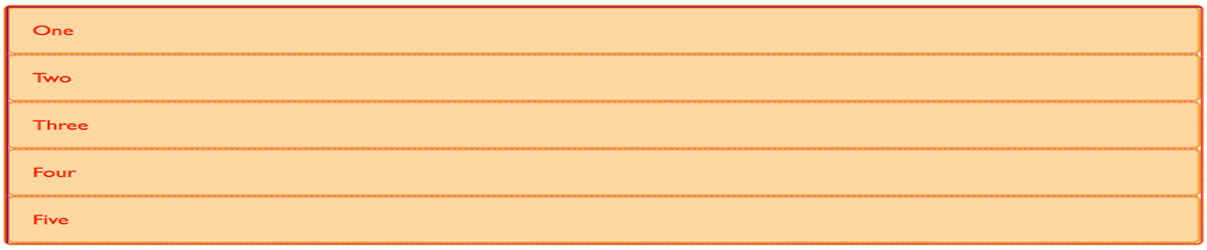
```
.wrapper {
  display: grid;
}
```

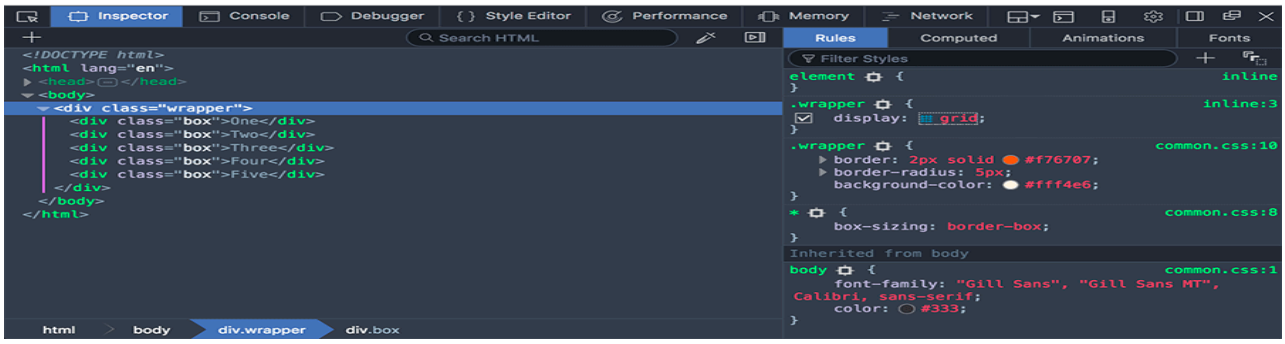
```
* {
  box-sizing: border-box;
}

.wrapper {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
}

.wrapper > div {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  padding: 1em;
  color: #d9480f;
}
```

All the direct children are now grid items. In a web browser, you won't see any difference to how these items are displayed before turning them into a grid, as grid has created a single column grid for the items. If you inspect the grid in your browsers developer tools, you may see a small icon next to the value `grid`. Click this and, in most browsers, the grid on this element will be overlaid in the browser window.



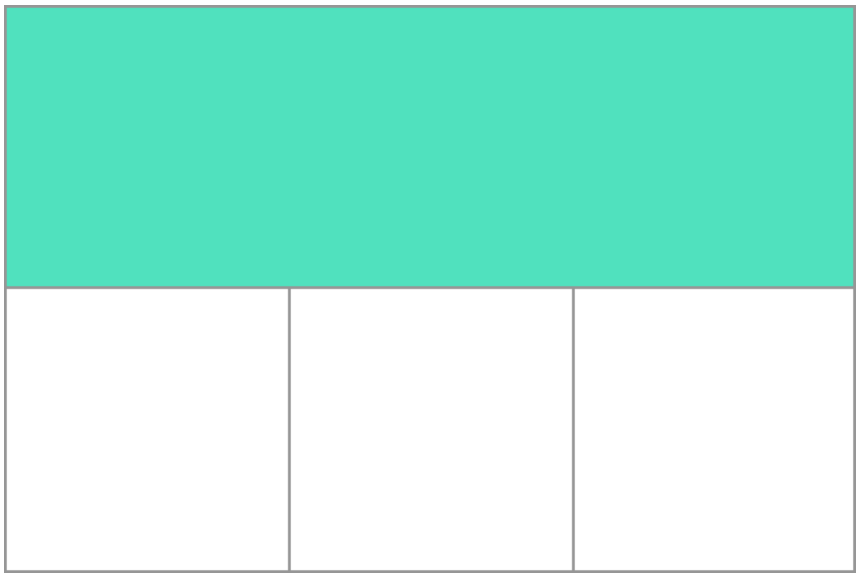


As you learn and then work with the CSS grid layout, your browser tools will give you a better idea of what is happening with your grids visually.

If we want to start making this more grid-like we need to add column tracks.

Grid tracks

We define rows and columns on our grid with the `grid-template-rows` and `grid-template-columns` properties. These define grid tracks. A *grid track* is the space between any two adjacent lines on the grid. The image below shows a highlighted track – this is the first-row track in our grid.



Grid tracks are defined in the explicit grid by using the `grid-template-columns` and `grid-template-rows` properties or the shorthand `grid` or `grid-template` properties. Tracks are also created in the implicit grid by positioning a grid item outside of the tracks created in the explicit grid.

Basic example

We can add column tracks to our earlier example by adding the `grid-template-columns` property, then defining the size of the column tracks.

We have now created a grid with three 200-pixel-wide column tracks. The child items will be laid out on this grid one in each grid cell.

```
<div class="wrapper">
  <div>One</div>
  <div>Two</div>
  <div>Three</div>
  <div>Four</div>
  <div>Five</div>
</div>
```

```
.wrapper {
  display: grid;
  grid-template-columns: 200px 200px 200px;
}
```

```
* {
  box-sizing: border-box;
}

.wrapper {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
}

.wrapper > div {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  padding: 1em;
  color: #d9480f;
}
```

The fr unit

Tracks can be defined using any length unit. Grid also introduces an additional length unit to help us create flexible grid tracks. The `fr` unit represents a fraction of the available space in the grid container. The next grid definition would create three equal width tracks that grow and shrink according to the available space.

```
<div class="wrapper">
  <div>One</div>
  <div>Two</div>
  <div>Three</div>
  <div>Four</div>
  <div>Five</div>
</div>
```

```
.wrapper {
  display: grid;
  grid-template-columns: 1fr 1fr 1fr;
}
```

```
* {
  box-sizing: border-box;
}

.wrapper {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
}

.wrapper > div {
  border: 2px solid #ffa94d;
```

```
  border-radius: 5px;
  background-color: #ffd8a8;
  padding: 1em;
  color: #d9480f;
}
```

Unequal sizes

In this example, we create a definition with a `2fr` track then two `1fr` tracks. The available space is split into four. Two parts are given to the first track and one part each to the next two tracks.

```
<div class="wrapper">
  <div>One</div>
  <div>Two</div>
  <div>Three</div>
  <div>Four</div>
  <div>Five</div>
</div>
```

```
.wrapper {
  display: grid;
  grid-template-columns: 2fr 1fr 1fr;
}
```

```
* {
  box-sizing: border-box;
}

.wrapper {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
}

.wrapper > div {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  padding: 1em;
  color: #d9480f;
}
```

Mixing flexible and absolute sizes

In this final example, we mix absolute sized tracks with `fr` units. The first track is `500px`, so the fixed width is taken away from the available space. The remaining space is divided into three and assigned in proportion to the two flexible tracks.

```
<div class="wrapper">
  <div>One</div>
  <div>Two</div>
  <div>Three</div>
  <div>Four</div>
  <div>Five</div>
</div>
```

```
.wrapper {
  display: grid;
  grid-template-columns: 500px 1fr 2fr;
}
```

```
* {
  box-sizing: border-box;
}

.wrapper {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
}

.wrapper > div {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  padding: 1em;
  color: #d9480f;
}
```

Track listings with repeat() notation

Large grids with many tracks can use the `repeat()` notation, to repeat all or a section of the list of grid tracks. For example the grid definition:

```
.wrapper {
  display: grid;
  grid-template-columns: 1fr 1fr 1fr;
}
```

Can also be written as:

```
.wrapper {
  display: grid;
  grid-template-columns: repeat(3, 1fr);
}
```

Repeat notation can be used for a part of the list of tracks. In this example, we create an 8-column grid; the initial track is `20px`, then a repeating section of 6 `1fr` tracks, and a final `20px` track.

```
.wrapper {
  display: grid;
```

```
  grid-template-columns: 20px repeat(6, 1fr) 20px;
}
```

Repeat notation (`repeat()`) uses the track listing to create a repeating pattern of tracks. In this example, the grid will have 10 tracks; a `1fr` track is followed by a `2fr` track, with this pattern being repeated five times.

```
.wrapper {
  display: grid;
  grid-template-columns: repeat(5, 1fr 2fr);
}
```

Implicit and explicit grids

When creating our example grid, we specifically defined our column tracks with the `grid-template-columns` property, with the grid creating rows as needed to fit the content. The columns define the explicit grid while the rows are part of the implicit grid.

The *explicit grid* consists of rows and columns defined with `grid-template-columns` or `grid-template-rows`. The *implicit grid* extends the defined explicit grid when content is placed outside of that grid, such as into the rows by drawing additional grid lines.

If you place something outside of the defined grid or, due to the amount of content, more grid tracks are needed, then the grid creates rows and columns in the *implicit grid*. These implicit tracks are auto-sized by default, meaning the size of the created rows or columns is influenced by both their content and by the available free space within the grid container. The `auto` keyword allows the generated tracks to accommodate content while also sharing any remaining space.

You can also define a set size for tracks created in the implicit grid with the `grid-auto-rows` and `grid-auto-columns` properties.

In this example, we set `grid-auto-rows: 200px`, ensuring the tracks created in this implicit grid are `200px` tall.

```
<div class="wrapper">
  <div>One</div>
  <div>Two</div>
  <div>Three</div>
  <div>Four</div>
  <div>Five</div>
</div>
```

```
.wrapper {
  display: grid;
  grid-template-columns: repeat(3, 1fr);
  grid-auto-rows: 200px;
}
```

```
* {
  box-sizing: border-box;
}

.wrapper {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
}

.wrapper > div {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  padding: 1em;
  color: #d9480f;
}
```

Track sizing and minmax

When setting up an explicit grid or defining the sizing for automatically created rows or columns we may want to give tracks a minimum size, but also ensure they expand to fit any content that is added. For example, we may want our rows to never collapse smaller than 100 pixels, but if our content stretches to 300 pixels in height, then we would like the row to stretch to that height. This is solved by the `minmax()` function.

In this example, we use `minmax()` within the `grid-auto-rows` property value. By setting `grid-auto-rows: minmax(100px, auto);`, automatically created rows will be a minimum of `100px` tall, and have a maximum of `auto`. Setting `auto` as the maximum value allows the track to grow to accommodate its content (up to its `max-content` size) while also sharing any available free space within the grid container.

```
.wrapper {
  display: grid;
  grid-template-columns: repeat(3, 1fr);
  grid-auto-rows: minmax(100px, auto);
}
```

```
* {
  box-sizing: border-box;
}

.wrapper {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
}

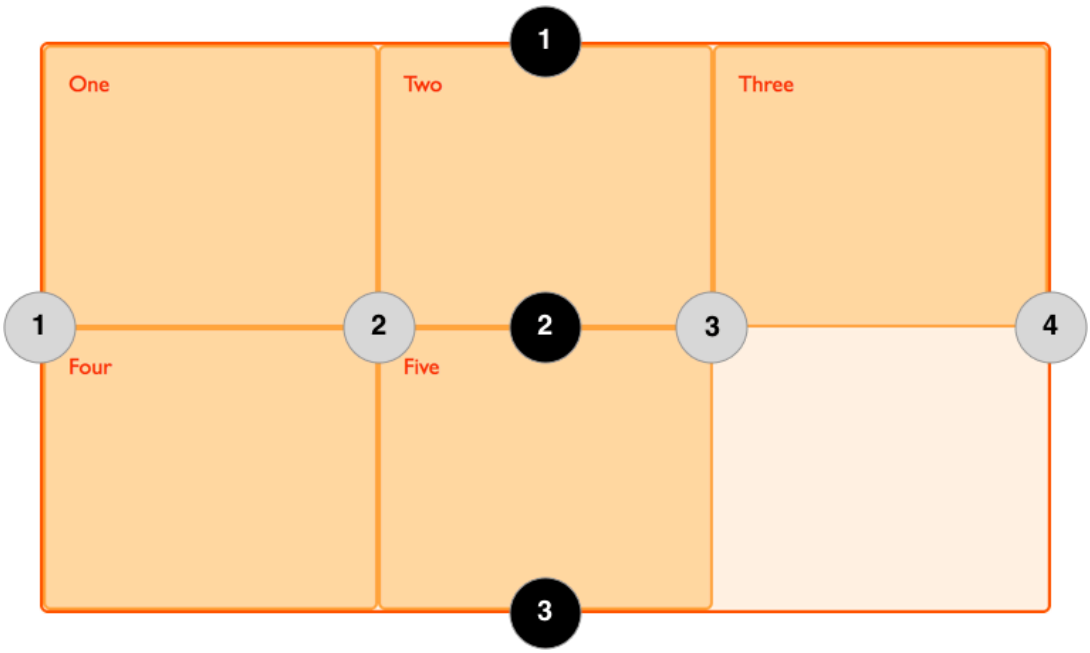
.wrapper > div {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  padding: 1em;
  color: #d9480f;
}
```

```
<div class="wrapper">
  <div>One</div>
  <div>
    Two
    <p>We have some more content.</p>
    <p>This makes me taller than 100 pixels.</p>
```

```
  </div>
  <div>Three</div>
  <div>Four</div>
  <div>Five</div>
</div>
```

Grid lines

It should be noted that when we define a grid we define the grid tracks, not the lines. Grid then gives us numbered lines to use when positioning items. In our three column, two row grid we have four column lines.



Lines are numbered according to the writing mode of the document. In a left-to-right language, line 1 is on the left-hand side of the grid. In a right-to-left language, it is on the right-hand side of the grid. Lines can also be named, which is discussed in the grid layout using named grid lines guide.

Positioning items against lines

The following example demonstrates basic line-based placement; when placing an item, we target the line rather than the track. We explore this in greater detail in the grid layout using line-based placement guide.

In this example, the first two items on our three column track grid are placed using the `grid-column-start`, `grid-column-end`, `grid-row-start` and `grid-row-end` properties. Working from left to right, the first item is placed against column line 1, and spans to column line 4, which in our case is the far-right line on the grid. It begins at row line 1 and ends at row line 3, therefore spanning two row tracks.

The second item starts on grid column line 1, and spans one track. This is the default, so we do not need to specify the end line. It also spans two row tracks from row line 3 to row line 5. The other items will place themselves into empty spaces on the grid.

```
<div class="wrapper">
  <div class="box1">One</div>
  <div class="box2">Two</div>
  <div class="box3">Three</div>
  <div class="box4">Four</div>
  <div class="box5">Five</div>
</div>
```

```
.wrapper {
  display: grid;
  grid-template-columns: repeat(3, 1fr);
  grid-auto-rows: 100px;
}

.box1 {
  grid-column-start: 1;
  grid-column-end: 4;
  grid-row-start: 1;
  grid-row-end: 3;
}

.box2 {
  grid-column-start: 1;
  grid-row-start: 3;
  grid-row-end: 5;
}
```

```
* {
  box-sizing: border-box;
}

.wrapper {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
}

.wrapper > div {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  padding: 1em;
```

```
  color: #d9480f;
}
```

Use the grid inspector in your developer tools to see how the items are positioned against the lines of the grid.

Line-positioning shorthands

The longhand values used above can be compressed onto one line for columns with the `grid-column` shorthand, and one line for rows with the `grid-row` shorthand. The following example would give the same positioning as in the previous code, but with far less CSS. The value before the forward slash character (`/`) is the start line, the value after the end line.

You can omit the end value if the area only spans one track.

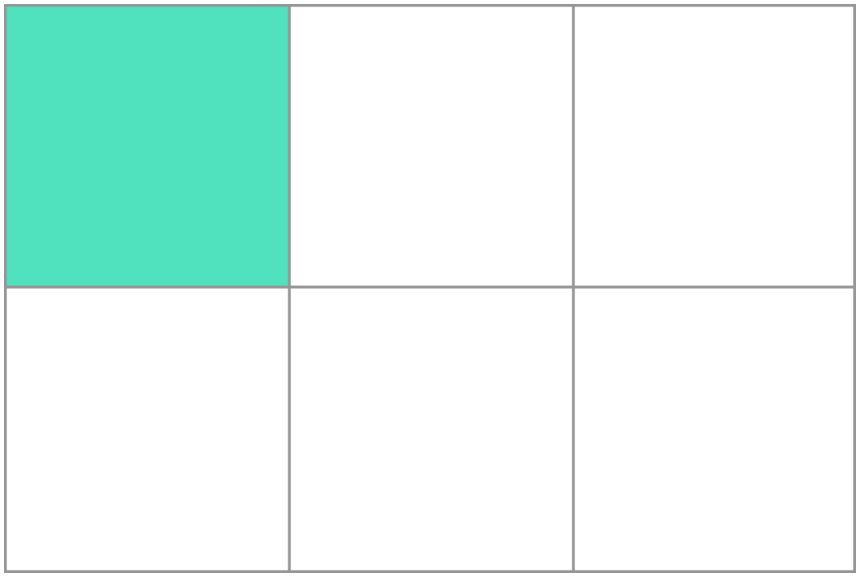
```
.wrapper {
  display: grid;
  grid-template-columns: repeat(3, 1fr);
  grid-auto-rows: 100px;
}

.box1 {
  grid-column: 1 / 4;
  grid-row: 1 / 3;
}

.box2 {
  grid-column: 1;
  grid-row: 3 / 5;
}
```

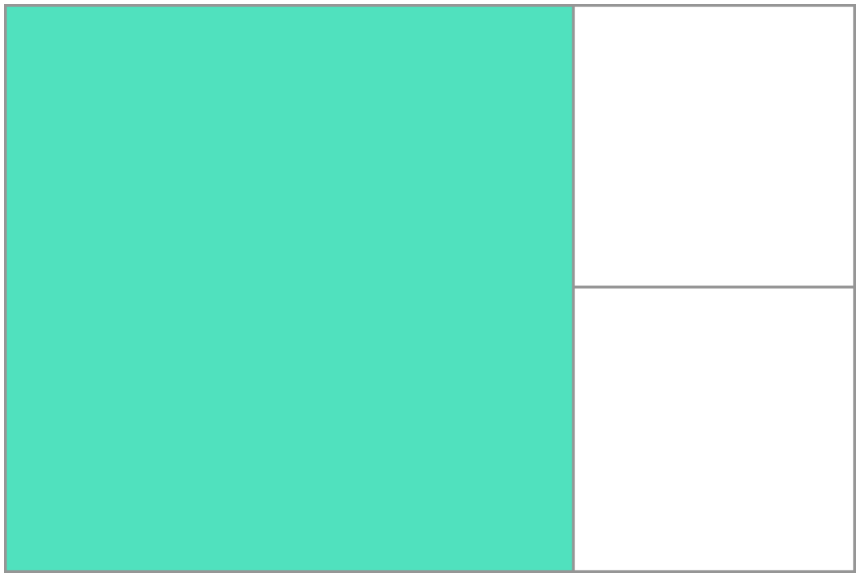
Grid cells

A *grid cell* is the smallest unit on a grid. Conceptually it is like a table cell. As we saw in our earlier examples, once a grid is defined as a parent the child items will lay themselves out in one cell each of the defined grid. In the below image, the first cell of the grid is highlighted.



Grid areas

Items can span one or more cells both by row or by column, and this creates a *grid area*. Grid areas must be rectangular – it isn't possible to create an L-shaped area for example. The highlighted grid area spans two row and two column tracks.



Gutters

Gutters or *alleys* between grid cells can be created using the `column-gap` and `row-gap` properties, or the shorthand `gap`. In the below example, we add a 10-pixel gap between columns and a `1em` gap between rows.

```
.wrapper {
  display: grid;
  grid-template-columns: repeat(3, 1fr);
  column-gap: 10px;
  row-gap: 1em;
}
```

```
<div class="wrapper">
  <div>One</div>
  <div>Two</div>
  <div>Three</div>
  <div>Four</div>
  <div>Five</div>
</div>
```

```
* {
  box-sizing: border-box;
}

.wrapper {
  column-gap: 10px;
  row-gap: 1em;
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
}

.wrapper > div {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  padding: 1em;
  color: #d9480f;
}
```

Any space used by gaps will be accounted for before space is assigned to the flexible length `fr` tracks, and gaps act for sizing purposes like a regular grid track, however you cannot place anything into a gap. In terms of line-based positioning, the gap acts like a thick, transparent line.

Nesting grids

A grid item can become a grid container. In the following example, we extend the three-column grid with two positioned items seen earlier, adding sub-items to the first grid item. As these nested items are not direct children of the grid they do not participate in grid layout and so display in a normal document flow.

Nesting without subgrid

If we set `box1` to `display: grid`, we can give it a track definition and it too will become a grid. The items then lay out on this new grid.

```
<div class="wrapper">
  <div class="box box1">
    <div class="nested">a</div>
    <div class="nested">b</div>
    <div class="nested">c</div>
  </div>
  <div class="box box2">Two</div>
  <div class="box box3">Three</div>
  <div class="box box4">Four</div>
  <div class="box box5">Five</div>
</div>
```

```
* {
  box-sizing: border-box;
}

.wrapper {
  border: 2px solid #f76707;
  border-radius: 5px;
```

```
  gap: 3px;
  background-color: #fff4e6;
  display: grid;
  grid-template-columns: repeat(3, 1fr);
}

.box {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  padding: 1em;
  color: #d9480f;
}

.box1 {
  grid-column-start: 1;
  grid-column-end: 4;
  grid-row-start: 1;
  grid-row-end: 3;
  display: grid;
  grid-template-columns: repeat(3, 1fr);
}

.nested {
  border: 2px solid #ffec99;
  border-radius: 5px;
  background-color: #fff9db;
  padding: 1em;
}
```

In this case the nested grid has no relationship to the parent. As you can see in the example it has not inherited the `gap` of the parent and the lines in the nested grid do not align to the lines in the parent grid.

Subgrid

In addition to regular grids, we can create *subgrid*. The `subgrid` value lets us create nested grids that use the track definition of the parent grid.

To use them, we edit the above nested grid example to change the track definition of `grid-template-columns: repeat(3, 1fr)`, to `grid-template-columns: subgrid`. The nested grid then uses the parent grid tracks to lay out items.

```
.box1 {
  grid-column-start: 1;
  grid-column-end: 4;
  grid-row-start: 1;
  grid-row-end: 3;
  display: grid;
  grid-template-columns: subgrid;
}
```

Layering items with z-index

Grid items can occupy the same cell, and in this case we can use the `z-index` property to control the order in which overlapping items stack.

Overlapping without z-index

If we return to our example with items positioned by line number, we can change this to make two items overlap.

```
<div class="wrapper">
  <div class="box box1">One</div>
  <div class="box box2">Two</div>
  <div class="box box3">Three</div>
  <div class="box box4">Four</div>
  <div class="box box5">Five</div>
</div>
```

```
.wrapper {
  display: grid;
  grid-template-columns: repeat(3, 1fr);
  grid-auto-rows: 100px;
}

.box1 {
  grid-column-start: 1;
  grid-column-end: 4;
  grid-row-start: 1;
  grid-row-end: 3;
}

.box2 {
  grid-column-start: 1;
  grid-row-start: 2;
  grid-row-end: 4;
}
```

```
* {
  box-sizing: border-box;
}

.wrapper {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
}

.box {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  padding: 1em;
  color: #d9480f;
}
```

The item `box2` is now overlapping `box1`, it displays on top as it comes later in the source order.

Controlling the order

We can control the order in which items stack up by using the `z-index` property - just like positioned items. If we give `box2` a lower `z-index` than `box1` it will display below `box1` in the stack.

```
.wrapper {
  display: grid;
  grid-template-columns: repeat(3, 1fr);
  grid-auto-rows: 100px;
}

.box1 {
  grid-column-start: 1;
  grid-column-end: 4;
  grid-row-start: 1;
  grid-row-end: 3;
  z-index: 2;
}

.box2 {
  grid-column-start: 1;
  grid-row-start: 2;
  grid-row-end: 4;
  z-index: 1;
}
```

```
<div class="wrapper">
  <div class="box box1">One</div>
  <div class="box box2">Two</div>
  <div class="box box3">Three</div>
  <div class="box box4">Four</div>
  <div class="box box5">Five</div>
</div>
```

```
* {
  box-sizing: border-box;
}

.wrapper {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
}

.box {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  padding: 1em;
  color: #d9480f;
}
```

Next steps

In this overview, we took a very quick look at the possibilities of grid layouts. Explore and play with the code examples, and then move on to the guide, relationship of grid layout with other layout methods, where we will really start to dig into the details of CSS grid layout.

Aligning items in CSS grid layout

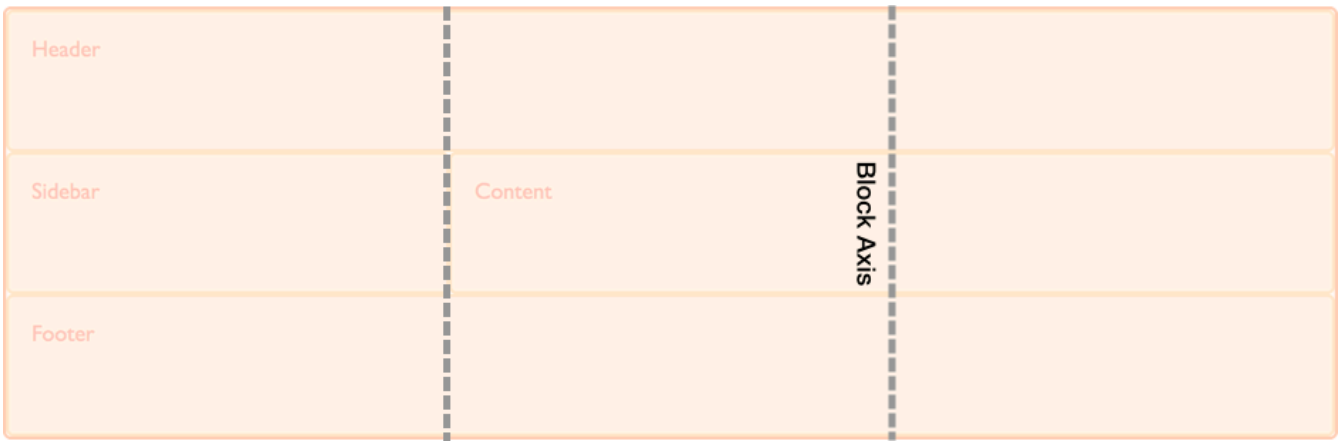
CSS grid layout implements CSS box alignment, which is the same standard flexbox uses for aligning items in its flex container. The alignment module details how alignment should work in all the layout methods.

In this guide, we look at how the box alignment properties are used to align items in grid layout.

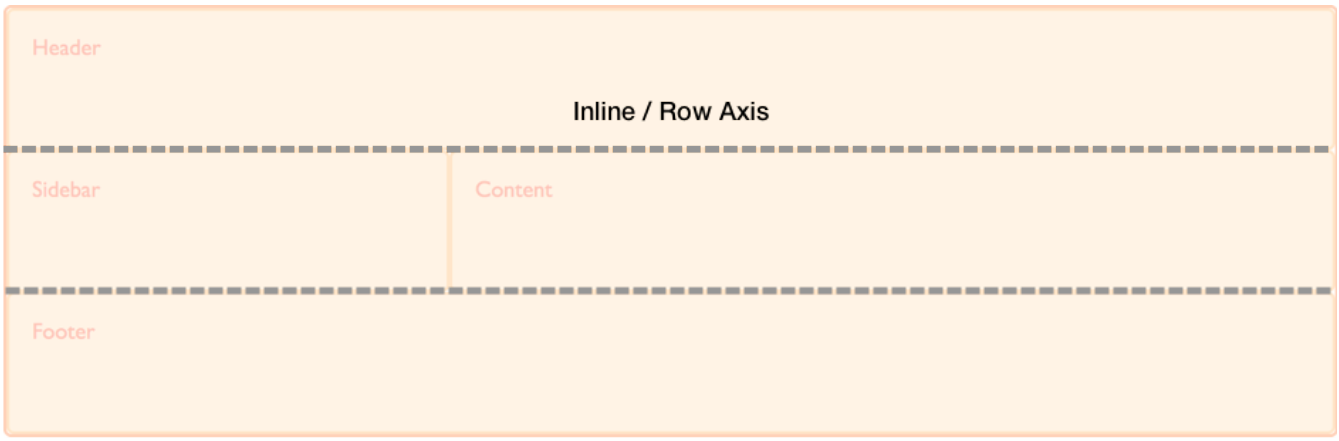
You may notice similarities to how these properties and values work in flexbox. Due to grid being two-dimensional and flexbox one-dimensional, there are some small differences that you should watch out for. For this reason, we will start by looking at the two axes that we deal with when aligning things in a grid.

The two axes of a grid layout

When working with grid layout you have two axes available to align things against – the *block axis* and the *inline axis*. The block axis is the axis upon which blocks are laid out in block layout. If you have two paragraphs on your page they display one below the other, so it is this direction we describe as the block axis.



The inline axis runs across the block axis, it is the direction in which text in regular inline flow runs.



We are able to align the content inside grid areas, and the grid tracks themselves on these two axes.

Aligning items on the block axis

The `align-self` and `align-items` properties control alignment on the block axis. When we use these properties, we are changing the alignment of the item within the grid area you have placed it.

Using align-items

In the following example, we have four grid areas within our grid. We can use the `align-items` property on the grid container, to align the items using `normal`, `stretch`, or `<self-position>` or `<baseline-position>` values:

- `normal`
- `stretch`
- `start`
- `end`
- `center`
- `baseline`
- `first baseline`
- `last baseline`
- `auto` (`align-self` only)

The default value is `normal`, which resolves to `stretch` for grid containers.

```
* {
  box-sizing: border-box;
}

.wrapper {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
}

.wrapper > div {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  padding: 1em;
  color: #d9480f;
}
```

```
.wrapper {
  display: grid;
  grid-template-columns: repeat(8, 1fr);
  gap: 10px;
  grid-auto-rows: 100px;
  grid-template-areas:
    "a a a a b b b b"
    "a a a a b b b b"
    "c c c c d d d d"
    "c c c c d d d d";
  align-items: start;
}
.item1 {
  grid-area: a;
}
.item2 {
  grid-area: b;
}
.item3 {
  grid-area: c;
}
.item4 {
  grid-area: d;
}
```

```
<div class="wrapper">
  <div class="item1">Item 1</div>
  <div class="item2">Item 2</div>
  <div class="item3">Item 3</div>
  <div class="item4">Item 4</div>
</div>
```

Keep in mind that once you set `align-items: start`, the height of each child `<div>` will be determined by the contents of the `<div>`. This is in contrast to omitting `align-items` completely, in which case the height of each `<div>` stretches to fill its grid area.

The `align-items` property sets the `align-self` property for all of the child grid items. This means that you can set the property individually, by using `align-self` directly on a grid item.

Using align-self

In this next example, we are using the `align-self` property, to demonstrate the different alignment values. The first area is showing the default behavior of `align-self`, which in this case resolves to `stretch`. The second item, has an `align-self` value of `start`, the third `end` and the fourth `center`.

```
* {
  box-sizing: border-box;
}

.wrapper {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
}

.wrapper > div {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  padding: 1em;
  color: #d9480f;
}
```

```
.wrapper {
  display: grid;
  grid-template-columns: repeat(8, 1fr);
  gap: 10px;
  grid-auto-rows: 100px;
  grid-template-areas:
    "a a a a b b b b"
    "a a a a b b b b"
    "c c c c d d d d"
    "c c c c d d d d";
}
.item1 {
  grid-area: a;
}
.item2 {
  grid-area: b;
  align-self: start;
}
.item3 {
  grid-area: c;
  align-self: end;
}
.item4 {
  grid-area: d;
  align-self: center;
}
```

```
<div class="wrapper">
  <div class="item1">Item 1</div>
  <div class="item2">Item 2</div>
  <div class="item3">Item 3</div>
  <div class="item4">Item 4</div>
</div>
```

Items with an intrinsic aspect ratio

The default behavior for `align-self` is to inherit from the grid container's `align-items` property, for which the `normal` default is to stretch, except for items which have an intrinsic aspect ratio, in this case they behave as `start`. The reason for this, is that if items with an aspect ratio are made to stretch, they would be distorted.

Justifying items on the inline axis

Whereas `align-items` and `align-self` align items on the block axis, `justify-items` and `justify-self` align items on the inline axis. The values you can choose from are similar to the `normal`, `stretch`, `<self-position>` and `<baseline-position>` values of the `align-self` property, along with `left` and `right`. Values include:

- `normal`
- `start`
- `end`
- `left`
- `right`
- `center`
- `stretch`
- `baseline`
- `first baseline`
- `last baseline`
- `auto` (`justify-self` only)

You can see the same example as used for `align-items`, below. This time, we are applying the `justify-self` property.

Once again, the default is `stretch` other than for items with an intrinsic aspect ratio. This means that grid items will cover their grid area by default, unless you change the alignment. In this example, the first item demonstrates the default `stretch` alignment value:

```
* {
  box-sizing: border-box;
}

.wrapper {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
}

.wrapper > div {
  border: 2px solid #ffa94d;
```

```
  border-radius: 5px;
  background-color: #ffd8a8;
  padding: 1em;
  color: #d9480f;
}
```

```
.wrapper {
  display: grid;
  grid-template-columns: repeat(8, 1fr);
  gap: 10px;
  grid-auto-rows: 100px;
  grid-template-areas:
    "a a a a b b b b"
    "a a a a b b b b"
    "c c c c d d d d"
    "c c c c d d d d";
}
.item1 {
  grid-area: a;
}
.item2 {
  grid-area: b;
  justify-self: start;
}
.item3 {
  grid-area: c;
  justify-self: end;
}
.item4 {
  grid-area: d;
  justify-self: center;
}
```

```
<div class="wrapper">
  <div class="item1">Item 1</div>
  <div class="item2">Item 2</div>
  <div class="item3">Item 3</div>
  <div class="item4">Item 4</div>
</div>
```

As with `align-self` and `align-items`, you can apply `justify-items` to the grid container to set a `justify-self` value for all the grid items within the container.

> **Note:** The `justify-self` and `justify-items` properties are not implemented in flexbox. This is due to the one-dimensional nature of flexbox, and that there may be multiple items along the axis, making it impossible to justify a single item. To align items along the main, inline axis in flexbox you use the `justify-content` property.

Shorthand properties

The `place-items` property is shorthand for `align-items` and `justify-items`.

The `place-self` property is shorthand for `align-self` and `justify-self`.

Center an item in the area

By combining the align and justify properties we can easily center an item inside a grid area.

```
* {
  box-sizing: border-box;
}

.wrapper {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
}

.wrapper > div {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  padding: 1em;
  color: #d9480f;
}
```

```
.wrapper {
  display: grid;
  grid-template-columns: repeat(4, 1fr);
  gap: 10px;
  grid-auto-rows: 200px;
  grid-template-areas:
    ". a a ."
    ". a a .";
}
.item1 {
  grid-area: a;
  align-self: center;
  justify-self: center;
}
```

```
<div class="wrapper">
  <div class="item1">Item 1</div>
</div>
```

Aligning the grid tracks on the block axis

If you have a situation where your grid tracks use an area that is smaller than the grid container you can align the grid tracks themselves inside that container. The `align-content` aligns the tracks on the block axis and `justify-content` aligns on the inline axis. As with the `*-items` and `*-item` properties, the `place-content` property is shorthand for `align-content` and `justify-content`.

The values for `align-content`, `justify-content` and `place-content` all include the `<content-distribution>` and `<content-position>` values. The `align-content` property also accepts `<baseline-position>` values and, like the other `justify-*` properties, `justify-content` also accepts `left` and `right`.

Valid keywords for `place-content` include:

- `normal`
- `start`
- `end`
- `center`
- `stretch`
- `space-around`
- `space-between`
- `space-evenly`
- `baseline`
- `first baseline`
- `last baseline`
- `left`
- `right`

The `align-content` property is applied to the grid container as it works on the entire grid.

Default alignment

In this example, the 500px by 500px grid container has three row and three column 100px tracks with a 10px gutter. This means there is space inside the grid container in both the block and inline directions.

By default, our grid tracks are in the top left corner of the grid, aligned against the start grid lines, as the default behavior in grid layout is `start`:

```
* {
  box-sizing: border-box;
}

.wrapper {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
}

.wrapper > div {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  padding: 1em;
  color: #d9480f;
}
```

```
.wrapper {
  display: grid;
  grid-template-columns: repeat(3, 100px);
  grid-template-rows: repeat(3, 100px);
  height: 500px;
  width: 500px;
  gap: 10px;
  grid-template-areas:
    "a a b"
    "a a b"
    "c d d";
}
.item1 {
  grid-area: a;
}
.item2 {
  grid-area: b;
}
.item3 {
  grid-area: c;
}
.item4 {
  grid-area: d;
}
```

```
<div class="wrapper">
  <div class="item1">Item 1</div>
  <div class="item2">Item 2</div>
  <div class="item3">Item 3</div>
  <div class="item4">Item 4</div>
</div>
```

Setting align-content: end

Using the same CSS and HTML, in this example we add `align-content` with a value of `end` to the container, so the tracks all move to the end line of the grid container in the block dimension:

```
.wrapper {
  align-content: end;
}
```

```
* {
  box-sizing: border-box;
}

.wrapper {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
}

.wrapper > div {
  border: 2px solid #ffa94d;
  border-radius: 5px;
```

```
  background-color: #ffd8a8;
  padding: 1em;
  color: #d9480f;
}

.wrapper {
  display: grid;
  grid-template-columns: repeat(3, 100px);
  grid-template-rows: repeat(3, 100px);
  height: 500px;
  width: 500px;
  gap: 10px;
  grid-template-areas:
    "a a b"
    "a a b"
    "c d d";
}
.item1 {
  grid-area: a;
}
.item2 {
  grid-area: b;
}
.item3 {
  grid-area: c;
}
.item4 {
  grid-area: d;
}
```

```
<div class="wrapper">
  <div class="item1">Item 1</div>
  <div class="item2">Item 2</div>
  <div class="item3">Item 3</div>
  <div class="item4">Item 4</div>
</div>
```

Setting align-content: space-between

We can also apply the `<content-distribution>` space distribution values of `space-between`, `space-around`, `space-evenly`, and `stretch`. In this example, we set `align-content`, which aligns the tracks on the block axis, to `space-between`, which spaces out the tracks:

```
.wrapper {
  align-content: space-between;
}
```

```
* {
  box-sizing: border-box;
}

.wrapper {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
}

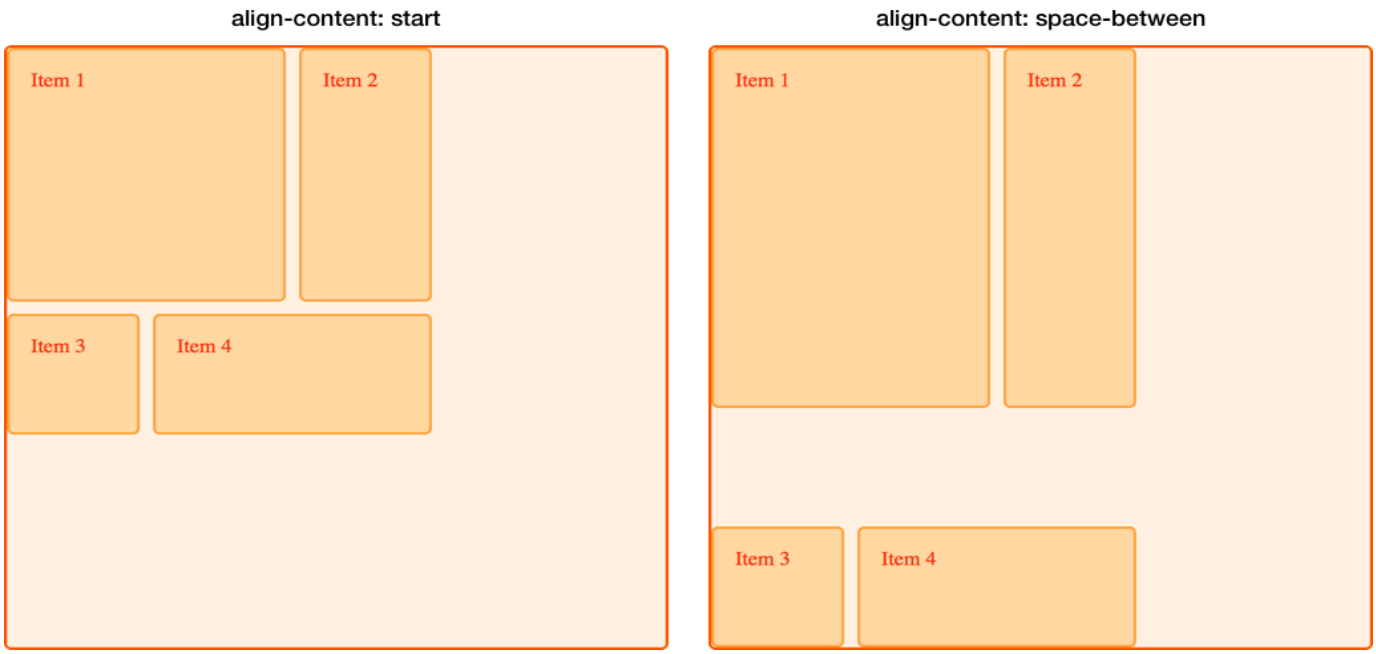
.wrapper > div {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  padding: 1em;
  color: #d9480f;
}

.wrapper {
  display: grid;
  grid-template-columns: repeat(3, 100px);
  grid-template-rows: repeat(3, 100px);
  height: 500px;
  width: 500px;
  gap: 10px;
  grid-template-areas:
    "a a b"
    "a a b"
    "c d d";
}
.item1 {
  grid-area: a;
}
.item2 {
  grid-area: b;
}
.item3 {
  grid-area: c;
}
.item4 {
  grid-area: d;
}
```

```
<div class="wrapper">
  <div class="item1">Item 1</div>
  <div class="item2">Item 2</div>
  <div class="item3">Item 3</div>
  <div class="item4">Item 4</div>
</div>
```

If an item spans more than one grid track, using a space distribution value will likely cause items on your grid to become larger because the space that's added between the tracks is added to the spanning item. Therefore, if you use these values, make sure the content of the tracks can cope with the extra space or that you have used alignment properties on the items, so they move to the start or end rather than stretch.

In the below image, we placed the grid with two different `align-content` values to compare `start` and `space-between`. You can see how the first two items, which span two row tracks, have taken on extra height in the `space-between` example as they gain the space that exists because of the free space that was distributed *between* the three rows:



Justifying the grid tracks on the inline axis

We can use `justify-content` to perform the same type of alignment on the inline axis that we used `align-content` for in the block axis.

Using the same example, we set `justify-content` to `space-around`. This once again causes tracks which span more than one column track to gain extra space:

```
.wrapper {
  align-content: space-between;
  justify-content: space-around;
}
```

```
* {
  box-sizing: border-box;
}

.wrapper {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
}

.wrapper > div {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  padding: 1em;
  color: #d9480f;
}

.wrapper {
  display: grid;
  grid-template-columns: repeat(3, 100px);
  grid-template-rows: repeat(3, 100px);
  height: 500px;
  width: 500px;
  gap: 10px;
  grid-template-areas:
    "a a b"
    "a a b"
    "c d d";
}
.item1 {
  grid-area: a;
}
.item2 {
  grid-area: b;
}
.item3 {
  grid-area: c;
}
.item4 {
  grid-area: d;
}
```

```
<div class="wrapper">
  <div class="item1">Item 1</div>
  <div class="item2">Item 2</div>
  <div class="item3">Item 3</div>
  <div class="item4">Item 4</div>
</div>
```

Alignment and auto margins

Another way to align items inside their area is to use auto margins. If you have ever centered a layout in the viewport, or any block level element within its parent, you may have done so by setting the right and left margin of element you wanted to center to `auto`. The auto margin absorbs all of the available space. Setting the margin to `auto` on both sides pushes the block-level element into the middle as both margins attempt to take all of the space.

In this next example, item 1 has its `margin-left` property set to `auto`. This pushes the content over to the right side of the area, as the auto margin takes up the available space that remained after space needed for the content has been assigned:

```
* {
  box-sizing: border-box;
}

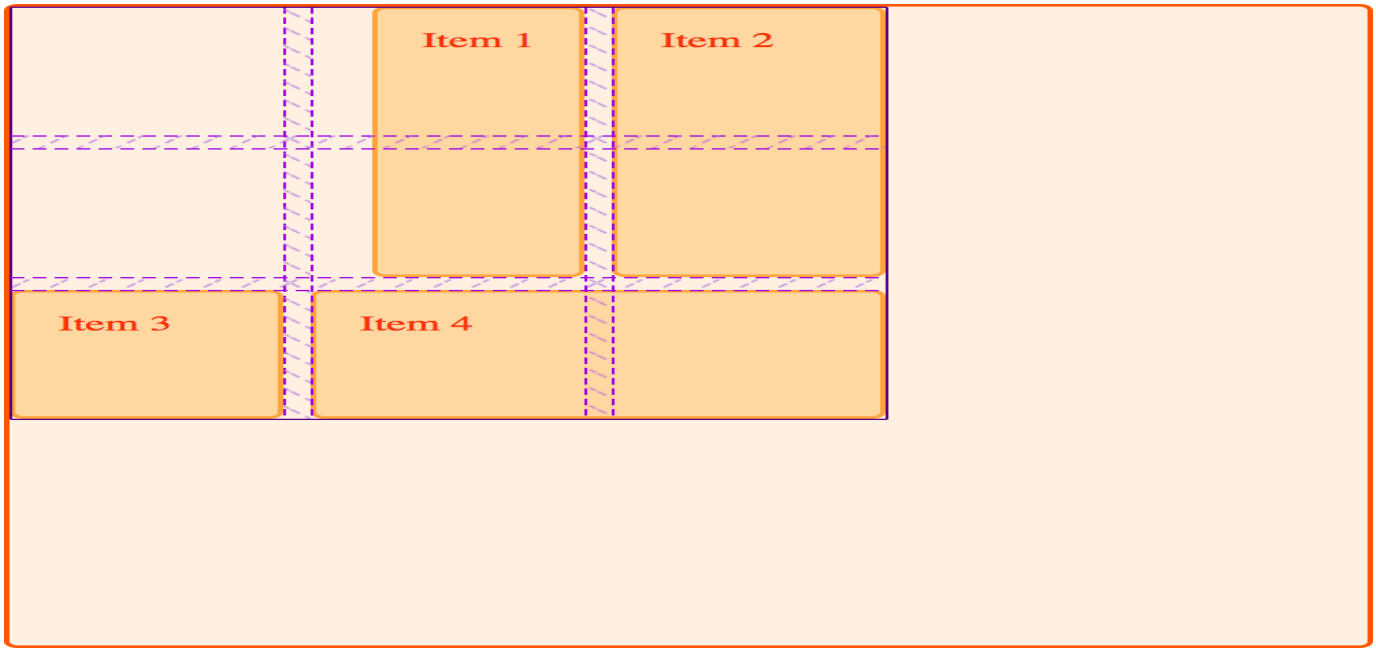
.wrapper {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
}

.wrapper > div {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  padding: 1em;
  color: #d9480f;
}
```

```
.wrapper {
  display: grid;
  grid-template-columns: repeat(3, 100px);
  grid-template-rows: repeat(3, 100px);
  height: 500px;
  width: 500px;
  gap: 10px;
  grid-template-areas:
    "a a b"
    "a a b"
    "c d d";
}
.item1 {
  grid-area: a;
  margin-left: auto;
}
.item2 {
  grid-area: b;
}
.item3 {
  grid-area: c;
}
.item4 {
  grid-area: d;
}
```

```
<div class="wrapper">
  <div class="item1">Item 1</div>
  <div class="item2">Item 2</div>
  <div class="item3">Item 3</div>
  <div class="item4">Item 4</div>
</div>
```

Use the grid inspector in your browser developer tools to see how the item is aligned:



Alignment and writing modes

All these examples were in English, a left-to-right language. This means that our start lines are top and left of our grid when thinking in physical directions.

CSS grid layout and CSS box alignment work with writing modes in CSS. When displaying a right to left language, such as Arabic, the start of the grid is the top right, so the default of `justify-content: start` would be for grid tracks to start on the right-hand side of the grid.

Setting physical properties, such as setting auto margins using `margin-right` or `margin-left`, or absolutely positioning items using the `top`, `right`, `bottom`, and `left` offsets, does not honor writing modes. In the grids, logical values, and writing modes guide, we will look further into this interaction between CSS grid layout, box alignment and writing modes. This will be important to understand, if you develop sites that are then displayed in multiple languages, or if you want to mix languages or writing modes in a design.

Realizing common layouts using grids

To round off this set of CSS grid layout guides, we're going to walk through a few different layouts, which demonstrate some of the techniques you can use when designing with grid layout. We will look at an example using `grid-template-areas`, a 12-column flexible grid system, and also a product listing using auto-placement. As you can see from this set of examples, there is often more than one way to get the results you want with CSS grid layout. Choose the method you find most helpful for the problems that you are solving and the designs that you need to implement.

A responsive layout with 1 to 3 fluid columns using <code>grid-template-areas</code>

Many websites are a variation of this type of layout, with content, sidebars, a header and a footer. In a responsive design, you may want to display the layout as a single column, adding a sidebar at a certain breakpoint and then bring in a three-column layout for wider screens.

We're going to create this layout using the *named template areas* that we learned about in the Grid template areas guide.

The markup is a container with elements inside for a header, footer, main content, navigation, sidebar, and a block to place advertising.

```
* {
  box-sizing: border-box;
}
.wrapper {
  max-width: 1024px;
  margin: 0 auto;
  font:
    1.2em "Helvetica",
    "Arial",
    sans-serif;
}

.wrapper > * {
  border: 2px solid #f08c00;
  background-color: #ffec99;
  border-radius: 5px;
  padding: 10px;
}

nav ul {
  list-style: none;
  margin: 0;
  padding: 0;
}
```

```
<div class="wrapper">
  <header class="main-head">The header</header>
  <nav class="main-nav">
    <ul>
      <li><a href="">Nav 1</a></li>
      <li><a href="">Nav 2</a></li>
      <li><a href="">Nav 3</a></li>
    </ul>
  </nav>
  <article class="content">
    <h1>Main article area</h1>
```

```
    <p>
      In this layout, we display the areas in source order for any screen less
      that 500 pixels wide. We go to a two column layout, and then to a three
      column layout by redefining the grid, and the placement of items on the
      grid.
    </p>
  </article>
  <aside class="side">Sidebar</aside>
  <div class="ad">Advertising</div>
  <footer class="main-footer">The footer</footer>
</div>
```

As we are using `grid-template-areas` to create the layout, we need to name the areas outside of any media queries. We name areas using the `grid-area` property.

```
.main-head {
  grid-area: header;
}
.content {
  grid-area: content;
}
.main-nav {
  grid-area: nav;
}
.side {
  grid-area: sidebar;
}
.ad {
  grid-area: ad;
}
.main-footer {
  grid-area: footer;
}
```

This does not create a layout. Rather, the items now have names we can use to do so. Staying outside of any media queries we're now going to set up the layout for the mobile width. Here we're keeping everything in source order to avoid any disconnect between the source and display as described in the Grid layout and accessibility guide. We've not explicitly defined any column or row tracks; this layout dictates a single column and creates rows as needed for each item in the implicit grid.

```
.wrapper {
  display: grid;
  gap: 20px;
  grid-template-areas:
    "header"
    "nav"
    "content"
    "sidebar"
    "ad"
    "footer";
}
```

With our mobile layout in place, we can now proceed to add a `@media` query to adapt this layout for bigger screens with enough real estate to display two columns.

```
@media (width >= 500px) {
  .wrapper {
    grid-template-columns: 1fr 3fr;
    grid-template-areas:
      "header  header"
      "nav     nav"
      "sidebar content"
      "ad      footer";
  }
  nav ul {
    display: flex;
    justify-content: space-between;
  }
}
```

You can see the layout taking shape in the value of `grid-template-areas`. The `header` spans over two column tracks, as does the `nav`. In the third row track, we place the `sidebar` alongside the `content`. We place the `ad` content in the fourth row track so it appears under the sidebar. The `footer` is next to it under the content. We use CSS flexible box layout on the navigation to evenly space the navigation items in a row.

We can now add a final breakpoint for wider screens able to display a three-column layout.

```
@media (width >= 700px) {
  .wrapper {
    grid-template-columns: 1fr 4fr 1fr;
    grid-template-areas:
      "header header  header"
      "nav    content sidebar"
      "nav    content ad"
      "footer footer  footer";
  }
  nav ul {
    flex-direction: column;
  }
}
```

The three-column layout has two `1fr` unit side columns and a middle column that has `4fr` as the track size. This means the available space in the container is split into six parts and assigned in proportion to our three tracks – one part each to the side columns and four parts to the center.

In this layout, we're displaying the `nav` in the left column, alongside the `content`. In the right column we have the `sidebar` and underneath it the advertisements (`ad`). The `footer` now spans across the entire bottom of the layout. Again, we use flexbox to display the navigation, but this time we display it as a column instead of a row.

This basic example demonstrates how to rearrange a grid layout across different breakpoints. In particular, we're changing the location of the `ad` block as appropriate in our different column setups. This named areas method can be very helpful, especially at the prototyping stage. You may find it easier to use names rather than numbers when playing with the location of elements on the grid.

A flexible 12-column layout

CSS frameworks and grid systems commonly use 12- or 16-column flexible grids. We can create this type of system using CSS grid layout. As an example, let's create a 12-column flexible grid with 12 `1fr`-unit column tracks, each with a start line named `col-start`. This means that we will have twelve grid lines named `col-start`.

```
.wrapper {
  max-width: 1024px;
  margin: 0 auto;
  font:
    1.2em "Helvetica",
    "Arial",
    sans-serif;
}
.wrapper > * {
  border: 2px solid #f08c00;
  background-color: #ffec99;
  border-radius: 5px;
  padding: 10px;
}
```

```
.wrapper {
  display: grid;
  grid-template-columns: repeat(12, [col-start] 1fr);
  gap: 20px;
}
```

To demonstrate how this grid system works, we have four child elements inside a wrapper.

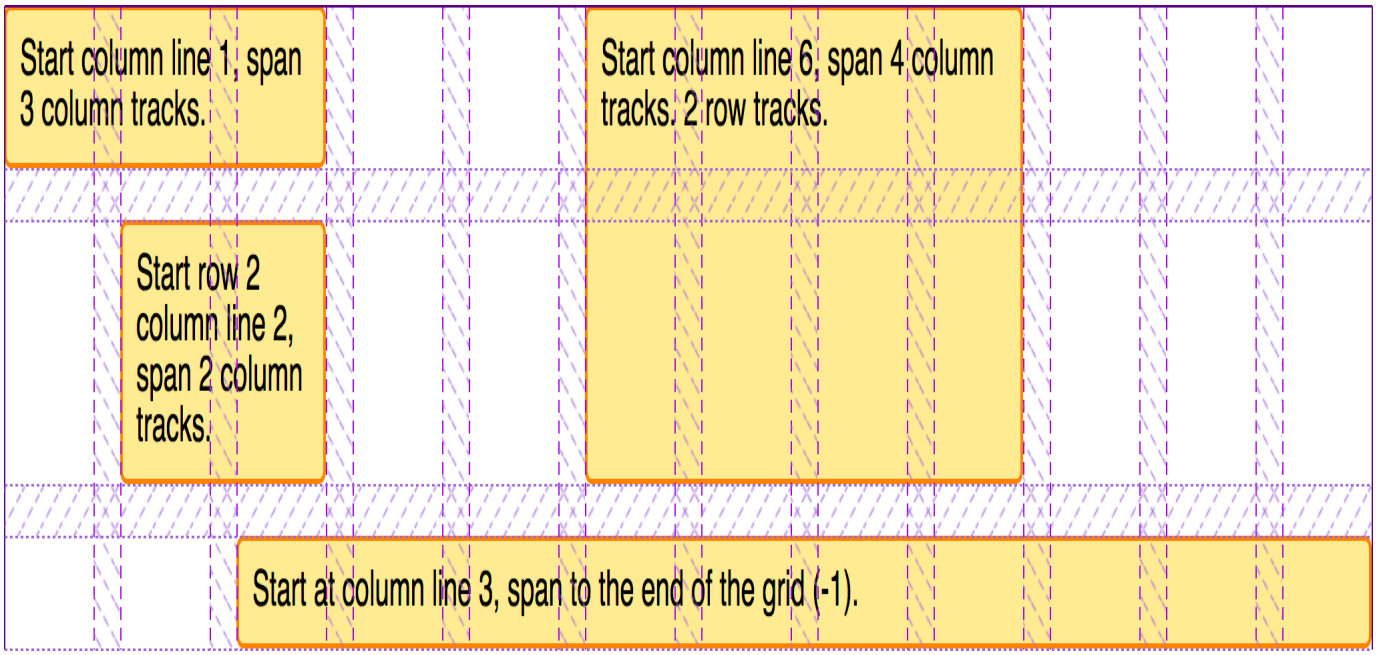
```
<div class="wrapper">
  <div class="item1">Start column line 1, span 3 column tracks.</div>
  <div class="item2">
    Start column line 6, span 4 column tracks. 2 row tracks.
  </div>
  <div class="item3">Start row 2 column line 2, span 2 column tracks.</div>
  <div class="item4">
    Start at column line 3, span to the end of the grid (-1).
  </div>
</div>
```

We can then place these on the grid using the named lines, and also the `span` keyword.

```
.item1 {
  grid-column: col-start / span 3;
}
.item2 {
  grid-column: col-start 6 / span 4;
  grid-row: 1 / 3;
}
.item3 {
  grid-column: col-start 2 / span 2;
  grid-row: 2;
}
.item4 {
  grid-column: col-start 3 / -1;
  grid-row: 3;
}
```

As described in the using named grid lines guide, we are using the named lines to place our items. As we have 12 lines all with the same name, we use the name and the index of the line. If you prefer, you can use the line index itself and avoid using named lines.

Rather than setting the end line number, we define how many tracks this element should span using the `span` keyword. When working with a multiple-column layout system, this method may be more intuitive for those who think of blocks in terms of the number of tracks of the grid they span, then adjusting for different breakpoints. To see how the blocks align themselves to the tracks, use the grid inspector in your browser developer tools; it likely clearly demonstrates how the items are placed.



We don't need to add any markup to create a row. CSS framework grid systems often did this to stop elements popping up into the row above for browsers that don't support CSS grid layout. However, this point is now moot — all modern browsers have supported CSS grid layout for a long time. CSS grids allow us to place items into rows, with no danger of them rising up into the row above if it is left empty. Due to this *strict* column and row placement, we can also easily leave white space in our layout. We also don't need special classes to indent items into the grid. All we need to do is specify the start and end line for the item.

Building a layout using the 12-column system

To see how this layout method works in practice, we can create the same layout we created with `grid-template-areas`, this time using the 12-column grid system. Let's start with the same markup as used for the grid template areas example.

```
* {
  box-sizing: border-box;
}
.wrapper {
  max-width: 1024px;
  margin: 0 auto;
  font:
    1.2em "Helvetica",
    "Arial",
    sans-serif;
}

.wrapper > * {
  border: 2px solid #f08c00;
  background-color: #ffec99;
  border-radius: 5px;
  padding: 10px;
}

nav ul {
  list-style: none;
  margin: 0;
  padding: 0;
}
```

```
<div class="wrapper">
  <header class="main-head">The header</header>
  <nav class="main-nav">
    <ul>
      <li><a href="">Nav 1</a></li>
      <li><a href="">Nav 2</a></li>
      <li><a href="">Nav 3</a></li>
    </ul>
  </nav>
  <article class="content">
    <h1>Main article area</h1>
    <p>
      In this layout, we display the areas in source order for any screen less
      that 500 pixels wide. We go to a two column layout, and then to a three
      column layout by redefining the grid, and the placement of items on the
      grid.
    </p>
  </article>
  <aside class="side">Sidebar</aside>
  <div class="ad">Advertising</div>
  <footer class="main-footer">The footer</footer>
</div>
```

We set up our grid as we did for the 12-column layout example above.

```
.wrapper {
  display: grid;
  grid-template-columns: repeat(12, [col-start] 1fr);
  gap: 20px;
}
```

We are again going to make this a responsive layout, this time using named lines. Every breakpoint will use a 12-column grid. However, the number of tracks items will span will change depending on the size of the screen.

We start mobile first. For the narrowest screens, we want the items to remain in source order and all span across the entire grid.

```
.wrapper > * {
  grid-column: col-start / span 12;
}
```

At the next breakpoint, we want a two-column layout. Our header and navigation still span the full grid, so we do not need to specify any positioning for them. The sidebar is starting on the first column line named `col-start`, spanning 3 lines. It goes after row line 3, as the header and navigation are in the first two row tracks.

The `ad` panel is below the sidebar, starting at grid row line 4. Then we have the content and footer starting at col-start 4 and spanning nine tracks, taking both to the end of the grid.

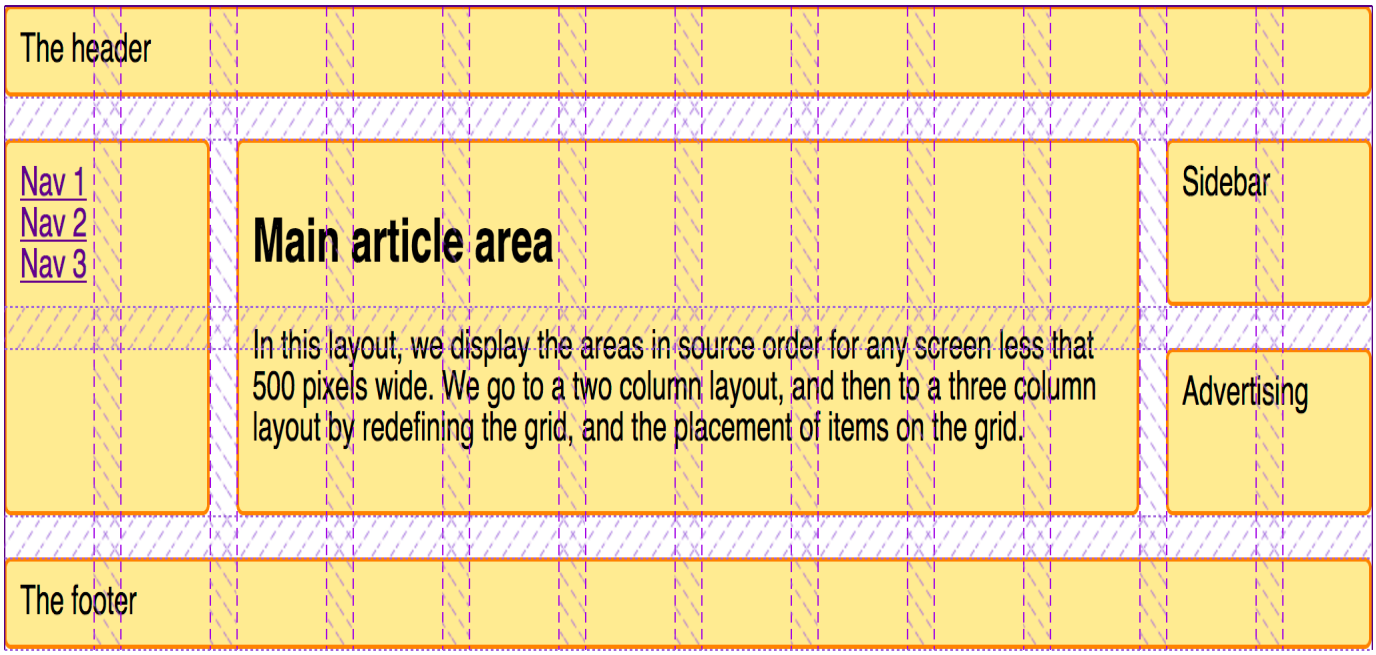
```
@media (width >= 500px) {
  .side {
    grid-column: col-start / span 3;
    grid-row: 3;
  }
  .ad {
    grid-column: col-start / span 3;
    grid-row: 4;
  }
  .content,
  .main-footer {
    grid-column: col-start 4 / span 9;
  }
  nav ul {
    display: flex;
    justify-content: space-between;
  }
}
```

Finally, for screens larger than our largest breakpoint, we define a three-column version of this layout. The header continues to span right across the grid, but now the navigation moves down to become the first sidebar, with the content and then the sidebar next to it. The footer now also spans across the full layout.

```
@media (width >= 700px) {
  .main-nav {
```

```
    grid-column: col-start / span 2;
    grid-row: 2 / 4;
  }
  .content {
    grid-column: col-start 3 / span 8;
    grid-row: 2 / 4;
  }
  .side {
    grid-column: col-start 11 / span 2;
    grid-row: 2;
  }
  .ad {
    grid-column: col-start 11 / span 2;
    grid-row: 3;
  }
  .main-footer {
    grid-column: col-start / span 12;
  }
  nav ul {
    flex-direction: column;
  }
}
```

Once again, check the grid inspector in your browser developer tools to see how the layout has taken shape.



Something to note as we created this layout is that we didn't need to explicitly position every element on the grid at each breakpoint. We inherited the placement set up for earlier breakpoints – an advantage of working "mobile first". We also took advantage of grid auto-placement. By keeping elements in a logical order, auto-placement does quite a lot of work for us in placing items onto the grid.

A product listing with auto-placement

In this last example in this guide, we create a layout that entirely relies on auto-placement.

Many layouts are essentially sets of "cards" – product listings, image galleries, and so on. A grid enables creating these listings in a way that is responsive without needing to add media queries. In this example, we combine CSS grid and flexbox layouts to make a basic product listing layout.

The markup for the listing is an unordered list of items. Each item contains a heading, some text of varying height, and a call to action link.

```
<ul class="listing">
  <li>
    <h2>Item One</h2>
    <div class="body">
      <p>The content of this listing item goes here.</p>
    </div>
    <div class="cta">
      <a href="">Call to action!</a>
    </div>
  </li>
  <li>
    <h2>Item Two</h2>
    <div class="body">
      <p>The content of this listing item goes here.</p>
    </div>
    <div class="cta">
      <a href="">Call to action!</a>
    </div>
  </li>
  <li class="wide">
    <h2>Item Three</h2>
    <div class="body">
      <p>The content of this listing item goes here.</p>
      <p>This one has more text than the other items.</p>
      <p>Quite a lot more</p>
      <p>Perhaps we could do something different with it?</p>
    </div>
    <div class="cta">
      <a href="">Call to action!</a>
    </div>
  </li>
```

```
  <li>
    <h2>Item Four</h2>
    <div class="body">
      <p>The content of this listing item goes here.</p>
    </div>
    <div class="cta">
      <a href="">Call to action!</a>
    </div>
  </li>
  <li>
    <h2>Item Five</h2>
    <div class="body">
      <p>The content of this listing item goes here.</p>
    </div>
    <div class="cta">
      <a href="">Call to action!</a>
    </div>
  </li>
</ul>
```

```
* {
  box-sizing: border-box;
}
img {
  max-width: 100%;
  display: block;
}
body {
  font:
    1.2em "Helvetica",
    "Arial",
    sans-serif;
}
a:link,
a:visited {
  text-decoration: none;
  color: #f08c00;
}

h2 {
  background-color: #f08c00;
  color: white;
  text-align: center;
  margin: 0;
  padding: 20px;
}
```

We create a grid with a flexible number of flexible columns. We want them to be at least 200 pixels wide and share any available remaining space equally – so we always get equal-width column tracks. We achieve this with the `minmax()` function in our `repeat()` notation for track sizing.

```
.listing {
  list-style: none;
  margin: 2em;
  display: grid;
  gap: 20px;
  grid-template-columns: repeat(auto-fill, minmax(200px, 1fr));
}
```

When we add this CSS, the items will be laid out as a grid. If we make the window smaller or wider, the number of column tracks changes – without media queries adding breakpoints and without needing to redefine the grid.

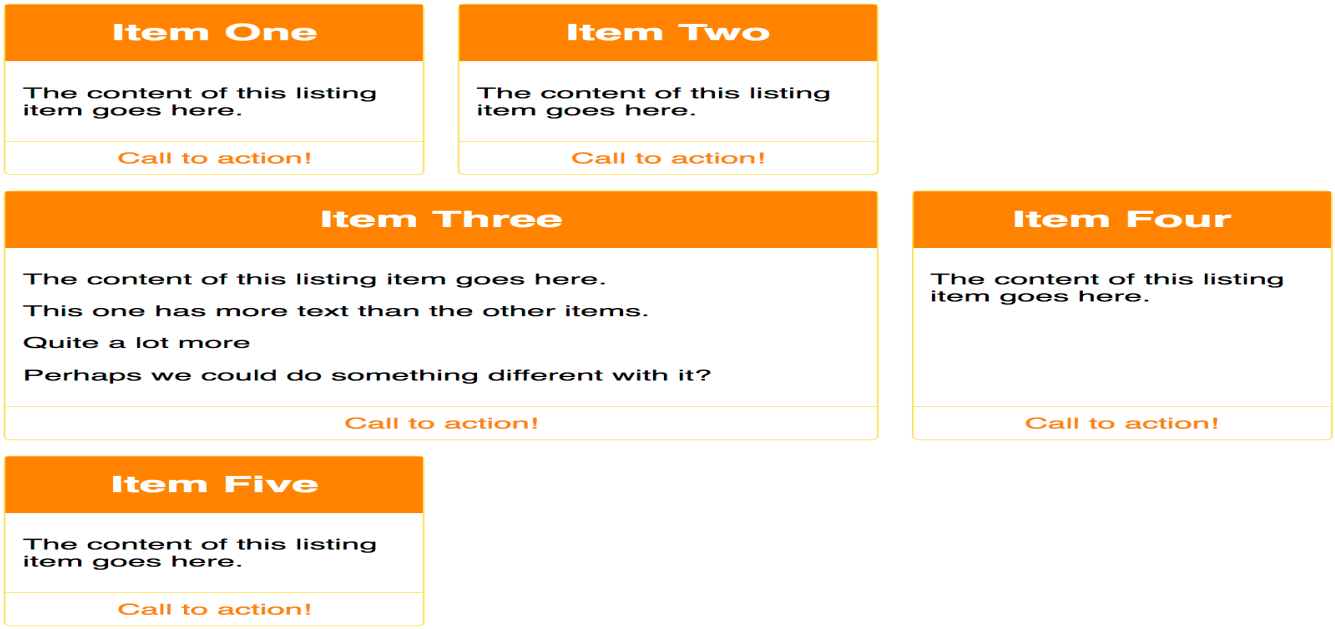
We can tidy up the internals of the boxes using a touch of flexbox. We set the list item to `display: flex` and the `flex-direction` to `column`. We can then use an auto margin on the `.cta` to push this bar down to the bottom of the box.

```
.listing li {
  border: 1px solid #ffe066;
  border-radius: 5px;
  display: flex;
  flex-direction: column;
}
.listing .cta {
  margin-block-start: auto;
  border-block-start: 1px solid #ffe066;
  padding: 10px;
  text-align: center;
}
.listing .body {
  padding: 10px;
}
```

This is one of the key reasons to use flexbox rather than CSS grid layout. If you're aligning or distributing content in a single dimension, that's a flexbox use case.

Preventing gaps with the dense keyword

This is all looking fairly complete now. However, we sometimes have cards that contain far more content than the others. It might be nice to make those span two tracks, then they won't be so tall. We add a `wide` class on the larger item, and add a rule giving it a `grid-column-end` with a value of `span 2`. When this item is encountered, it will be assigned to two tracks. This means that, at some breakpoints, we'll get a gap in the grid – where there isn't enough space to lay out a two-track item.



We can make the grid backfill those gaps by setting `grid-auto-flow: dense` on the grid container. Take care when doing this as it can cause items to be taken out of their logical source order. You should only do this if your items do not have a set order. Additionally, be aware of the accessibility and re-ordering issues resulting from the tab order following the source and not your reordered display.

```
<ul class="listing">
  <li>
    <h2>Item One</h2>
    <div class="body"><p>The content of this listing item goes here.</p></div>
    <div class="cta"><a href="">Call to action!</a></div>
  </li>
  <li>
    <h2>Item Two</h2>
    <div class="body"><p>The content of this listing item goes here.</p></div>
    <div class="cta"><a href="">Call to action!</a></div>
  </li>
  <li class="wide">
    <h2>Item Three</h2>
    <div class="body">
      <p>The content of this listing item goes here.</p>
      <p>This one has more text than the other items.</p>
      <p>Quite a lot more</p>
      <p>Perhaps we could do something different with it?</p>
    </div>
    <div class="cta"><a href="">Call to action!</a></div>
  </li>
  <li>
    <h2>Item Four</h2>
    <div class="body"><p>The content of this listing item goes here.</p></div>
    <div class="cta"><a href="">Call to action!</a></div>
  </li>
  <li>
    <h2>Item Five</h2>
    <div class="body"><p>The content of this listing item goes here.</p></div>
    <div class="cta"><a href="">Call to action!</a></div>
  </li>
</ul>
```

```
* {
  box-sizing: border-box;
}
img {
  max-width: 100%;
  display: block;
}
body {
  font:
    1.2em "Helvetica",
    "Arial",
    sans-serif;
}
a:link,
a:visited {
  text-decoration: none;
  color: #f08c00;
}

h2 {
  background-color: #f08c00;
  color: white;
  text-align: center;
  margin: 0;
  padding: 20px;
}

.listing li {
  border: 1px solid #ffe066;
  border-radius: 5px;
  display: flex;
  flex-direction: column;
```

```
}
.listing .cta {
  margin-block-start: auto;
  border-block-start: 1px solid #ffe066;
  padding: 10px;
  text-align: center;
}
.listing .body {
  padding: 10px;
}
```

```
.listing {
  list-style: none;
  margin: 2em;
  display: grid;
  gap: 20px;
  grid-auto-flow: dense;
  grid-template-columns: repeat(auto-fill, minmax(200px, 1fr));
}
.listing .wide {
  grid-column-end: span 2;
}
```

Using auto-placement with some rules applied to certain items is very useful and can help with content you can't control, such as CMS output, where you have repeated items and can use structural pseudo-classes to target them.

Further exploration

CSS grid layout provides so many possibilities. The best way to learn to use grid layout is to continue to build examples like the ones we have covered here. Pick a layout from a responsive site you like and see if you can build it using grid. You can even take inspiration from magazines or other non-web sources.

Grid lanes layout

> **Experimental: This is an experimental technology**
> Check the Browser compatibility table carefully before using this in production.

Level 3 of the CSS grid layout specification defines **grid lanes layout**, which is accessed via the `display` values `grid-lanes` and `inline-grid-lanes`. This guide explains how grid lanes layout works and how to use it.

Grid lanes layout is a layout method where one axis uses a strict grid layout and the other uses a stacking algorithm. Each item is placed into the lane with the most available space, producing a tightly packed layout without strict tracks on the stacking axis.

Grid lanes layout is often referred to as *masonry layout*, because it resembles the way bricks are laid in a wall, filling gaps as efficiently as possible.

Creating a grid lanes layout

To create the most common grid lanes layout, where the columns are laid out in a grid and the rows are packed using the grid lanes layout algorithm, use **`display: grid-lanes`** along with `grid-template-columns`.

The child elements of this container will lay out item by item along the stacking axis according to the grid lanes layout algorithm: each row of items loads into the column with the most room, causing a tightly packed layout without strict row tracks.

```
* {
  box-sizing: border-box;
}

body {
  font: 1.2em sans-serif;
}

.grid {
  padding: 10px;
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
}

.item {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  color: #d9480f;
}
```

```
.grid {
  display: grid-lanes;
  gap: 10px;
  grid-template-columns: repeat(auto-fill, minmax(120px, 1fr));
}
```

```
<div class="grid">
  <div class="item"></div>
  <div class="item"></div>
  <div class="item"></div>
  <div class="item"></div>
  <div class="item"></div>
  <div class="item"></div>
  <div class="item"></div>
  <div class="item"></div>
  <div class="item"></div>
  <div class="item"></div>
</div>
```

```
// prettier-ignore
const itemSizes = [
  "2em", "3em", "1.6em", "4em", "3.2em",
  "3em", "4.5em", "1em", "3.5em", "2.8em",
];
const items = document.querySelectorAll(".item");
for (let i = 0; i < items.length; i++) {
  items[i].style.blockSize = itemSizes[i];
}
```

It is also possible to create a grid lanes layout with items loading into rows.

```
// prettier-ignore
const itemSizes = [
  "2em", "3em", "1.6em", "4em", "2.2em",
  "3em", "4.5em", "1em", "3.5em", "2.8em",
];
const items = document.querySelectorAll(".item");
for (let i = 0; i < items.length; i++) {
  items[i].style.inlineSize = itemSizes[i];
}
```

```
.grid {
  display: grid-lanes;
  gap: 10px;
  grid-template-rows: repeat(3, 100px);
}
```

Controlling the grid axis

On the grid axis, things will work just as you expect them to in grid layout. You can cause items to span multiple tracks while remaining in auto-placement, using the `span` keyword. Items may also be positioned using line-based positioning.

Grid lanes layout with spanning items

In this example two of the items span two tracks, and the remaining items are packed around them by the grid lanes layout algorithm.

```
<div class="grid">
  <div class="item"></div>
  <div class="item span-2"></div>
  <div class="item"></div>
  <div class="item"></div>
  <div class="item span-2"></div>
  <div class="item"></div>
  <div class="item"></div>
  <div class="item"></div>
  <div class="item"></div>
  <div class="item"></div>
</div>
```

```
.grid {
  display: grid-lanes;
  gap: 10px;
  grid-template-columns: repeat(auto-fill, minmax(120px, 1fr));
}

.span-2 {
  grid-column-end: span 2;
}
```

This example includes an item which has positioning for columns. Items with definite placement are placed before the grid lanes layout algorithm runs.

```
<div class="grid">
  <div class="item"></div>
  <div class="item"></div>
  <div class="item"></div>
  <div class="item"></div>
  <div class="item positioned">positioned.</div>
  <div class="item"></div>
  <div class="item"></div>
  <div class="item"></div>
  <div class="item"></div>
  <div class="item"></div>
</div>
```

```
.grid {
  display: grid-lanes;
  gap: 10px;
  grid-template-columns: repeat(auto-fill, minmax(120px, 1fr));
}

.positioned {
  padding: 1em;
  grid-column: 2 / 4;
}
```

- `grid-auto-flow` for controlling grid auto-placement

Grid template areas

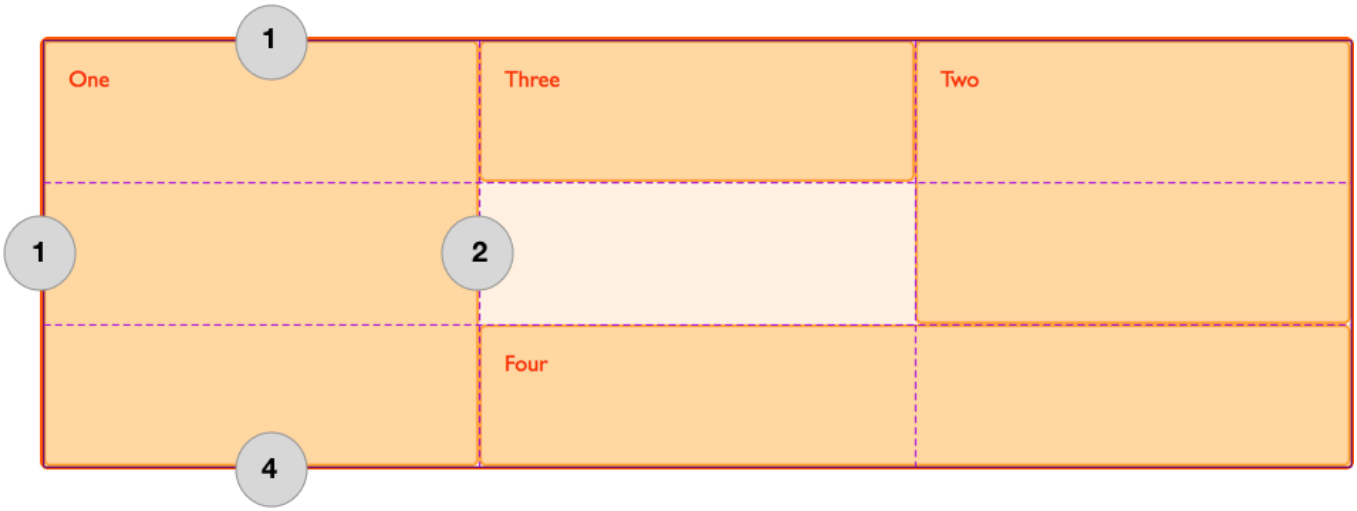
In the grid layout using line-based placement guide, we looked at grid lines and how to position items against those lines. When you use CSS grid layout, you always have lines, and this can be a straightforward way to place items on your grid. However, there is an alternate method to use for positioning items on the grid which you can use alone or in combination with line-based placement. This method involves placing our items using named template areas. You will see very quickly why we sometimes call this the ascii-art method of grid layout!

Naming a grid area

You have already encountered the `grid-area` property. This is the property that can take as a value all four of the lines used to position a grid area.

```
.box1 {
  grid-area: 1 / 1 / 4 / 2;
}
```

What we are doing here when defining all four lines, is defining the area by specifying the lines that enclose that area.



We can also define an area by giving it a name and then specify the location of that area in the value of the `grid-template-areas` property. You can choose what you would like to name your area. For example, if we wish to create the layout shown below we can identify four main areas.

- a header
- a footer
- a sidebar
- the main content

With the `grid-area` property we can assign each of these areas a name. By itself, this does not create any layout. Rather, it provides named areas to use in a layout.

```
.header {
  grid-area: hd;
}
.footer {
  grid-area: ft;
}
.content {
  grid-area: main;
}
.sidebar {
  grid-area: sd;
}
```

Having defined these names, we then create the layout. This time, instead of placing items using line numbers specified on the items themselves, we create the whole layout on the grid container. Here we create a 9-column grid and specify that the `hd` and `ft` areas span all 9 columns, while `sd` spans three and `main` spans six. Each area spans only one row.

```
.wrapper {
  display: grid;
  grid-template-columns: repeat(9, 1fr);
  grid-auto-rows: minmax(100px, auto);
  grid-template-areas:
    "hd hd hd hd   hd   hd   hd   hd   hd"
    "sd sd sd main main main main main main"
```

```
    "ft ft ft ft   ft   ft   ft   ft   ft";
}
```

```
* {
  box-sizing: border-box;
}

.wrapper {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
  max-width: 940px;
  margin: 0 auto;
}

.wrapper > div {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  padding: 1em;
  color: #d9480f;
}
```

```
<div class="wrapper">
  <div class="header">Header</div>
  <div class="sidebar">Sidebar</div>
  <div class="content">Content</div>
  <div class="footer">Footer</div>
</div>
```

Using this method we do not need to specify anything at all on the individual grid items, everything happens on our grid container. We can see the layout described as the value of the `grid-template-areas` property.

Leaving a grid cell empty

We have completely filled our grid with areas in this example, leaving no white space. However you can leave grid cells empty with this method of layout. To leave a cell empty use the full stop character, `.`. If we want to only display the footer directly under the main content we would need to leave the three cells underneath the sidebar empty.

```
.header {
  grid-area: hd;
}
.footer {
  grid-area: ft;
}
.content {
  grid-area: main;
}
.sidebar {
  grid-area: sd;
}
```

```
* {
  box-sizing: border-box;
}

.wrapper {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
  max-width: 940px;
  margin: 0 auto;
}

.wrapper > div {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  padding: 1em;
  color: #d9480f;
}
```

```
.wrapper {
  display: grid;
  grid-template-columns: repeat(9, 1fr);
  grid-auto-rows: minmax(100px, auto);
  grid-template-areas:
    "hd hd hd hd   hd   hd   hd   hd   hd"
    "sd sd sd main main main main main main"
    ".  .  .  ft   ft   ft   ft   ft   ft";
}
```

```
<div class="wrapper">
  <div class="header">Header</div>
  <div class="sidebar">Sidebar</div>
  <div class="content">Content</div>
  <div class="footer">Footer</div>
</div>
```

In order to make the layout neater we can use multiple `.` characters. As long as there is at least one white space between the full stops it will be counted as one cell. For a complex layout there is a benefit to having the rows and columns neatly aligned. It means that you can actually see, right there in the CSS, what this layout looks like.

Spanning multiple cells

In our example, each area spans multiple grid cells and we achieve this by repeating the name of that grid area multiple times with white space between. You can add extra white space to keep your columns neatly lined up in the value of `grid-template-areas`. You can see that we have done this so that the `hd` and `ft` areas line up with `main`.

The area that you create by chaining the area names must be rectangular, at this point there is no way to create an L-shaped area. The specification does note that a future level might provide this functionality. You can however span rows just as easily as columns. For example we could make our sidebar span down to the end of the footer by replacing the `.` with `sd`.

```
.header {
  grid-area: hd;
}
.footer {
  grid-area: ft;
}
.content {
  grid-area: main;
}
.sidebar {
  grid-area: sd;
}
```

```
* {
  box-sizing: border-box;
}

.wrapper {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
  max-width: 940px;
  margin: 0 auto;
}

.wrapper > div {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  padding: 1em;
  color: #d9480f;
}
```

```
.wrapper {
  display: grid;
  grid-template-columns: repeat(9, 1fr);
  grid-auto-rows: minmax(100px, auto);
  grid-template-areas:
    "hd hd hd hd   hd   hd   hd   hd   hd"
    "sd sd sd main main main main main main"
    "sd sd sd  ft  ft   ft   ft   ft   ft";
}
```

```
<div class="wrapper">
  <div class="header">Header</div>
  <div class="sidebar">Sidebar</div>
  <div class="content">Content</div>
  <div class="footer">Footer</div>
</div>
```

The value of `grid-template-areas` must show a complete grid, otherwise it is invalid (and the property is ignored). This means that you must have the same number of cells for each row, if empty with a full stop character demonstrating that the cell is to be left empty. You will also create an invalid grid if your areas are not rectangular.

Redefining the grid using media queries

As our layout is now contained in one part of the CSS, we can make changes for different breakpoints in one location in our codebase. You can do this by redefining the grid, the position of items on the grid, or both at once.

When doing this, define the names for your areas outside of any media queries. That way the content area would always be called `main` no matter where on the grid it is placed.

For our layout above, we might like to have a very basic layout at narrow widths, defining a single column grid and stacking our four items into four rows.

```
* {
  box-sizing: border-box;
}

.wrapper {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
  max-width: 940px;
  margin: 0 auto;
}

.wrapper > div {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  padding: 1em;
  color: #d9480f;
}
```

```
.header {
  grid-area: hd;
}
.footer {
  grid-area: ft;
}
.content {
  grid-area: main;
}
.sidebar {
  grid-area: sd;
}

.wrapper {
  display: grid;
  grid-auto-rows: minmax(100px, auto);
  grid-template-columns: 1fr;
  grid-template-areas:
```

```
    "hd"
    "main"
    "sd"
    "ft";
}
```

We can then redefine that layout inside media queries to go to our two columns layout, and perhaps take it to a three column layout if the available space is even wider. Note that for the wide layout, we keep the nine-column track grid, redefining where items are placed using `grid-template-areas`.

```
@media (width >= 30em) {
  .wrapper {
    grid-template-columns: repeat(9, 1fr);
    grid-template-areas:
      "hd hd hd hd   hd   hd   hd   hd   hd"
      "sd sd sd main main main main main main"
      "sd sd sd  ft  ft   ft   ft   ft   ft";
  }
}
@media (width >= 60em) {
  .wrapper {
    grid-template-areas:
      "hd hd hd   hd   hd   hd   hd   hd hd"
      "sd sd main main main main main ft ft";
  }
}
```

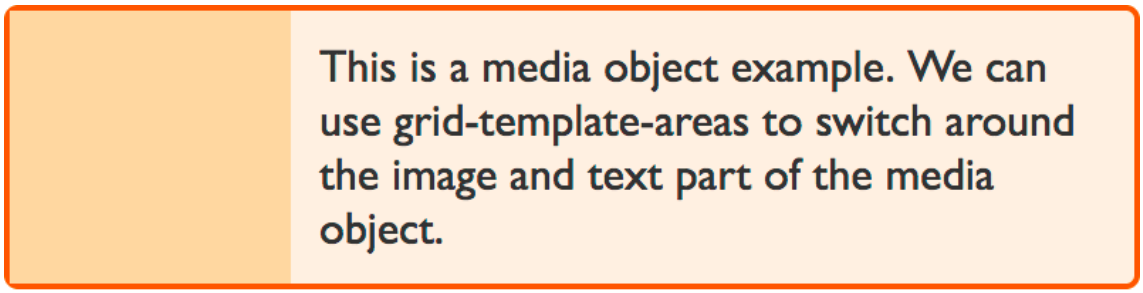
```
<div class="wrapper">
  <div class="header">Header</div>
  <div class="sidebar">Sidebar</div>
  <div class="content">Content</div>
  <div class="footer">Footer</div>
</div>
```

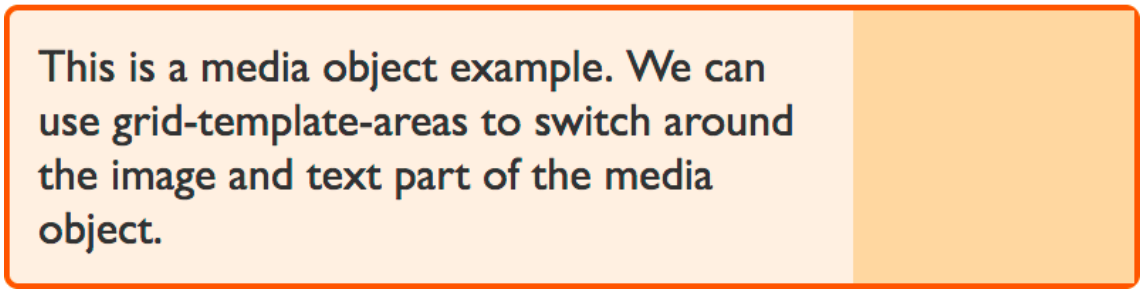
Using <code>grid-template-areas</code> for UI elements

Many of the grid examples you will find online assume you are using grid for whole page layouts; however, grid can be just as useful for laying out small sections. Using `grid-template-areas` can be especially nice as it allows you to visualize what your element looks like in the code.

Media object example

As an example, we can create a "media object". This is a component with space for an image or other media on one side and content on the other. The image might be displayed on the right or left of the box.





Our grid is a two-column track grid, with the column for the image sized at `1fr` and the text `3fr`. If you wanted a fixed width image area, then you could set the image column as a pixel width, and assign the text area `1fr`. A single column track of `1fr` would then take up the rest of the space.

We give the image area a grid area name of `img` and the text area `content`, then we can lay those out using the `grid-template-areas` property.

```
* {
  box-sizing: border-box;
}

.media {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
  max-width: 400px;
  display: grid;
  grid-template-columns: 1fr 3fr;
  grid-template-areas: "img content";
  margin-bottom: 1em;
}

.media .image {
  grid-area: img;
  background-color: #ffd8a8;
}

.media .text {
```

```
  grid-area: content;
  padding: 10px;
}
```

```
<div class="media">
  <div class="image"></div>
  <div class="text">
    This is a media object example. We can use grid-template-areas to switch
    around the image and text part of the media object.
  </div>
</div>
```

Displaying the image on the other side of the box

We might want to be able to display our box with the image the other way around. To do this, we redefine the grid to put the `1fr` track last, and flip the values in `grid-template-areas`.

```
* {
  box-sizing: border-box;
}

.media {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
  max-width: 400px;
  display: grid;
  grid-template-columns: 1fr 3fr;
  grid-template-areas: "img content";
  margin-bottom: 1em;
}

.media.flipped {
  grid-template-columns: 3fr 1fr;
  grid-template-areas: "content img";
}

.media .image {
  grid-area: img;
  background-color: #ffd8a8;
}

.media .text {
  grid-area: content;
  padding: 10px;
}
```

```
<div class="media flipped">
  <div class="image"></div>
  <div class="text">
    This is a media object example. We can use grid-template-areas to switch
    around the image and text part of the media object.
  </div>
</div>
```

Grid definition shorthands

Having looked at various ways of placing items on our grids and many of the properties used to define grid, this is a good time to take a look at a couple of shorthands that are available for defining the grid and many things about it all in one line of CSS.

These can quickly become difficult to read for other developers, or even your future self. However they are part of the specification and it is likely you will come across them in examples or in use by other developers, even if you choose not to use them.

Before using any shorthand it is worth remembering that shorthands not only enable the setting of many properties in one go, but they also **reset** everything that you do not (or cannot) set in the shorthand to their initial values. Therefore if you use a shorthand, be aware that it may reset things you have applied elsewhere.

The two shorthands for the grid container are the explicit grid shorthand `grid-template` and the grid definition shorthand `grid` .

<code>grid-template</code>

The `grid-template` shorthand property sets the following longhand properties:

- `grid-template-rows`
- `grid-template-columns`
- `grid-template-areas`

The property is referred to as the *explicit grid shorthand* because it sets values that you control when you define an explicit grid, and not those that impact any implicit row or column tracks that might be created.

The following code creates a layout using `grid-template` that is the same as the layout created earlier in this guide.

```
.wrapper {
  display: grid;
  grid-template:
    "hd hd hd hd   hd   hd   hd   hd   hd" minmax(100px, auto)
    "sd sd sd main main main main main main" minmax(100px, auto)
    "ft ft ft ft   ft   ft   ft   ft   ft" minmax(100px, auto)
    / 1fr 1fr 1fr 1fr 1fr 1fr 1fr 1fr 1fr;
}
```

The first value is our `grid-template-areas` value but we also declare the size of the row at the end of each row. This is what the `minmax(100px, auto)` is doing.

Then after `grid-template-areas` we have a forward slash, after that is an explicit track listing of column tracks.

<code>grid</code>

The `grid` shorthand goes a step further and also sets properties used by the implicit grid. So you will be setting:

- `grid-template-rows`
- `grid-template-columns`

- `grid-template-areas`
- `grid-auto-rows`
- `grid-auto-columns`
- `grid-auto-flow`

You can use this syntax in the exact same way as the `grid-template` shorthand. Just be aware that when doing so you will reset the other values set by the property.

```
.wrapper {
  display: grid;
  grid:
    "hd hd hd hd   hd   hd   hd   hd   hd" minmax(100px, auto)
    "sd sd sd main main main main main main" minmax(100px, auto)
    "ft ft ft ft   ft   ft   ft   ft   ft" minmax(100px, auto)
    / 1fr 1fr 1fr 1fr 1fr 1fr 1fr 1fr 1fr;
}
```

We will revisit the other functionality offered by this shorthand when we take a look at auto-placement in grid layout and the `grid-auto-flow` property.

Next steps

If you've been working along the grid guides, you should be in a position to create grid layouts using line-based placement or named template areas. Now let's take a look at creating grid layouts using named grid lines.

Grid layout using line-based placement

In the basic concepts of grid layout guide, we took a brief look at positioning items on a grid using line numbers. In this guide, we will fully explore how this fundamental feature of the specification works.

Starting your exploration of grid with numbered lines is the most logical place to begin because when you use grid layout, you always have numbered lines. The lines are numbered for columns and rows, and are indexed from 1. Note that grid is indexed according to the writing mode of the document. In a left-to-right language, such as English, line 1 is on the left-hand side of the grid. If you are working in a right-to-left language, such as Arabic, then line 1 will be on the right-hand of the grid. We will learn more about the interaction between writing modes and grids in the grids, logical values, and writing modes guide.

A basic example

As a basic example, we create a grid with 3 column tracks and 3 row tracks. This gives us 4 lines in each dimension.

```
* {
  box-sizing: border-box;
}

.wrapper {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
}

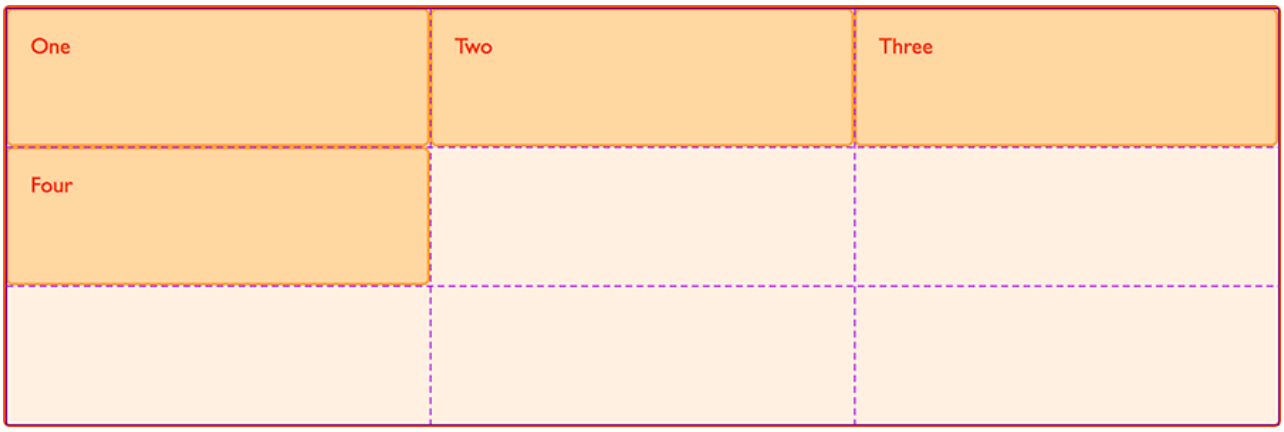
.wrapper > div {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  padding: 1em;
  color: #d9480f;
}
```

```
.wrapper {
  display: grid;
  grid-template-columns: repeat(3, 1fr);
  grid-template-rows: repeat(3, 100px);
}
```

Inside our grid container, we include four child elements.

```
<div class="wrapper">
  <div class="box1">One</div>
  <div class="box2">Two</div>
  <div class="box3">Three</div>
  <div class="box4">Four</div>
</div>
```

If we do not place these onto the grid in any way, they will lay out according to the auto-placement rules, one item in each of the first four cells. You can inspect the grid with your browser developer tools to see how the grid defines columns and rows.



Positioning items by line number

We can use line-based placement to control where these items sit on the grid. We can use the `grid-column-start` and `grid-column-end` properties to make the first item start on the far left of the grid and span a single column track. With `grid-row-start` and `grid-row-end`, we make the item start on the first row line at the top of the grid, and span to the fourth row line.

```
.box1 {
  grid-column-start: 1;
  grid-column-end: 2;
  grid-row-start: 1;
  grid-row-end: 4;
}
```

As you position some items, other items on the grid will continue to be laid out using the auto-placement rules. This behavior is explained in the Auto-placement in grid layout guide. For now, observe how the grid is laying out un-placed items into empty cells of the grid.

Addressing each item individually using the same properties but with different values, we place all four items, spanning row and column tracks.

```
* {
  box-sizing: border-box;
}

.wrapper {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
  display: grid;
  grid-template-columns: repeat(3, 1fr);
  grid-template-rows: repeat(3, 100px);
}

.wrapper > div {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  padding: 1em;
  color: #d9480f;
}
```

```
<div class="wrapper">
  <div class="box1">One</div>
  <div class="box2">Two</div>
  <div class="box3">Three</div>
  <div class="box4">Four</div>
</div>
```

```
.box1 {
  grid-column-start: 1;
  grid-column-end: 2;
  grid-row-start: 1;
  grid-row-end: 4;
}
.box2 {
  grid-column-start: 3;
  grid-column-end: 4;
  grid-row-start: 1;
  grid-row-end: 3;
}
.box3 {
  grid-column-start: 2;
  grid-column-end: 3;
  grid-row-start: 1;
  grid-row-end: 2;
}
.box4 {
  grid-column-start: 2;
  grid-column-end: 4;
  grid-row-start: 3;
  grid-row-end: 4;
}
```

Note that we can leave cells empty if we wish. One of the very nice things about grid layout is the ability to have white space in our designs without any hacks.

The <code>grid-column</code> and <code>grid-row</code> shorthands

The previous example had quite a lot of code to position each item. It should come as no surprise to know there is a shorthand. The `grid-column-start` and `grid-column-end` properties can be combined into `grid-column`, `grid-row-start` and `grid-row-end` into `grid-row`. In this example, we replicate the above example using these shorthand properties:

```
* {
  box-sizing: border-box;
}

.wrapper {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
  display: grid;
  grid-template-columns: repeat(3, 1fr);
  grid-template-rows: repeat(3, 100px);
}

.wrapper > div {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  padding: 1em;
  color: #d9480f;
}
```

```
<div class="wrapper">
  <div class="box1">One</div>
  <div class="box2">Two</div>
  <div class="box3">Three</div>
  <div class="box4">Four</div>
</div>
```

```
.box1 {
  grid-column: 1 / 2;
  grid-row: 1 / 4;
}
.box2 {
  grid-column: 3 / 4;
  grid-row: 1 / 3;
}
.box3 {
  grid-column: 2 / 3;
  grid-row: 1 / 2;
}
.box4 {
  grid-column: 2 / 4;
  grid-row: 3 / 4;
}
```

Default spans

In the above examples, we specified every end row and column line, in order to demonstrate the properties, however in practice if an item only spans one track you can omit the `grid-column-end` or `grid-row-end` value. Grid defaults to spanning one track.

Default spans with longhand placement

This means that our initial, long-hand, example would look like this:

```
* {
  box-sizing: border-box;
}

.wrapper {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
  display: grid;
  grid-template-columns: repeat(3, 1fr);
  grid-template-rows: repeat(3, 100px);
}

.wrapper > div {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  padding: 1em;
  color: #d9480f;
}
```

```
<div class="wrapper">
  <div class="box1">One</div>
  <div class="box2">Two</div>
  <div class="box3">Three</div>
  <div class="box4">Four</div>
</div>
```

```
.box1 {
  grid-column-start: 1;
  grid-row-start: 1;
  grid-row-end: 4;
}
.box2 {
  grid-column-start: 3;
  grid-row-start: 1;
  grid-row-end: 3;
}
.box3 {
  grid-column-start: 2;
  grid-row-start: 1;
}
.box4 {
  grid-column-start: 2;
  grid-column-end: 4;
  grid-row-start: 3;
}
```

Default spans with shorthand placement

Our shorthand would look like the following code, with no forward slash and second value for the items spanning one track only.

```
* {
  box-sizing: border-box;
}

.wrapper {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
  display: grid;
  grid-template-columns: repeat(3, 1fr);
  grid-template-rows: repeat(3, 100px);
}

.wrapper > div {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  padding: 1em;
  color: #d9480f;
}
```

```
<div class="wrapper">
  <div class="box1">One</div>
  <div class="box2">Two</div>
  <div class="box3">Three</div>
  <div class="box4">Four</div>
</div>
```

```
.box1 {
  grid-column: 1;
  grid-row: 1 / 4;
}
.box2 {
  grid-column: 3;
  grid-row: 1 / 3;
}
.box3 {
  grid-column: 2;
  grid-row: 1;
}
.box4 {
  grid-column: 2 / 4;
  grid-row: 3;
}
```

The <code>grid-area</code> property

We can take things a step further and define each area with a single property – `grid-area`. The order of the values for `grid-area` is as follows.

– `grid-row-start` – `grid-column-start` – `grid-row-end` – `grid-column-end`

```
* {
  box-sizing: border-box;
}

.wrapper {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
  display: grid;
  grid-template-columns: repeat(3, 1fr);
  grid-template-rows: repeat(3, 100px);
}

.wrapper > div {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  padding: 1em;
  color: #d9480f;
}
```

```
<div class="wrapper">
  <div class="box1">One</div>
  <div class="box2">Two</div>
  <div class="box3">Three</div>
  <div class="box4">Four</div>
</div>
```

```
.box1 {
  grid-area: 1 / 1 / 4 / 2;
}
.box2 {
  grid-area: 1 / 3 / 3 / 4;
}
.box3 {
  grid-area: 1 / 2 / 2 / 3;
}
.box4 {
  grid-area: 3 / 2 / 4 / 4;
}
```

This order of values for `grid-area` can seem a little strange — it is the opposite of the direction in which we specify margins and padding as a shorthand, for example. It may help to realize that this is due to CSS grid layout using the flow-relative directions defined in CSS writing modes. We explore how grids work with writing modes in grids, logical values, and writing modes. For now, consider the concept of four flow-relative directions:

- `block-start`
- `block-end`
- `inline-start`
- `inline-end`

We are working in English, a left-to-right language. Our `block-start` is the top row line of the grid container, `block-end` is the final row line of the container. Our `inline-start` is the left-hand column line as `inline-start` is always the point from which text would be written in the current writing mode, while `inline-end` is the final column line of our grid.

When we specify our grid area using the `grid-area` property we first define both start lines `block-start` and `inline-start`, then both end lines `block-end` and `inline-end`. This seems unusual at first as we are used to the physical properties of `top`, `right`, `bottom`, and `left`, but it makes more sense if you start to think of websites as being multi-directional in different writing modes.

Counting backwards

We can also count backwards from the block and inline ends of the grid, for English that would be the right-hand column line and final row line. The last lines of the explicit grid can be addressed as `-1`, and you can count back from there – so the second to last line is `-2`.

Do note that negative values are relevant only to the explicit grid. The final line is the final line of the grid defined by `grid-template-columns` and `grid-template-rows`, and does not take into account any rows or columns added in the *implicit grid* outside of that.

In this next example, we have flipped the layout we were working with by working from the right and bottom of our grid when placing the items.

```
* {
  box-sizing: border-box;
```

```
}

.wrapper {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
  display: grid;
  grid-template-columns: repeat(3, 1fr);
  grid-template-rows: repeat(3, 100px);
}

.wrapper > div {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  padding: 1em;
  color: #d9480f;
}
```

```
<div class="wrapper">
  <div class="box1">One</div>
  <div class="box2">Two</div>
  <div class="box3">Three</div>
  <div class="box4">Four</div>
</div>
```

```
.box1 {
  grid-column-start: -1;
  grid-column-end: -2;
  grid-row-start: -1;
  grid-row-end: -4;
}
.box2 {
  grid-column-start: -3;
  grid-column-end: -4;
  grid-row-start: -1;
  grid-row-end: -3;
}
.box3 {
  grid-column-start: -2;
  grid-column-end: -3;
  grid-row-start: -1;
  grid-row-end: -2;
}
.box4 {
  grid-column-start: -2;
  grid-column-end: -4;
  grid-row-start: -3;
  grid-row-end: -4;
}
```

Stretching an item across the grid

Being able to address the start and end lines of the grid is useful as you can then stretch an item right across the grid with:

```
.item {
  grid-column: 1 / -1;
}
```

Gutters or Alleys

CSS grid includes the ability to add gutters between column and row tracks with the `column-gap` and `row-gap` properties, or `gap` shorthand.

Gaps only appear between tracks of the grid, they do not add space to the top and bottom, left or right of the container. We can add gaps to our earlier example by using these properties on the grid container.

```
* {
  box-sizing: border-box;
}

.wrapper {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
  display: grid;
  grid-template-columns: repeat(3, 1fr);
  grid-template-rows: repeat(3, 100px);
}

.wrapper > div {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  padding: 1em;
  color: #d9480f;
}
```

```
<div class="wrapper">
  <div class="box1">One</div>
  <div class="box2">Two</div>
  <div class="box3">Three</div>
  <div class="box4">Four</div>
</div>
```

```
.box1 {
  grid-column: 1;
  grid-row: 1 / 4;
}
.box2 {
  grid-column: 3;
  grid-row: 1 / 3;
```

```
}
.box3 {
  grid-column: 2;
  grid-row: 1;
}
.box4 {
  grid-column: 2 / 4;
  grid-row: 3;
}
.wrapper {
  display: grid;
  grid-template-columns: repeat(3, 1fr);
  grid-template-rows: repeat(3, 100px);
  column-gap: 20px;
  row-gap: 1em;
}
```

The gap shorthand

The two properties can also be expressed as a shorthand, `gap`. If you only give one value for `gap` it will apply to both column and row gaps. If you specify two values, the first is used for `row-gap` and the second for `column-gap`.

```
.wrapper {
  display: grid;
  grid-template-columns: repeat(3, 1fr);
  grid-template-rows: repeat(3, 100px);
  gap: 1em 20px;
}
```

In terms of line-based positioning of items, the gap acts as if the line has gained extra width. Anything starting at that line starts after the gap and you cannot address the gap or place anything into it. If you want gutters that act more like regular tracks you can define a track for that purpose.

Using the <code>span</code> keyword

In addition to specifying the start and end lines by number, you can specify a start line and then the number of tracks you would like the area to span using the `span` keyword.

```
* {
  box-sizing: border-box;
}

.wrapper {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
  display: grid;
  grid-template-columns: repeat(3, 1fr);
  grid-template-rows: repeat(3, 100px);
}

.wrapper > div {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  padding: 1em;
  color: #d9480f;
}
```

```
<div class="wrapper">
  <div class="box1">One</div>
  <div class="box2">Two</div>
  <div class="box3">Three</div>
  <div class="box4">Four</div>
</div>
```

```
.box1 {
  grid-column: 1;
  grid-row: 1 / span 3;
}
.box2 {
  grid-column: 3;
  grid-row: 1 / span 2;
}
.box3 {
  grid-column: 2;
  grid-row: 1;
}
.box4 {
  grid-column: 2 / span 2;
  grid-row: 3;
}
```

You can also use the `span` keyword in the value of `grid-row-start`/`grid-row-end` and `grid-column-start`/`grid-column-end`. The following two examples will create the same grid area. In the first we set the start row line, then the end line we specify that we want the area to cover 3 tracks. The area will start at line 1 and end 3 lines from line 1; that is, the area will end at line 4.

```
.box1 {
  grid-column-start: 1;
  grid-row-start: 1;
  grid-row-end: span 3;
}
```

In the second example, we specify the end row line we want the item to finish at and then set the start line as `span 3`. This means the item will need to span upwards from the specified row line. The area will start at line 4 and span 3 lines to line 1.

```
.box1 {
  grid-column-start: 1;
  grid-row-start: span 3;
  grid-row-end: 4;
}
```

To become familiar with line based positioning in grid, try to build a few common layouts by placing items onto grids with varying numbers of columns. Remember that if you do not place all of the items, any leftover items will be placed according to auto-placement rules. This may result in the layout you want, but if something is appearing somewhere unexpected, check that you have set a position for it.

Also, remember that items on the grid can overlap when you place them explicitly like this. Overlapping items can create some nice effects, however, you can also end up with incorrect overlapping if you specify the wrong start or end line. Inspecting grids with your browser developer tools can be very helpful for identifying such problems as you learn, especially if your grid is quite complicated.

Grids, logical values, and writing modes

One of the most important features of CSS grid layout is the support for different writing modes built into the specification. In this guide, we look at this feature of CSS grid layout and other modern layout methods, learning a little about writing modes and logical vs. physical properties as we do so.

Logical and physical properties and values

CSS is full of **physical** positioning properties and keywords – `left` and `right`, `top` and `bottom`. In the code snippet below, we position an item using absolute positioning and use the physical inset properties as offset values to push the item around. The item is placed 20 pixels from the top and 30 pixels from the left of the container:

```
.container {
  position: relative;
}
.item {
  position: absolute;
  top: 20px;
  left: 30px;
}
```

```
<div class="container">
  <div class="item">Item</div>
</div>
```

This example uses the `left` and `right` properties; these are just two of the many **physical properties** in CSS. We can also add margins, padding, and borders using physical properties, for example `margin-left` and `padding-left`. You might also see physical keywords in use, such as when using `text-align: right` to align text to the right.

We call these keywords and properties *physical* because they relate to the screen you are looking at. Left is always left, no matter what direction your text is running.

Issues with physical properties

Physical properties can cause issues when developing a site that has to work in multiple languages, including languages where the text flows from right to left, or top to bottom. Browsers are designed to correctly display content regardless of the language. Some CSS features can override browser defaults and cause content to display less than optimally.

In this example, the `direction` property has been set to rtl, which switches the writing mode from the default for an English language document of `ltr`. We have two paragraphs. These should both flow from right to left because of the `direction` value set on an ancestor element (`<body>`). The first paragraph has `text-align` set to `left`, so it aligns with the left of its container. The second paragraph aligns with the right and flows from right to left.

```
<p class="left">
  I have my text set to <code>text-align: left</code> I will always align left
  even if the direction of the text in this document is rtl.
</p>

<p>I have no alignment set and use the direction set in the document.</p>
```

```
body {
  direction: rtl;
}
.left {
  text-align: left;
}
```

```
p {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  padding: 1em;
  margin: 1em;
  color: #d9480f;
}
```

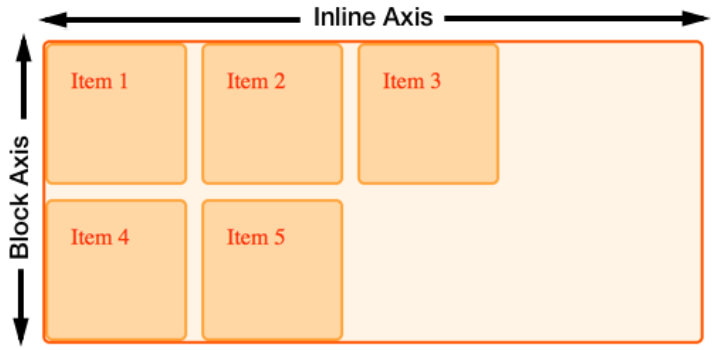
This is a basic demonstration of the problems that can arise when using physical values and properties in CSS. If we write CSS using physical properties and keywords, we tell the browser our assumption as to how the text will flow and prevent it from handling alternative writing modes.

Logical properties and values

Logical properties and values do not assume a text direction. This is why we use the keyword `start` in CSS grid layout to align something with the start of a container. When working with English content, `start` will be on the left, however, it doesn't have to be. The word `start` infers no physical location, which enables websites to start the content on the right when right-to-left languages, such as Arabic, are used.

Block and Inline

When using logical rather than physical properties, we don't see the world as left to right, and top to bottom. We have a different reference point. This is where understanding the *block* and *inline* axes, introduced in the grid alignment guide, becomes very useful. If you think about layout in terms of block and inline, the way things work in CSS grid layout makes a lot of sense.



CSS writing modes

The CSS writing modes module specifies how writing modes work in CSS. These features are not just for supporting languages with a different writing mode to English; they can also be used for creative purposes. The examples in this section make use of the `writing-mode` property to make changes to the writing mode applied to our grid, demonstrating how logical values work in the process.

<code>writing-mode</code>

Writing modes are more than just left to right and right to left text, and the `writing-mode` property helps us display text running in other directions. The `writing-mode` property can have values of:

- `horizontal-tb`
- `vertical-rl`
- `vertical-lr`
- `sideways-rl`
- `sideways-lr`

The value `horizontal-tb`, which stands for "horizontal, top to bottom", is the default for text on the web. It is the direction in which you are reading this guide. The other values change how text flows in our document, matching the different writing modes found worldwide.

As an example, we have two paragraphs below. The first uses the default `horizontal-tb` value, and the second uses `vertical-rl`. In the second writing mode, text still runs left to right, however the direction of the text is vertical — inline text now runs down the page, from top to bottom.

```
.wrapper > p {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  padding: 1em;
  margin: 1em;
  color: #d9480f;
  max-width: 300px;
}
```

```
<div class="wrapper">
  <p class="horizontal-tb">
    I have writing mode set to the default <code>horizontal-tb</code>
  </p>
  <p class="vertical-rl">I have writing mode set to <code>vertical-rl</code></p>
</div>
```

```
.horizontal-tb {
  writing-mode: horizontal-tb;
}
.vertical-rl {
  writing-mode: vertical-rl;
}
```

Writing modes in grid layouts

Applying this to a grid layout example, we can see how changing the writing mode means changing our idea of where the block and inline axes are.

Default writing mode

In this example, the grid has three columns and two row tracks. This means there are three tracks running down the block axis. In default writing mode, grid auto-places items starting at the top left, moving along to the right, filling up the three cells on the inline axis. It then moves to the next line, creating a new row track, and fills in more items:

```
* {
  box-sizing: border-box;
}

.wrapper {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
}

.wrapper > div {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  padding: 1em;
  color: #d9480f;
}
```

```
.wrapper {
  display: grid;
  grid-template-columns: repeat(3, 100px);
  grid-template-rows: repeat(2, 100px);
  gap: 10px;
}
```

```
<div class="wrapper">
  <div class="item1">Item 1</div>
  <div class="item2">Item 2</div>
  <div class="item3">Item 3</div>
  <div class="item4">Item 4</div>
  <div class="item5">Item 5</div>
</div>
```

Setting writing mode

If we add `writing-mode: vertical-lr` to the grid container in the previous example, we can see that the block and inline axes now run in a different direction. The block or *column* axis now runs across the page from left to right, while the inline axis runs down the page, creating rows from top to bottom.

```
* {
  box-sizing: border-box;
}

.wrapper {
  border: 2px solid #f76707;
```

```
  border-radius: 5px;
  background-color: #fff4e6;
}

.wrapper > div {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  padding: 1em;
  color: #d9480f;
}
.wrapper {
  display: grid;
  grid-template-columns: repeat(3, 100px);
  grid-template-rows: repeat(2, 100px);
  gap: 10px;
}
```

```
.wrapper {
  writing-mode: vertical-lr;
}
```

```
<div class="wrapper">
  <div class="item1">Item 1</div>
  <div class="item2">Item 2</div>
  <div class="item3">Item 3</div>
  <div class="item4">Item 4</div>
  <div class="item5">Item 5</div>
</div>
```

Logical values for alignment

With the block and inline axis able to change direction, the logical values for the alignment properties start to make more sense.

In this example, we use alignment (the `align-self` and `justify-self` properties) to align items inside a grid that is set to `writing-mode: vertical-lr`. The `start` and `end` properties work in exactly the same way that they do in the default writing mode, and remain logical in a way that using left and right, top and bottom to align items would not do. This occurs once we've flipped the grid onto the side, like this:

```
* {
  box-sizing: border-box;
}

.wrapper {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
}

.wrapper > div {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  padding: 1em;
  color: #d9480f;
}
```

```
.wrapper {
  writing-mode: vertical-lr;
  display: grid;
  grid-template-columns: repeat(3, 1fr);
  grid-template-rows: repeat(3, 100px);
  gap: 10px;
}

.item1 {
  grid-column: 1 / 4;
  align-self: start;
}

.item2 {
  grid-column: 1 / 3;
  grid-row: 2 / 4;
  align-self: start;
}

.item3 {
  grid-column: 3;
  grid-row: 2 / 4;
  align-self: end;
  justify-self: end;
}
```

```
<div class="wrapper">
  <div class="item1">Item 1</div>
  <div class="item2">Item 2</div>
  <div class="item3">Item 3</div>
</div>
```

If you want to see how these work, with a right to left as well as top to bottom writing mode, switch `vertical-lr` to `vertical-rl`, which is a vertical writing mode running from right to left.

Auto-placement and writing modes

As we've seen in the previous examples, writing mode can change the visual direction in which items place themselves onto the grid. Items will, by default, place themselves along the inline axis, adding new rows in the block direction. We've now seen that the inline axis does not always run from left to right, and the block axis does not always run from top to bottom.

Line-based placement and Writing Modes

The key thing to remember when placing items by line number, is that line 1 is the start line and line -1 is the end line, no matter which writing mode you are in.

Line-based placement with left to right text

In this example, we have a grid laid out in the default `ltr` direction, with three items positioned using line-based placement.

- Item 1 starts at column line 1, spanning one track.
- Item 2 starts at column line -1, spanning to -3.
- Item 3 starts at column line 1, spanning to column line 3.

```
* {
  box-sizing: border-box;
}

.wrapper {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
}

.wrapper > div {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  padding: 1em;
  color: #d9480f;
}
```

```
.wrapper {
  display: grid;
  grid-template-columns: repeat(3, 1fr);
  grid-template-rows: repeat(2, 100px);
  gap: 10px;
}
.item1 {
  grid-column: 1;
}
.item2 {
  grid-column: -1 / -3;
}
.item3 {
  grid-column: 1 / 3;
  grid-row: 2;
}
```

```
<div class="wrapper">
  <div class="item1">Item 1</div>
  <div class="item2">Item 2</div>
  <div class="item3">Item 3</div>
</div>
```

Line-based placement with right to left text

If we add the `direction` property with a value of `rtl` to the grid container in the previous example, line 1 is placed on the right-hand side of the grid, and line -1 on the left.

```
* {
  box-sizing: border-box;
}

.wrapper {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
}

.wrapper > div {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  padding: 1em;
  color: #d9480f;
}

.wrapper {
  display: grid;
  grid-template-columns: repeat(3, 1fr);
  grid-template-rows: repeat(2, 100px);
  gap: 10px;
}

.item1 {
  grid-column: 1;
}

.item2 {
  grid-column: -1 / -3;
}

.item3 {
  grid-column: 1 / 3;
  grid-row: 2;
}
```

```
.wrapper {
  direction: rtl;
}
```

```
<div class="wrapper">
  <div class="item1">Item 1</div>
  <div class="item2">Item 2</div>
```

```
  <div class="item3">Item 3</div>
</div>
```

If you are switching the direction of your text, either for entire pages or for parts of pages, and are using lines, you may want to name your lines to avoid the layout completely switching direction. For some things, for example, where a grid contains text content, this switching may be exactly what you want. For other uses it may not.

The strange order of values in the <code>grid-area</code> property

You can use the `grid-area` property to specify all four lines of a grid area as one value. When people first encounter this, they are often surprised that the values do not follow the same order as the shorthand for `margin` – which runs clockwise: top, right, bottom, left.

The order of `grid-area` values is:

- `grid-row-start`
- `grid-column-start`
- `grid-row-end`
- `grid-column-end`

Which for English, in left-to-right means the order is:

- `top`
- `left`
- `bottom`
- `right`

This is counter-clockwise! It's the reverse of what we do for margins and padding. If we remember that `grid-area` sees the world as "block and inline", you'll notice we are setting the two starts, then the two ends, which is much more logical once you know!

Mixed writing modes and grid layout

In addition to displaying documents using the correct writing mode for the language, writing modes can be used creatively within documents that are otherwise `ltr`. In this example, we have a grid layout with a set of links down one side. We use writing modes (`writing-mode: vertical-lr`) to turn these on their side in the column track:

```
.wrapper {
  display: grid;
  grid-gap: 20px;
  grid-template-columns: 1fr auto;
  font:
    1em "Helvetica",
    "Arial",
    sans-serif;
}
nav {
  writing-mode: vertical-lr;
}
nav ul {
  list-style: none;
  margin: 0;
  padding: 1em;
  display: flex;
  justify-content: space-between;
}
nav a {
  text-decoration: none;
}
```

```
<div class="wrapper">
  <div class="content">
    <p>
      Turnip greens yarrow ricebean rutabaga endive cauliflower sea lettuce
      kohlrabi amaranth water spinach avocado daikon napa cabbage asparagus
      winter purslane kale. Celery potato scallion desert raisin horseradish
      spinach carrot soko. Lotus root water spinach fennel kombu maize bamboo
      shoot green bean swiss chard seakale pumpkin onion chickpea gram corn pea.
      Brussels sprout coriander water chestnut gourd swiss chard wakame kohlrabi
      beetroot carrot watercress. Corn amaranth salsify bunya nuts nori azuki
      bean chickweed potato bell pepper artichoke.
    </p>
    <p>
      Nori grape silver beet broccoli kombu beet greens fava bean potato
      quandong celery. Bunya nuts black-eyed pea prairie turnip leek lentil
      turnip greens parsnip. Sea lettuce water chestnut eggplant winter purslane
      fennel azuki bean earthnut pea sierra leone bologi leek soko chicory
      celtuce parsley jícama salsify.
    </p>
  </div>
  <nav>
    <ul>
      <li><a href="">Link 1</a></li>
      <li><a href="">Link 2</a></li>
      <li><a href="">Link 3</a></li>
    </ul>
  </nav>
</div>
```

Physical values and logical properties

If you combine logical grid properties with physical properties, remember that physical properties will not change according to writing mode. In our Aligning items in CSS grid layout guide, we use auto margins to push one item away from the others; this employs physical properties. There are logical property equivalents for most physical properties, which respect writing modes in the same way as grid placement and alignment properties and values.

Similarly, when using absolute positioning within a grid area, you can use logical inset properties to place items inside the grid area. When mixing logical and physical properties or values, be aware of the tension between them. For example, you may need to change your CSS to cope with a switch from `ltr` to `rtl`. Your understanding of block and inline through grid will help you to understand CSS logical properties and values.

Layout using named grid lines

In previous guides, we've looked at placing items on the lines created by defining grid tracks and also how to place items using named template areas. In this guide, we look at how these two things work together when we use named lines.

Line naming is incredibly useful, but some of the more confusing grid syntax comes from this combination of names and track sizes. Once you work through some examples, it should become clearer and easier to work with.

Naming lines when defining a grid

You can assign some or all of the lines in your grid a name when you define your grid with the `grid-template-rows` and `grid-template-columns` properties. To demonstrate, we'll use the basic layout created in the guide on line-based placement. This time, we'll create the grid using named lines.

```
* {
  box-sizing: border-box;
}

.wrapper {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
}

.wrapper > div {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  padding: 1em;
  color: #d9480f;
}
```

When defining the grid, we name our lines inside square brackets (`[]`). Those names can be anything you like. We define a name for the start and end of the container, both for rows and columns. In this case, the grid center block's start rows and columns are both named `content-start`, and its end rows and columns are both named `content-end`.

```
.wrapper {
  display: grid;
  grid-template-columns: [main-start] 1fr [content-start] 1fr [content-end] 1fr [main-end];
  grid-template-rows: [main-start] 100px [content-start] 100px [content-end] 100px [main-end];
}
```

We don't need to name all of the lines in our grids; you may choose to name just the key lines of your layout.

Once the lines have names, we can use the name we defined, rather than the line number, to place the grid items.

```
.box1 {
  grid-column-start: main-start;
  grid-row-start: main-start;
  grid-row-end: main-end;
}

.box2 {
  grid-column-start: content-end;
  grid-row-start: main-start;
  grid-row-end: content-end;
}

.box3 {
  grid-column-start: content-start;
  grid-row-start: main-start;
}

.box4 {
  grid-column-start: content-start;
  grid-column-end: main-end;
  grid-row-start: content-end;
}
```

```
<div class="wrapper">
  <div class="box1">One</div>
  <div class="box2">Two</div>
  <div class="box3">Three</div>
  <div class="box4">Four</div>
</div>
```

Everything else about line-based placement still works in the same way. In our grid layout, we provided each numeric line with an alias name. In our grid items, we reference a name rather than a number. Naming lines in this way is useful — when creating a responsive design, we can update the container's grid properties rather than updating the grid items within each media query.

Giving lines multiple names

You may want to give a line more than one name, perhaps it denotes the sidebar-end and the main-start for example. To do this add the names inside the square brackets with whitespace between them `[sidebar-end main-start]`. You can then refer to that line by either of the names.

Implicit grid areas from named lines

When naming the lines, we mentioned that you can name these anything you like. The name is a `<custom-ident>`, an author-defined name. When choosing the name you need to avoid words that might appear in the specification and be confusing - such as `span`. Idents are not quoted.

While you can choose any name, if you append `-start` and `-end` to the lines around an area, as we have in the example above, grid will create a named area of the main name used. Taking the above example, we have `content-start` and `content-end` both for rows and for columns. This means we get a grid area named `content`, and could place something in that area should we wish to.

```
* {
  box-sizing: border-box;
}

.wrapper {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
}
```

```
.wrapper > div {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  padding: 1em;
  color: #d9480f;
}
```

We use the same grid definitions as above, placing a single item into the named area `content`.

```
.wrapper {
  display: grid;
  grid-template-columns: [main-start] 1fr [content-start] 1fr [content-end] 1fr [main-end];
  grid-template-rows: [main-start] 100px [content-start] 100px [content-end] 100px [main-end];
}
.thing {
  grid-area: content;
}
```

```
<div class="wrapper">
  <div class="thing">I am placed in an area named content.</div>
</div>
```

We don't need to define where our areas are with `grid-template-areas` as our named lines have created an area for us.

Implicit grid lines from named areas

We have seen how named lines create a named area, and this also works in reverse. Named template areas create named lines that you can use to place your items. If we take the layout created in the guide to grid template areas, we can use the lines created by our areas to see how this works.

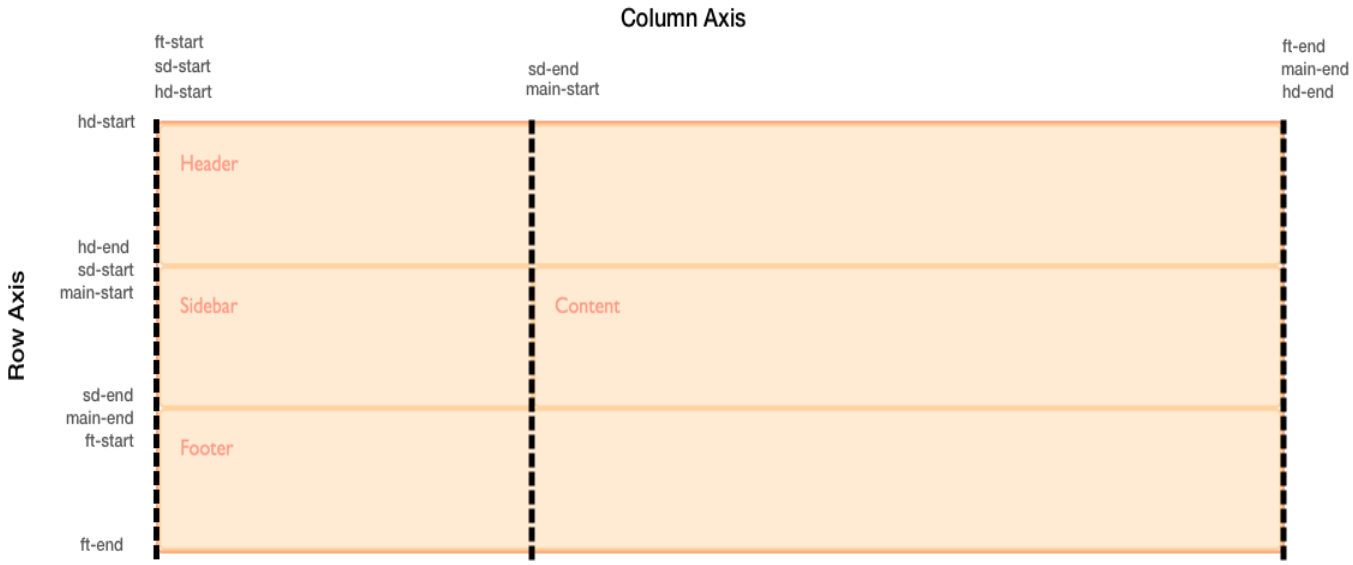
In this example, we have added an extra `<div>` with a class of `overlay`. We have named areas created using the `grid-area` property, then a layout created in `grid-template-areas`. The area names are:

- `hd`
- `ft`
- `main`
- `sd`

This gives us column and row lines:

- `hd-start`
- `hd-end`
- `sd-start`
- `sd-end`
- `main-start`
- `main-end`
- `ft-start`
- `ft-end`

You can see the named lines in the image. Note that some lines have two names - for example, `sd-end` and `main-start` refer to the same column line.



Positioning `overlay` using these implicit named lines is the same as positioning an item using named lines.

```
* {
  box-sizing: border-box;
}

.wrapper {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
}

.wrapper > div {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  padding: 1em;
```

```
  color: #d9480f;
}
```

```
.wrapper {
  display: grid;
  grid-template-columns: repeat(9, 1fr);
  grid-auto-rows: minmax(100px, auto);
  grid-template-areas:
    "hd hd hd hd   hd   hd   hd   hd   hd"
    "sd sd sd main main main main main main"
    "ft ft ft ft   ft   ft   ft   ft   ft";
}

.header {
  grid-area: hd;
}

.footer {
  grid-area: ft;
}

.content {
  grid-area: main;
}

.sidebar {
  grid-area: sd;
}

.wrapper > div.overlay {
  z-index: 10;
  grid-column: main-start / main-end;
  grid-row: hd-start / ft-end;
  border: 4px solid rgb(92 148 13);
  background-color: rgb(92 148 13 / 40%);
  color: rgb(92 148 13);
  font-size: 150%;
}
```

```
<div class="wrapper">
  <div class="header">Header</div>
  <div class="sidebar">Sidebar</div>
  <div class="content">Content</div>
  <div class="footer">Footer</div>
  <div class="overlay">Overlay</div>
</div>
```

Given that we have this ability to position created lines from named areas and areas from named lines, it is worth taking a little bit of time to plan your naming strategy when starting out creating your grid layout. Selecting names that make sense to you and your team will make your layouts more intuitive.

Multiple lines with the same name with repeat()

If you want to give all your grid lines a unique name, you need to define the track definition with long-hand properties rather than using the repeat syntax, as the names need to be added in square brackets when defining tracks. If you do use the repeat syntax, you will get multiple lines that have the same name, which can be useful or confusing, depending on your layout requirements.

Twelve-column grid using repeat()

In this example, we create a grid with 12 equal-width columns. Before defining the `1fr` size of the column track, we define a line named `[col-start]`. This means we will have a grid with 12 column lines all named `col-start` before a `1fr` width column.

```
* {
  box-sizing: border-box;
}

.wrapper {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
}

.wrapper > div {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  padding: 1em;
  color: #d9480f;
}
```

```
.wrapper {
  display: grid;
  grid-template-columns: repeat(12, [col-start] 1fr);
}
```

Once you have created the grid you can place items onto it. As we have multiple lines named `col-start` if you place an item to start after line `col-start`, the first line named `col-start` will be used. In our case, this is the far left line. To address another line, use the name with the number for that line.

To place an item spanning from the first line named `col-start` to the 5th line with that name, we can use:

```
.item1to5 {
  grid-column: col-start / col-start 5;
}
```

You can also use the `span` keyword. This item will span 3 lines starting from the 7th line named `col-start`:

```
.item7to9 {
  grid-column: col-start 7 / span 3;
}
```

```
<div class="wrapper">
  <div class="item1to5">I am placed from col-start line 1 to col-start 5</div>
  <div class="item7to9">I am placed from col-start line 7 spanning 3 lines</div>
</div>
```

If you look at this layout in your browser's developer tools, you will see how the column lines are shown, and how our items are placed against these lines.

Defining named lines with a track list

The `repeat()` syntax can also take a track list; it is not just single track sizes that can be repeated.

This CSS creates an eight track grid, with a narrower `1fr` width column named `col1-start` followed by a wider `3fr` column named `col2-start`.

```
.wrapper {
  grid-template-columns: repeat(4, [col1-start] 1fr [col2-start] 3fr);
}
```

If your repeating syntax puts two lines next to each other then they will be merged and create the same result as giving a line multiple names in a non-repeating track definition. The following definition creates four `1fr` tracks, each with a start and end line.

```
.wrapper {
  grid-template-columns: repeat(4, [col-start] 1fr [col-end]);
}
```

If we write this declaration without using repeat notation, it looks like this:

```
.wrapper {
  grid-template-columns: [col-start] 1fr [col-end col-start] 1fr [col-end col-start] 1fr [col-end col-start] 1fr [col-end];
}
```

Using a track list, we can use the `span` keyword to span a number of lines, including lines of a certain name:

```
* {
  box-sizing: border-box;
}

.wrapper {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
}

.wrapper > div {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  padding: 1em;
  color: #d9480f;
}
```

```
.wrapper {
  display: grid;
  grid-template-columns: repeat(6, [col1-start] 1fr [col2-start] 3fr);
}

.item1 {
  grid-column: col1-start / col2-start 2;
}

.item2 {
  grid-row: 2;
  grid-column: col1-start 2 / span 2 col1-start;
}
```

```
<div class="wrapper">
  <div class="item1">
    I am placed from col1-start line 1 to col2-start line 2
  </div>
  <div class="item2">
    I am placed from col1-start line 2 spanning 2 lines named col1-start
  </div>
</div>
```

Twelve-column grid framework

Having learned about numeric and named line-based placement and grid template areas, we now know there are several ways to place items using CSS grid layout. This may seem overly complex, but you don't need to use all of them. In practice, using named template areas works well for straightforward layouts as this method gives a good visual representation of what your layout looks like, and makes it more intuitive to move things around on the grid. For example, when working with a strict multiple-column layout, the named lines demonstration in the last part of this guide works well.

Legacy grid systems such as Foundation or Bootstrap are based on a 12-column grid. These frameworks import code to do calculations that ensure the columns add up to 100%. Frameworks aren't needed! The only CSS we need for a 12-column grid "framework" is:

```
.wrapper {
  display: grid;
  gap: 10px;
```

```
  grid-template-columns: repeat(12, [col-start] 1fr);
}
```

We can then use this "framework" to lay out our page.

For example, to create a three-column layout with a header and footer, we can use the following markup.

```
* {
  box-sizing: border-box;
}

.wrapper {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
}

.wrapper > * {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  padding: 1em;
  color: #d9480f;
}
```

```
<div class="wrapper">
  <header class="main-header">I am the header</header>
  <aside class="side1">I am sidebar 1</aside>
  <article class="content">I am the main article</article>
  <aside class="side2">I am sidebar 2</aside>
  <footer class="main-footer">I am the footer</footer>
</div>
```

We can place this on our grid layout framework:

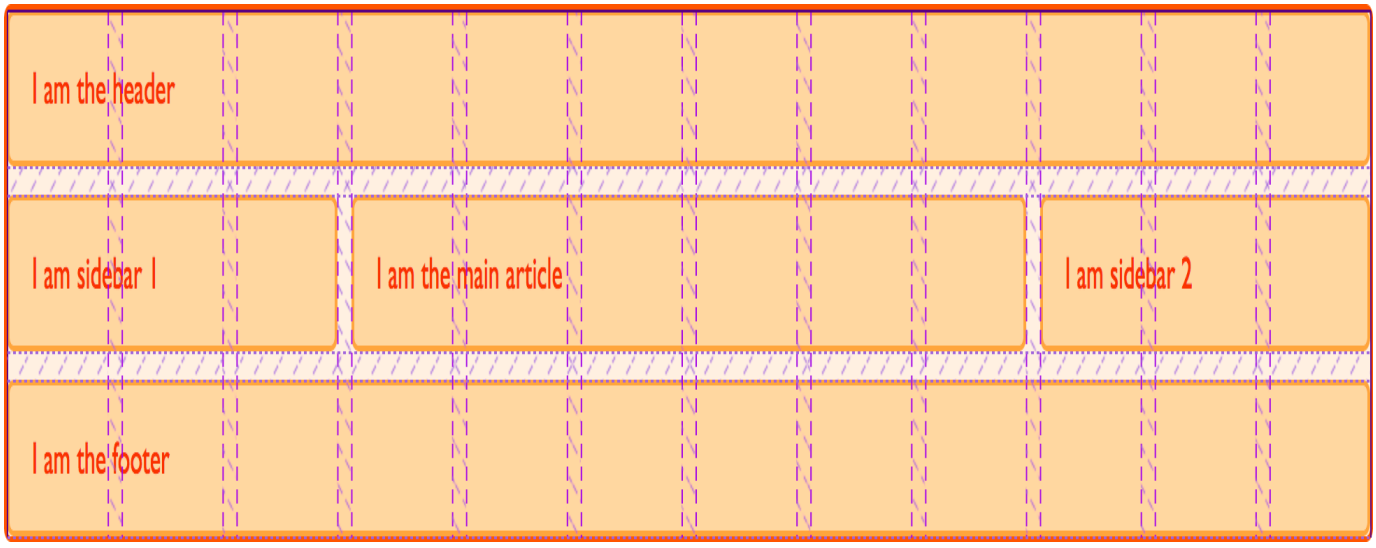
```
.main-header,
.main-footer {
  grid-column: col-start / span 12;
}

.side1 {
  grid-column: col-start / span 3;
  grid-row: 2;
}

.content {
  grid-column: col-start 4 / span 6;
  grid-row: 2;
}

.side2 {
  grid-column: col-start 10 / span 3;
  grid-row: 2;
}
```

Once again, the developer tool's grid highlighter is helpful to show us how the grid we have placed our items on works.



That's all we need. We don't need to do any calculations! CSS grid layout automatically removed our 10-pixel gutter track before assigning the space to the `1fr` column tracks.

Up next, we will look at how CSS grid layout can position items for us without requiring placement properties at all, in the auto-placement in grid layout guide.

Relationship of grid layout to other layout methods

CSS grid layout is designed to work alongside other parts of CSS, as part of a complete system for doing the layout. This guide explains how grid layout fits together with other techniques.

Grid and flexbox

The basic difference between CSS grid layout and CSS flexbox layout is that flexbox was designed for layout in one dimension - either a row *or* a column. Grid was designed for two-dimensional layout - rows, and columns at the same time. The two specifications both use CSS box alignment features. If you have already learned how to use flexbox, the similarities should help you get to grips with grid.

One-dimensional versus two-dimensional layout

A basic example can demonstrate the difference between one- and two-dimensional layouts.

In this first example, we use flexbox to lay out a set of boxes. We have five child items in our container, and we have given the flex properties values so that they can grow and shrink from a flex-basis of 150 pixels.

We also set the `flex-wrap` property to `wrap`, so that if the space in the container becomes too narrow to maintain the flex basis, items will wrap onto a new row.

```
* {
  box-sizing: border-box;
}

.wrapper {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
}

.wrapper > div {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  padding: 1em;
  color: #d9480f;
}
```

```
<div class="wrapper">
  <div>One</div>
  <div>Two</div>
  <div>Three</div>
  <div>Four</div>
  <div>Five</div>
</div>
```

```
.wrapper {
  width: 500px;
  display: flex;
  flex-wrap: wrap;
}
.wrapper > div {
  flex: 1 1 150px;
}
```

In the image, you can see that two items have wrapped onto a new line. These items are sharing the available space and not lining up underneath the items above. This is because when you wrap flex items, each new row (or column when working by column) is an independent flex line in the flex container. Space distribution happens across the flex line.

A common question then is how to make those items line up. This is where you want a two-dimensional layout method: You want to control the alignment by row and column, and this is where grid comes in.

The same layout with CSS grids

In this next example, we create the same layout using grid. This time we have three `1fr` column tracks. We do not need to set anything on the items themselves; they will lay themselves out one into each cell of the created grid. As you can see, they stay in a strict grid, lining up in rows and columns. With five items, we get a gap on the end of row two.

```
* {
  box-sizing: border-box;
}

.wrapper {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
}

.wrapper > div {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  padding: 1em;
  color: #d9480f;
}
```

```
<div class="wrapper">
  <div>One</div>
  <div>Two</div>
  <div>Three</div>
  <div>Four</div>
  <div>Five</div>
</div>
```

```
.wrapper {
  display: grid;
  grid-template-columns: repeat(3, 1fr);
}
```

An important question to ask yourself when deciding between grid or flexbox is:

- Do we only need to control the layout by row *or* column? If yes, use flexbox.
- Do we need to control the layout by row *and* column? If yes, use grid layout.

Content out or layout in?

In addition to the one-dimensional versus two-dimensional distinction, there is another way to decide if you should use flexbox or grid for a layout. Flexbox works from the content out. An ideal use case for flexbox is when you have a set of items and want to space them out evenly in a container. You let the size of the content decide how much individual space each item takes up. If the items wrap onto a new line, they will work out their spacing based on their size and the available space *on that line*.

Grid works from the layout in. When you use CSS grid layout you create a layout and then you place items into it, or you allow the auto-placement rules to place the items into the grid cells according to that strict grid. It is possible to create tracks that respond to the size of the content, however, they will also change the entire track.

If you are using flexbox and find yourself disabling some of the flexibility, you probably need to use CSS grid layout. For example, if you are setting a width on a flex item to make it line up with other items in a row above, a grid is likely a better choice.

Box alignment

Most grid alignment features were originally defined in the CSS flexible box layout. These features provided proper alignment control for the first time and enabled centering a box on the page. Flex items can stretch to the height of the flex container, meaning that equal height columns were possible. These properties are now defined in the CSS box alignment module, and are used in multiple layout modes, including grid layout.

We will be taking a proper look at Aligning items in CSS grid layout later. For now, here is a comparison between examples of flexbox and grid.

In the first example, which uses flexbox, we have a container with three items inside. The container's `min-height` is set, so it defines the height of the flex container. We have set `align-items` on the flex container to `flex-end` so the items will line up at the end of the flex container. We have also set the `align-self` property on `box1` so it will override the default and stretch to the height of the container and on `box2` so it aligns to the start of the flex container.

```
* {
  box-sizing: border-box;
}

.wrapper {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
}

.wrapper > div {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  padding: 1em;
  color: #d9480f;
}
```

```
<div class="wrapper">
  <div class="box1">One</div>
  <div class="box2">Two</div>
  <div class="box3">Three</div>
</div>
```

```
.wrapper {
  display: flex;
  align-items: flex-end;
  min-height: 200px;
}
.box1 {
  align-self: stretch;
}
.box2 {
  align-self: flex-start;
}
```

Alignment in CSS grids

This example uses a grid to create the same layout. We use the box alignment properties as they apply to a grid layout. We align to `start` and `end`. (We could have used the `<content-position>` synonyms `flex-start` and `flex-end`.) In the case of a grid layout, we are aligning the items inside their grid area. In this case that is a single grid cell, but it could be an area made up of several grid cells.

```
* {
  box-sizing: border-box;
}

.wrapper {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
}

.wrapper > div {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  padding: 1em;
  color: #d9480f;
}
```

```
<div class="wrapper">
  <div class="box1">One</div>
  <div class="box2">Two</div>
  <div class="box3">Three</div>
</div>
```

```
.wrapper {
  display: grid;
  grid-template-columns: repeat(3, 1fr);
  align-items: end;
  grid-auto-rows: 200px;
}
.box1 {
  align-self: stretch;
}
.box2 {
  align-self: start;
}
```

The <code>fr</code> unit and <code>flex-basis</code>

We have already seen how the `fr` unit works to assign a proportion of available space in the grid container to our grid tracks. The `fr` unit, when combined with the `minmax()` function can give us very similar behavior to the `flex` properties in flexbox while still enabling the creation of a layout in two dimensions.

If we look back at the example where we demonstrated the difference between one and two-dimensional layouts, you can see there is a difference between the way that the two layouts work responsively. With the flex layout, if we drag our window wider and smaller, the flexbox does a nice job of adjusting the number of items in each row according to the available space. If we have a lot of space all five items can fit on one row. If we have a very narrow container we may only have space for one.

In comparison, the grid version always has three column tracks. The tracks themselves will grow and shrink, but there are always three since we asked for three when defining our grid.

Auto-filling grid tracks

We can use grid to create a similar effect to flexbox, while still keeping the content arranged in strict rows and columns, by creating our track listing using repeat notation and the `auto-fill` and `auto-fit` properties.

In this next example, we have used the `auto-fill` keyword in place of an integer in the repeat notation and set the track listing to 200 pixels. This means that grid will create as many 200 pixels column tracks as will fit in the container.

```
* {
  box-sizing: border-box;
}

.wrapper {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
}

.wrapper > div {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  padding: 1em;
  color: #d9480f;
}
```

```
<div class="wrapper">
  <div>One</div>
  <div>Two</div>
  <div>Three</div>
</div>
```

```
.wrapper {
  display: grid;
  grid-template-columns: repeat(auto-fill, 200px);
}
```

A flexible number of tracks

This isn't quite the same as flexbox. In the flexbox example, the items are larger than the 200 pixel basis before wrapping. We can achieve the same in grid by combining `auto-fit` and the `minmax()` function.

In this example, we create auto filled tracks with `minmax`. We want our tracks to be a minimum of 200 pixels, so we set the maximum to be `1fr`. Once the browser has worked out how many times 200 pixels will fit into the container–also taking account of grid gaps–it will treat the `1fr` maximum as an instruction to share out the remaining space between the items.

```
* {
  box-sizing: border-box;
}

.wrapper {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
}

.wrapper > div {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  padding: 1em;
  color: #d9480f;
}
```

```
<div class="wrapper">
  <div>One</div>
  <div>Two</div>
  <div>Three</div>
</div>
```

```
.wrapper {
  display: grid;
  grid-template-columns: repeat(auto-fit, minmax(200px, 1fr));
}
```

With grid layout, we can create a grid with a dynamic number of flexible tracks and have the items laid out on the grid aligned by rows and columns.

Grid and absolutely positioned elements

Grid interacts with absolutely positioned elements, which can be useful if you want to position an item inside a grid or grid area. The specification defines the behavior when a grid container is a containing block and a parent of the absolutely positioned item.

A grid container as containing block

To make the grid container a containing block, you need to add the `position` property to the container with a value of `relative`, just as you would make a containing block for any other absolutely positioned items. Once you have done this, if you give a grid item `position: absolute` it will take as its containing block the grid container or, if the item also has a grid position, the area of the grid it is placed into.

In the below example we have a wrapper containing four child items. Item three is absolutely positioned and also placed on the grid using line-based placement. The grid container has `position: relative` and so becomes the positioning context of this item.

```
* {
  box-sizing: border-box;
}
```

```
.wrapper {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
}

.wrapper > div {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  padding: 1em;
  color: #d9480f;
}
```

```
<div class="wrapper">
  <div class="box1">One</div>
  <div class="box2">Two</div>
  <div class="box3">
    This block is absolutely positioned. In this example the grid container is
    the containing block and so the absolute positioning offset values are
    calculated in from the outer edges of the area it has been placed into.
  </div>
  <div class="box4">Four</div>
</div>
```

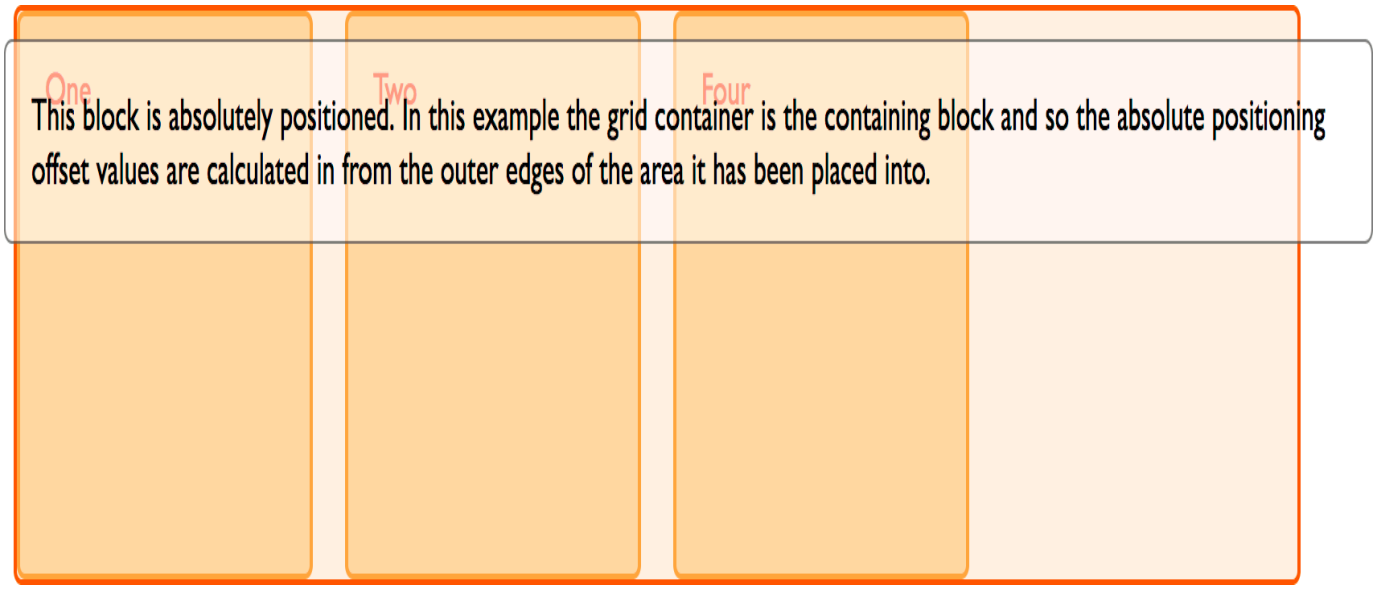
```
.wrapper {
  display: grid;
  grid-template-columns: repeat(4, 1fr);
  grid-auto-rows: 200px;
  gap: 20px;
  position: relative;
}
.box3 {
  grid-column-start: 2;
  grid-column-end: 4;
  grid-row-start: 1;
  grid-row-end: 3;
  position: absolute;
  top: 40px;
  left: 40px;
}
```

You can see that the item is taking the area from grid column line 2 to 4, and starting after line 1. Then it is offset in that area using the top and left properties. However, it has been taken out of flow as is usual for absolutely positioned items and so the auto-placement rules now place items into the same space. The item also doesn't cause the additional row to be created to span to row line 3.

If we remove `position: absolute` from the rules for `.box3`, you can see how it would display without the positioning.

A grid container as parent

If the absolutely positioned child has a grid container as a parent but that container does not create a new positioning context, then it is taken out of flow as in the previous example. The *positioning context* is the element the absolutely positioned element is positioned relative to. The positioning context will be whatever element creates a positioning context as is common to other layout methods. In our case, if we remove `position: relative` from the wrapper above, positioning context is from the viewport, as shown in this image.



Once again, the item no longer participates in the grid layout in terms of sizing or when other items are auto-placed.

With a grid area as the parent

If the absolutely positioned item is nested inside a grid area, then you can create a positioning context on that area. In this example, we have our grid as before, but this time we have nested an item inside `.box3` of the grid.

We have given `.box3` position relative and then positioned the sub-item with the offset properties. In this case, the positioning context is the grid area.

```
* {
  box-sizing: border-box;
}

.wrapper {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
```

```
}

.wrapper > div {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  padding: 1em;
  color: #d9480f;
}
```

```
<div class="wrapper">
  <div class="box1">One</div>
  <div class="box2">Two</div>
  <div class="box3">
    Three
    <div class="abspos">
      This block is absolutely positioned. In this example the grid area is the
      containing block and so the absolute positioning offset values are
      calculated in from the outer edges of the grid area.
    </div>
  </div>
  <div class="box4">Four</div>
</div>
```

```
.wrapper {
  display: grid;
  grid-template-columns: repeat(4, 1fr);
  grid-auto-rows: 200px;
  gap: 20px;
}
.box3 {
  grid-column-start: 2;
  grid-column-end: 4;
  grid-row-start: 1;
  grid-row-end: 3;
  position: relative;
}
.abspos {
  position: absolute;
  top: 40px;
  left: 40px;
  background-color: rgb(255 255 255 / 50%);
  border: 1px solid rgb(0 0 0 / 50%);
  color: black;
  padding: 10px;
}
```

Grid and display: contents

A final interaction worth noting is the interaction between CSS grid layout and `display: contents`, defined in the CSS display module. When the `display` property is set to `contents`, the element itself does not generate any boxes, but its children and pseudo-elements still generate boxes as normal. This means that, for the purposes of box generation and layout, the element is treated as if it had been replaced with its children and pseudo-elements in the document tree.

If you set an item to `display: contents`, the box it would normally create disappears and the boxes of the child elements appear as if they have risen up a level. This means that children of a grid item can become grid items. Sound odd? Here is an example.

Grid layout with nested child elements

In this example, first item of our grid is set to span all three column tracks. It contains three nested items. As these items are not direct children, they don't become part of the grid layout and so display using regular block layout.

```
* {
  box-sizing: border-box;
}

.wrapper {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
}

.box {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  padding: 1em;
  color: #d9480f;
}
.nested {
  border: 2px solid #ffec99;
  border-radius: 5px;
  background-color: #fff9db;
  padding: 1em;
}
```

```
<div class="wrapper">
  <div class="box box1">
    <div class="nested">a</div>
    <div class="nested">b</div>
    <div class="nested">c</div>
  </div>
  <div class="box box2">Two</div>
  <div class="box box3">Three</div>
  <div class="box box4">Four</div>
  <div class="box box5">Five</div>
</div>
```

```
.wrapper {
  display: grid;
  grid-template-columns: repeat(3, 1fr);
```

```
  grid-auto-rows: minmax(100px, auto);
}
.box1 {
  grid-column-start: 1;
  grid-column-end: 4;
}
```

Using display: contents

If we now add `display: contents` to the rules for `box1`, the box for that item vanishes and the sub-items now become grid items and lay themselves out using the auto-placement rules.

```
* {
  box-sizing: border-box;
}

.wrapper {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
}

.box {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  padding: 1em;
  color: #d9480f;
}
.nested {
  border: 2px solid #ffec99;
  border-radius: 5px;
  background-color: #fff9db;
  padding: 1em;
}
```

```
<div class="wrapper">
  <div class="box box1">
    <div class="nested">a</div>
    <div class="nested">b</div>
    <div class="nested">c</div>
  </div>
  <div class="box box2">Two</div>
  <div class="box box3">Three</div>
  <div class="box box4">Four</div>
  <div class="box box5">Five</div>
</div>
```

```
.wrapper {
  display: grid;
  grid-template-columns: repeat(3, 1fr);
  grid-auto-rows: minmax(100px, auto);
}
.box1 {
  grid-column-start: 1;
  grid-column-end: 4;
  display: contents;
}
```

This can be a way to get items nested into the grid to act as if they are part of the grid. You can also use `display: contents` in a similar way with flexbox to enable nested items to become flex items.

As you can see from this guide, CSS grid layout is just one part of your toolkit. Don't be afraid to mix it with other methods of doing layout to get the different effects you need.

Subgrid

The CSS grid layout module includes a `subgrid` value for `grid-template-columns` and `grid-template-rows`. This guide details what subgrid does and gives some use cases and design patterns that the feature solves.

Introduction to subgrid

When you add `display: grid` to a grid container, only the direct children become grid items, which can then be placed on the grid you created. The children of these items display in normal flow.

You can "nest" grids by making a grid item a grid container. These grids, however, are independent of the parent grid and of each other, meaning that they do not take their track sizing from the parent grid. This makes it difficult to line nested grid items up with the main grid.

If you set the value `subgrid` on `grid-template-columns`, `grid-template-rows` or both, instead of creating a new track listing, the nested grid uses the tracks defined on the parent.

For example, if you use `grid-template-columns: subgrid` and the nested grid spans three column tracks of the parent, the nested grid will have three column tracks of the same size as the parent grid. While gaps are inherited, they can be overridden with a different `gap` value. Line names can be passed from the parent into the subgrid, and the subgrid can also declare its own line names.

Subgrid for columns

In the example below, the grid layout has nine `1fr` column tracks and four rows that are a minimum of `100px` tall.

The `.item` is placed between column lines 2 to 7 and rows 2 to 4. This grid item is itself specified as a grid using `display: grid` and then defined as a subgrid by giving it column tracks that are a subgrid (`grid-template-columns: subgrid`) and normally defined rows. The subgrid has five-column tracks as it spans five column tracks.

Because the `.item` is a subgrid, even though the `.subitem` is not a direct child of the outer `.grid`, it can be placed on that outer grid, with its columns aligned with the outer grid's columns. The rows are not a subgrid, so behave as a nested grid normally does. The grid area on the parent expands to be large enough for this nested grid.

```
<div class="grid">
  <div class="item">
    <div class="subitem"></div>
  </div>
</div>
```

```
* {
  box-sizing: border-box;
}

.grid {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
}

.item {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  color: #d9480f;
}

.subitem {
  background-color: rgb(40 240 83);
}
```

```
.grid {
  display: grid;
  grid-template-columns: repeat(9, 1fr);
  grid-template-rows: repeat(4, minmax(100px, auto));
}

.item {
  display: grid;
  grid-column: 2 / 7;
  grid-row: 2 / 4;
  grid-template-columns: subgrid;
  grid-template-rows: repeat(3, 80px);
}

.subitem {
  grid-column: 3 / 6;
  grid-row: 1 / 3;
}
```

Note that line numbering restarts inside the subgrid — column line 1, when inside the subgrid, is the first line of the subgrid. The subgridded element doesn't inherit the line numbers of the parent grid. This means that you can safely lay out a component that may be placed in different positions on the main grid, knowing that the line numbers on the component will always be the same.

Subgrid for rows

This example uses the same HTML as above, but here the `subgrid` is applied as the value of `grid-template-rows` instead, with explicitly defined column tracks. In this case, the column tracks behave as a regular nested grid, but the rows are tied to the two tracks that the `.item` spans.

```
<div class="grid">
  <div class="item">
    <div class="subitem"></div>
  </div>
</div>
```

```
* {
  box-sizing: border-box;
}

.grid {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
}

.item {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  color: #d9480f;
}

.subitem {
  background-color: rgb(40 240 83);
}
```

```
.grid {
  display: grid;
  grid-template-columns: repeat(9, 1fr);
  grid-template-rows: repeat(4, minmax(100px, auto));
}

.item {
  display: grid;
  grid-column: 2 / 7;
  grid-row: 2 / 4;
  grid-template-columns: repeat(3, 1fr);
  grid-template-rows: subgrid;
}

.subitem {
  grid-column: 2 / 4;
  grid-row: 1 / 3;
}
```

A subgrid in both dimensions

In this example, both rows and columns are defined as a subgrid, tying the subgrid to the parent grid's tracks in both dimensions.

```
<div class="grid">
  <div class="item">
```

```
    <div class="subitem"></div>
  </div>
</div>
```

```
* {
  box-sizing: border-box;
}

.grid {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
}

.item {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  color: #d9480f;
}

.subitem {
  background-color: rgb(40 240 83);
}
```

```
.grid {
  display: grid;
  grid-template-columns: repeat(9, 1fr);
  grid-template-rows: repeat(4, minmax(100px, auto));
}

.item {
  display: grid;
  grid-column: 2 / 7;
  grid-row: 2 / 4;
  grid-template-columns: subgrid;
  grid-template-rows: subgrid;
}

.subitem {
  grid-column: 3 / 6;
  grid-row: 1 / 3;
}
```

No implicit grid in a subgridded dimension

If you need to autoplace items and do not know how many items you will have, take care when creating a subgrid, as it will prevent additional rows from being created to hold those items.

Take a look at the next example — it uses the same parent and child grid as in the example above. There are twelve items inside the subgrid trying to autoplace themselves into ten grid cells. As the subgrid is on both dimensions, there is nowhere for the extra two items to go, so they go into the last track of the grid. This is the behavior defined in the specification.

```
<div class="grid">
  <div class="item">
    <div class="subitem">1</div>
    <div class="subitem">2</div>
    <div class="subitem">3</div>
    <div class="subitem">4</div>
    <div class="subitem">5</div>
    <div class="subitem">6</div>
    <div class="subitem">7</div>
    <div class="subitem">8</div>
    <div class="subitem">9</div>
    <div class="subitem">10</div>
    <div class="subitem">11</div>
    <div class="subitem">12</div>
  </div>
</div>
```

```
* {
  box-sizing: border-box;
}
body {
  font: 1.2em sans-serif;
}

.grid {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
}

.item {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  color: #d9480f;
}

.subitem {
  background-color: #d9480f;
  color: white;
  border-radius: 5px;
}
```

```
.grid {
  display: grid;
  grid-template-columns: repeat(9, 1fr);
  grid-template-rows: repeat(4, minmax(100px, auto));
}

.item {
  display: grid;
```

```
  grid-column: 2 / 7;
  grid-row: 2 / 4;
  grid-template-columns: subgrid;
  grid-template-rows: subgrid;
}
```

By removing the `grid-template-rows` value, the regular creation of implicit tracks is enabled, creating as many rows as required. These won't line up with the tracks of the parent.

```
<div class="grid">
  <div class="item">
    <div class="subitem">1</div>
    <div class="subitem">2</div>
    <div class="subitem">3</div>
    <div class="subitem">4</div>
    <div class="subitem">5</div>
    <div class="subitem">6</div>
    <div class="subitem">7</div>
    <div class="subitem">8</div>
    <div class="subitem">9</div>
    <div class="subitem">10</div>
    <div class="subitem">11</div>
    <div class="subitem">12</div>
  </div>
</div>
```

```
* {
  box-sizing: border-box;
}
body {
  font: 1.2em sans-serif;
}

.grid {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
}

.item {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  color: #d9480f;
}

.subitem {
  background-color: #d9480f;
  color: white;
  border-radius: 5px;
}
```

```
.grid {
  display: grid;
  grid-template-columns: repeat(9, 1fr);
  grid-template-rows: repeat(4, minmax(100px, auto));
}

.item {
  display: grid;
  grid-column: 2 / 7;
  grid-row: 2 / 4;
  grid-template-columns: subgrid;
  grid-auto-rows: minmax(100px, auto);
}
```

The gap properties and subgrid

Any `gap`, `column-gap`, or `row-gap` values specified on the parent are passed into the subgrid, creating the same spacing between tracks as the parent. This default behavior can be overridden by applying `gap-*` properties on the subgrid container.

In this example, the parent grid has a gap of `20px` for rows and columns and the subgrid has `row-gap` set to `0`.

```
<div class="grid">
  <div class="item">
    <div class="subitem"></div>
    <div class="subitem2"></div>
  </div>
</div>
```

```
* {
  box-sizing: border-box;
}

.grid {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
}

.item {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  color: #d9480f;
}

.subitem {
  background-color: rgb(40 240 83);
}
```

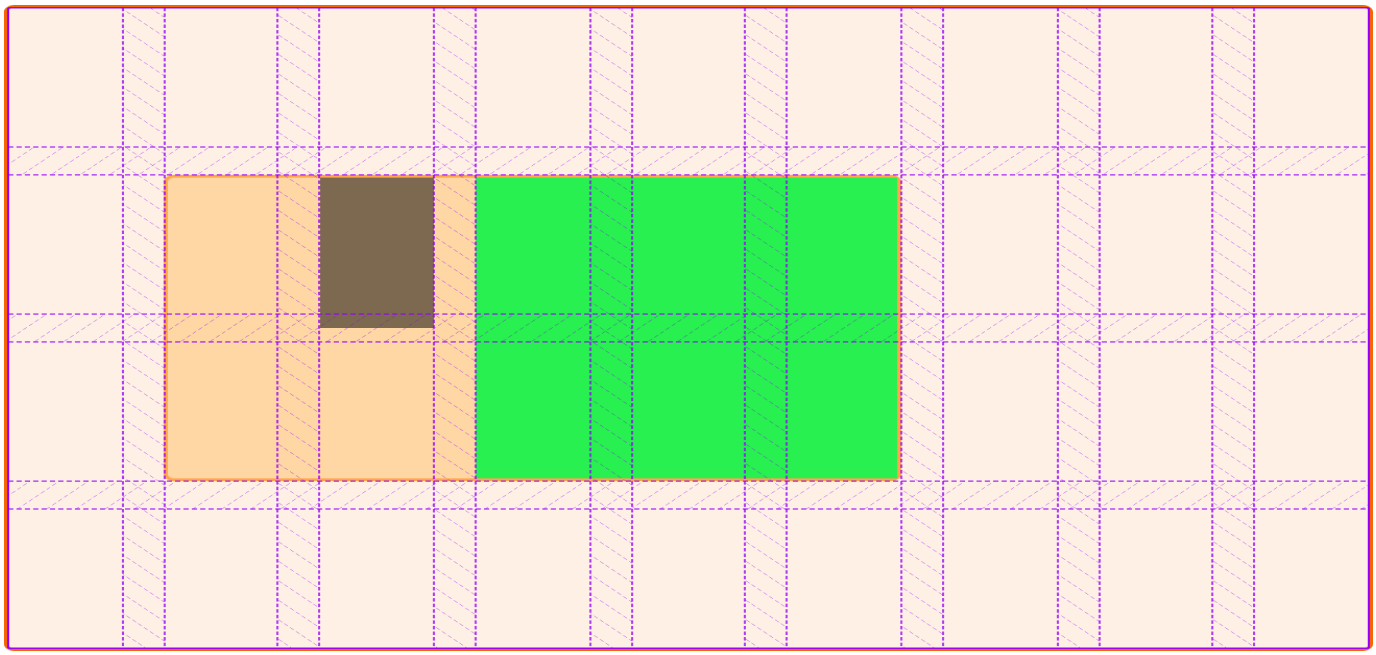
```
.grid {
  display: grid;
  grid-template-columns: repeat(9, 1fr);
  grid-template-rows: repeat(4, minmax(100px, auto));
  gap: 20px;
}

.item {
  display: grid;
  grid-column: 2 / 7;
  grid-row: 2 / 4;
  grid-template-columns: subgrid;
  grid-template-rows: subgrid;
  row-gap: 0;
}

.subitem {
  grid-column: 3 / 6;
  grid-row: 1 / 3;
}

.subitem2 {
  background-color: rgb(0 0 0 / 0.5);
  grid-column: 2;
  grid-row: 1;
}
```

If you inspect this in your developer tools grid inspector, you will note that the subgrid line is at the center of the gap. Setting the gap to `0` acts in a similar way to applying a negative margin to an element, giving the space from the gap back to the item.



Named grid lines

When using CSS grid, you can name lines on your grid and then position items based on those names rather than the line number. The line names on the parent grid are passed into the subgrid, and you can place items using them. In the example below, the named lines of the parent `col-start` and `col-end` are used to place the subitem.

```
<div class="grid">
  <div class="item">
    <div class="subitem"></div>
  </div>
</div>
```

```
* {
  box-sizing: border-box;
}

.grid {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
}

.item {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  color: #d9480f;
}

.subitem {
  background-color: rgb(40 240 83);
}
```

```
.grid {
  display: grid;
  grid-template-columns: 1fr 1fr 1fr [col-start] 1fr 1fr 1fr [col-end] 1fr 1fr 1fr;
  grid-template-rows: repeat(4, minmax(100px, auto));
  gap: 20px;
```

```
}

.item {
  display: grid;
  grid-column: 2 / 7;
  grid-row: 2 / 4;
  grid-template-columns: subgrid;
  grid-template-rows: subgrid;
}

.subitem {
  grid-column: col-start / col-end;
  grid-row: 1 / 3;
}
```

You can also specify line names on the subgrid. This is achieved by adding a list of line names enclosed in square brackets after the `subgrid` keyword. For example, if you have four lines in your subgrid, to name them all, you could use the syntax `grid-template-columns: subgrid [line1] [line2] [line3] [line4]`

Lines specified on the subgrid are added to any lines specified on the parent, so you can use either or both. In this example, one item is placed below using the parent lines and one using the subgrid lines.

```
<div class="grid">
  <div class="item">
    <div class="subitem"></div>
    <div class="subitem2"></div>
  </div>
</div>
```

```
* {
  box-sizing: border-box;
}

.grid {
  border: 2px solid #f76707;
  border-radius: 5px;
  background-color: #fff4e6;
}

.item {
  border: 2px solid #ffa94d;
  border-radius: 5px;
  background-color: #ffd8a8;
  color: #d9480f;
}

.subitem {
  background-color: rgb(40 240 83);
}
```

```
.grid {
  display: grid;
  grid-template-columns: 1fr 1fr 1fr [col-start] 1fr 1fr 1fr [col-end] 1fr 1fr 1fr;
  grid-template-rows: repeat(4, minmax(100px, auto));
  gap: 20px;
}

.item {
  display: grid;
  grid-column: 2 / 7;
  grid-row: 2 / 4;
  grid-template-columns: subgrid [sub-a] [sub-b] [sub-c] [sub-d] [sub-e] [sub-f];
  grid-template-rows: subgrid;
}

.subitem {
  grid-column: col-start / col-end;
  grid-row: 1 / 3;
}

.subitem2 {
  background-color: rgb(0 0 0 / 0.5);
  grid-column: sub-b / sub-d;
  grid-row: 1;
}
```

Using subgrids

A subgrid acts very similarly to any nested grid; the only difference is that the track sizing of the subgrid is set on the parent grid. As with any nested grid, however, the size of the content in the subgrid can change the track sizing, assuming a track sizing method is used that allows content to affect the size. In such a case, auto-sized row tracks will grow to fit content in the main grid and content in the subgrid.

As the subgrid value acts in much the same way as a regular nested grid, it is easy to switch between the two. For example, if you realize that you need an implicit grid for rows, you would need to remove the `subgrid` value of `grid-template-rows` and perhaps give a value for `grid-auto-rows` to control the implicit track sizing.

CSS images

The **CSS images** module defines the types of images that can be used (the `<image>` type, containing URLs, gradients and other types of images), how to resize them and how they, and other replaced content, interact with the different layout models.

Reference

Properties

- `image-orientation`
- `image-rendering`

- `object-fit`
- `object-position`
- `object-view-box`

The CSS images module also defines the `image-resolution` property. Currently, no browsers support this feature.

Functions

- `linear-gradient()`
- `radial-gradient()`
- `repeating-linear-gradient()`
- `repeating-radial-gradient()`
- `conic-gradient()`
- `repeating-conic-gradient()`
- `cross-fade()`
- `element()`
- `image-set()`

The CSS images module also defines the `image()` function. Currently, no browsers support this feature.

Data types

- `<gradient>`
- `<image>`

Guides

Using CSS gradients

Presents a specific type of CSS images, *gradients*, and how to create and use these.

Implementing image sprites in CSS

Describes the common technique grouping several images in one single document to save download requests and speed up the availability of a page.

Styling replaced elements

Introduces the properties that only apply to *replaced elements*.

Understanding aspect ratios

Learn about the `aspect-ratio` property, discuss aspect ratios for replaced and non-replaced elements, and examine some common aspect ratio use cases.

Using the CSS `object-view-box` property

Learn the CSS `object-view-box` property, including how to zoom in, zoom out, and pan across images.

Implementing image sprites in CSS

Image sprites are used in numerous web apps where multiple images are used. Rather than include each image as a separate image file, it is much more memory- and bandwidth-friendly to send them as a single image; using background position as a way to distinguish between individual images in the same image file, so the number of HTTP requests is reduced.

> **Note:** When using HTTP/2, it may in fact be more bandwidth-friendly to use multiple small requests.

Implementation

Suppose an image is given to every item with class `tool-btn`:

```
.tool-btn {
  background: url("myfile.png");
  display: inline-block;
  height: 20px;
  width: 20px;
}
```

A background position can be added either as two x, y values after the `<url>` in the background, or as `background-position`. For example:

```
#btn1 {
  background-position: -20px 0px;
}

#btn2 {
  background-position: -40px 0px;
}
```

This would slide the starting point of the background image for the element with the ID `btn1` 20 pixels to the left and the element with the ID `btn2` 40 pixels to the left (assuming they have the class `tool-btn` assigned and are affected by the image rule above).

Similarly, you can also make hover states by targeting `#btn:hover`.

Styling replaced elements

Some CSS properties apply to all elements, some only to grid and flex containers, others only to transformable elements. This guide introduces the properties that only apply to *replaced elements*.

A **replaced element** is an element whose representation is outside the scope of CSS; they're external objects whose representation is independent of the CSS formatting model. Some replaced elements, such as `<iframe>` elements, may have stylesheets of their own, but they don't inherit the styles of the parent document.

Using CSS with replaced elements

CSS handles replaced elements specifically in some cases, like when calculating margins and some `auto` values. Only replaced elements can ever have intrinsic dimensions. Some replaced elements, but not all, have intrinsic dimensions or a defined baseline, which is used by some CSS properties, such as `vertical-align`.

While document styles can set the size and position of replaced elements, document styles don't affect the replaced elements' content, with some exceptions: The CSS images module includes properties which support controlling the positioning of the element's content within its box.

Controlling object position within the content box

The CSS images module defines two properties which can be used to specify how the object contained within the replaced element should be positioned within the element's box area. The `object-fit` property is used to size objects, while the `object-position` property is used to position them.

The <code>object-fit</code> property

The `object-fit` property specifies how the replaced element's content object should be fitted to the containing element's box. The property defines how images, videos and other embeddable media formats respond to the height and width of the replaced element's content box. If the height, width, or aspect-ratio of an element differ from the resource that will be occupying space reserved for the element, the `fill`, `contain`, `cover`, `scale-down`, and `none` values define whether the browser should scale the resource, cover the allocated space, contain the asset within the space, or allow the resource to be distorted.

When contained or scaled down, any areas of the box not covered by the replaced element will show the element's background.

The `object-fit` property has no effect on `<iframe>`, `<embed>`, and `<fencedframe>` elements.

If we place the image, a square with a 1:1 aspect ratio, in a 100px x 300px box (1:3 aspect ratio), by default the image will fill the box, distorting itself. We can use the `object-fit` property to define how the image should be rendered when forced into a box with a different size and aspect ratio:

```
<img
  src="https://mdn.github.io/shared-assets/images/examples/progress-pride-flag.jpg"
  alt="Pride flag" />
<img
  src="https://mdn.github.io/shared-assets/images/examples/progress-pride-flag.jpg"
  alt="Pride flag" />
<img
  src="https://mdn.github.io/shared-assets/images/examples/progress-pride-flag.jpg"
  alt="Pride flag" />
<img
  src="https://mdn.github.io/shared-assets/images/examples/progress-pride-flag.jpg"
  alt="Pride flag" />
<img
  src="https://mdn.github.io/shared-assets/images/examples/progress-pride-flag.jpg"
  alt="Pride flag" />
<img
  src="https://mdn.github.io/shared-assets/images/examples/progress-pride-flag.jpg"
  alt="Pride flag" />
<p>
  <label><input type="checkbox" /> Change dimensions</label>
</p>
```

```
body {
  display: flex;
  gap: 20px;
  flex-flow: row wrap;
  grid-auto-flow: column;
  max-width: 98%;
  margin: 10px auto 0;
}
img {
  width: 100px;
  height: 300px;
  outline: 2px solid purple;
}
body:has(:checked) img {
  width: 300px;
  height: 100px;
}
```

```
img:nth-of-type(1) {
  object-fit: fill;
}
img:nth-of-type(2) {
  object-fit: cover;
}
img:nth-of-type(3) {
  object-fit: contain;
}
img:nth-of-type(4) {
  object-fit: scale-down;
```

```
}
img:nth-of-type(5) {
  object-fit: none;
}
img:nth-of-type(6) {
  /* no object-fit property */
  outline: 2px dashed red;
}
```

Check the box to set the height and width values. Note that only the `fill` value (the default) distorts the original image. With all other values, the intrinsic aspect ratio of the image is maintained.

The <code>object-position</code> property

The `object-position` property specifies the alignment of the replaced element's content object within the element's box.

Often used in conjunction with the `object-fit` property, it takes as its value a `<position>` value, the same value type as used for `background-position`.

```
img {
  object-position: bottom right;
}
```

```
<img
  src="https://mdn.github.io/shared-assets/images/examples/progress-pride-flag.jpg"
  alt="Pride flag" />
```

It can be used without `object-fit`. In this case, the image is rendered at it's intrinsic size (218px x 218px), with the position of the contents of the image set by the `object-position` value.

```
img {
  margin: 10px 0 0 10px;
}
```

```
img {
  outline: 2px solid;
  object-position: 114px 72px;
}
```

The `object-position` property works equally well with `<iframe>`, `<video>`, and `<embed>` elements as it does for `<img>`.

Using CSS gradients

CSS gradients are represented by the `<gradient>` data type, a special type of `<image>` made of a progressive transition between two or more colors. You can choose between three types of gradients: *linear* (created with the `linear-gradient()` function), *radial* (created with the `radial-gradient()` function), and *conic* (created with the `conic-gradient()` function). You can also create repeating gradients with the `repeating-linear-gradient()`, `repeating-radial-gradient()`, and `repeating-conic-gradient()` functions.

Gradients can be used anywhere you would use an `<image>`, such as in backgrounds. Because gradients are dynamically generated, they can negate the need for the raster image files that traditionally were used to achieve similar effects. In addition, because gradients are generated by the browser, they look better than raster images when zoomed in, and can be resized on the fly.

We'll start by introducing linear gradients, then introduce features that are supported in all gradient types using linear gradients as the example, then move on to radial, conic and repeating gradients

Using linear gradients

A linear gradient creates a band of colors that progress in a straight line.

A basic linear gradient

To create the most basic type of gradient, all you need is to specify two colors. These are called *color stops*. You must have at least two, but you can have as many as you want.

```
<div class="simple-linear"></div>
```

```
div {
  width: 120px;
  height: 120px;
}
```

```
.simple-linear {
  background: linear-gradient(blue, pink);
}
```

Changing the direction

By default, linear gradients run from top to bottom. You can change their rotation by specifying a direction.

```
<div class="horizontal-gradient"></div>
```

```
div {
  width: 120px;
  height: 120px;
}
```

```
.horizontal-gradient {
  background: linear-gradient(to right, blue, pink);
}
```

Diagonal gradients

You can even make the gradient run diagonally, from corner to corner.

```
<div class="diagonal-gradient"></div>
```

```
div {
  width: 200px;
  height: 100px;
}
```

```
.diagonal-gradient {
  background: linear-gradient(to bottom right, blue, pink);
}
```

Using angles

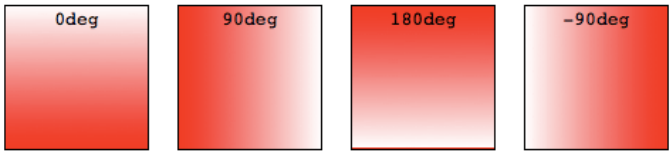
If you want more control over its direction, you can give the gradient a specific angle.

```
<div class="angled-gradient"></div>
```

```
div {
  width: 120px;
  height: 120px;
}
```

```
.angled-gradient {
  background: linear-gradient(70deg, blue, pink);
}
```

When using an angle, `0deg` creates a vertical gradient running bottom to top, `90deg` creates a horizontal gradient running left to right, and so on in a clockwise direction. Negative angles run in the counterclockwise direction.



Declaring colors & creating effects

All CSS gradient types are a range of position-dependent colors. The colors produced by CSS gradients can vary continuously with position, producing smooth color transitions. It is also possible to create bands of solid colors, and hard transitions between two colors. The following are valid for all gradient functions:

Using more than two colors

You don't have to limit yourself to two colors—you may use as many as you like! By default, colors are evenly spaced along the gradient.

```
<div class="auto-spaced-linear-gradient"></div>
```

```
div {
  width: 120px;
  height: 120px;
}
```

```
.auto-spaced-linear-gradient {
  background: linear-gradient(red, yellow, blue, orange);
}
```

Positioning color stops

You don't have to leave your color stops at their default positions. To fine-tune their locations, you can give each one zero, one, or two percentage or, for radial and linear gradients, absolute length values. If you specify the location as a percentage, `0%` represents the starting point, while `100%` represents the ending point; however, you can use values outside that range if necessary to get the effect you want. If you leave a location unspecified, the position of that particular color stop will be automatically calculated for you, with the first color stop being at `0%` and the last color stop being at `100%`, and any other color stops being half way between their adjacent color stops.

```
<div class="multicolor-linear"></div>
```

```
div {
  width: 120px;
  height: 120px;
}
```

```
.multicolor-linear {
  background: linear-gradient(to left, lime 28px, red 77%, cyan);
}
```

Creating hard lines

To create a hard line between two colors, creating a stripe instead of a gradual transition, adjacent color stops can be set to the same location. In this example, the colors share a color stop at the `50%` mark, halfway through the gradient:

```
<div class="striped"></div>
```

```
div {
  width: 120px;
  height: 120px;
}
```

```
.striped {
  background: linear-gradient(to bottom left, cyan 50%, palegoldenrod 50%);
}
```

Creating color bands & stripes

To include a solid, non-transitioning color area within a gradient, include two positions for the color stop. Color stops can have two positions, which is equivalent to two consecutive color stops with the same color at different positions. The color will reach full saturation at the first color stop, maintain that saturation through to the second color stop, and transition to the adjacent color stop's color through the adjacent color stop's first position.

```
<div class="multiposition-stops"></div>
<div class="multiposition-stop2"></div>
```

```
div {
  width: 120px;
  height: 120px;
  float: left;
  margin-right: 10px;
  box-sizing: border-box;
}
```

```
.multiposition-stops {
  background: linear-gradient(
    to left,
    lime 20%,
    red 30% 45%,
    cyan 55% 70%,
    yellow 80%
  );
}
.multiposition-stop2 {
  background: linear-gradient(
    to left,
    lime 25%,
    red 25% 50%,
    cyan 50% 75%,
    yellow 75%
  );
}
```

In the first example above, the lime goes from the 0% mark, which is implied, to the 20% mark, transitions from lime to red over the next 10% of the width of the gradient, reach solid red at the 30% mark, and staying solid red up until 45% through the gradient, where it fades to cyan, being fully cyan for 15% of the gradient, and so on.

In the second example, the second color stop for each color is at the same location as the first color stop for the adjacent color, creating a striped effect.

Controlling the progression of a gradient using color hints

By default, a gradient evenly progresses between the colors of two adjacent color stops, with the midpoint between those two color stops being the midpoint color value. You can control the interpolation, or progression, between two color stops by including a color hint location. In this example, the color reaches the midpoint between lime and cyan 20% of the way through the gradient rather than 50% of the way through. The second example does not contain the hint to highlight the difference the color hint can make:

```
<div class="color-hint-gradient"></div>
<div class="regular-progression"></div>
```

```
div {
  width: 120px;
  height: 120px;
  float: left;
  margin-right: 10px;
  box-sizing: border-box;
}
```

```
.color-hint-gradient {
  background: linear-gradient(to top, lime, 20%, cyan);
}
.regular-progression {
  background: linear-gradient(to top, lime, cyan);
}
```

Overlaying gradients

Gradients support transparency, so you can stack multiple backgrounds to achieve some pretty fancy effects. The backgrounds are stacked from top to bottom, with the first specified being on top.

```
<div class="layered-image"></div>
```

```
div {
  width: 300px;
  height: 150px;
}
```

```
.layered-image {
  background:
    linear-gradient(to right, transparent, mistyrose), url("critters.png");
}
```

Stacked gradients

You can even stack gradients with other gradients. As long as the top gradients aren't entirely opaque, the gradients below will still be visible.

```
<div class="stacked-linear"></div>
```

```
div {
  width: 200px;
  height: 200px;
}
```

```
.stacked-linear {
  background:
    linear-gradient(217deg, rgb(255 0 0 / 80%), transparent 70.71%),
    linear-gradient(127deg, rgb(0 255 0 / 80%), transparent 70.71%),
```

```
    linear-gradient(336deg, rgb(0 0 255 / 80%), transparent 70.71%);
}
```

Blending gradients

In addition to transparency, stacking multiple semi-transparent gradients and stacking gradients over raster background images, gradients can be used with other CSS effects. In this example, the four `<div>` elements have the same two fully-opaque gradients as background images. We apply different `background-blend-mode` CSS property values to the last three that blend the two background images creating different effects.

```
<div class="original"></div>
<div class="screen"></div>
<div class="overlay"></div>
<div class="difference"></div>
```

```
div {
  width: 120px;
  height: 120px;
  float: left;
  margin-right: 10px;
  box-sizing: border-box;
}
```

```
div {
  background:
    linear-gradient(to top, red, blue),
    linear-gradient(to right, #5500ff, #00ff55);
}

.screen {
  background-blend-mode: screen;
}

.overlay {
  background-blend-mode: overlay;
}

.difference {
  background-blend-mode: difference;
}
```

Using radial gradients

Radial gradients are similar to linear gradients, except that they radiate out from a central point. You can dictate where that central point is. You can also make them circular or elliptical.

A basic radial gradient

As with linear gradients, all you need to create a radial gradient are two colors. By default, the center of the gradient is at the 50% 50% mark, and the gradient is elliptical matching the aspect ratio of its box:

```
<div class="simple-radial"></div>
```

```
div {
  width: 240px;
  height: 120px;
}
```

```
.simple-radial {
  background: radial-gradient(red, blue);
}
```

Positioning radial color stops

Again like linear gradients, you can position each radial color stop with a percentage or absolute length.

```
<div class="radial-gradient"></div>
```

```
div {
  width: 120px;
  height: 120px;
}
```

```
.radial-gradient {
  background: radial-gradient(red 10px, yellow 30%, dodgerblue 50%);
}
```

Positioning the center of the gradient

You can position the center of the gradient with keyterms, percentage, or absolute lengths, length and percentage values repeating if only one is present, otherwise in the order of position from the left and position from the top.

```
<div class="radial-gradient"></div>
```

```
div {
  width: 120px;
  height: 240px;
}
```

```
.radial-gradient {
  background: radial-gradient(at 0% 30%, red 10px, yellow 30%, dodgerblue 50%);
}
```

Sizing radial gradients

Unlike linear gradients, you can specify the size of radial gradients. Possible values include `closest-corner`, `closest-side`, `farthest-corner`, and `farthest-side`, with `farthest-corner` being the default. Circles can also be sized with a length, and ellipses a length or percentage.

Example: `closest-side` for ellipses

This example uses the `closest-side` size value, which means the size is set by the distance from the starting point (the center) to the closest side of the enclosing box.

```
<div class="radial-ellipse-side"></div>
```

```
div {
  width: 240px;
  height: 100px;
}
```

```
.radial-ellipse-side {
  background: radial-gradient(
    ellipse closest-side,
    red,
    yellow 10%,
    dodgerblue 50%,
    beige
  );
}
```

Example: `farthest-corner` for ellipses

This example is similar to the previous one, except that its size is specified as `farthest-corner`, which sets the size of the gradient by the distance from the starting point to the farthest corner of the enclosing box from the starting point.

```
<div class="radial-ellipse-far"></div>
```

```
div {
  width: 240px;
  height: 100px;
}
```

```
.radial-ellipse-far {
  background: radial-gradient(
    ellipse farthest-corner at 90% 90%,
    red,
    yellow 10%,
    dodgerblue 50%,
    beige
  );
}
```

Example: `closest-side` for circles

This example uses `closest-side`, which makes the circle's radius to be the distance between the center of the gradient and the closest side. In this case the radius is the distance between the center and the bottom edge, because the gradient is placed 25% from the left and 25% from the bottom, and the div element's height is smaller than the width.

```
<div class="radial-circle-close"></div>
```

```
div {
  width: 240px;
  height: 120px;
}
```

```
.radial-circle-close {
  background: radial-gradient(
    circle closest-side at 25% 75%,
    red,
    yellow 10%,
    dodgerblue 50%,
    beige
  );
}
```

Example: length or percentage for ellipses

For ellipses only, you can size the ellipse using a length or percentage. The first value represents the horizontal radius, the second the vertical radius, where you use a percentage this corresponds to the size of the box in that dimension. In the below example I have used a percentage for the horizontal radius.

```
<div class="radial-ellipse-size"></div>
```

```
div {
  width: 240px;
  height: 120px;
}
```

```
.radial-ellipse-size {
  background: radial-gradient(
    ellipse 50% 50px,
    red,
    yellow 10%,
    dodgerblue 50%,
    beige
  );
}
```

Example: length for circles

For circles the size may be given as a `<length>`, which is the size of the circle.

```
<div class="radial-circle-size"></div>
```

```
div {
  width: 240px;
```

```
  height: 120px;
}
```

```
.radial-circle-size {
  background: radial-gradient(
    circle 50px,
    red,
    yellow 10%,
    dodgerblue 50%,
    beige
  );
}
```

Stacked radial gradients

Just like linear gradients, you can also stack radial gradients. The first specified is on top, the last on the bottom.

```
<div class="stacked-radial"></div>
```

```
div {
  width: 200px;
  height: 200px;
}
```

```
.stacked-radial {
  background:
    radial-gradient(circle at 50% 0, rgb(255 0 0 / 50%), transparent 70.71%),
    radial-gradient(circle at 6.7% 75%, rgb(0 0 255 / 50%), transparent 70.71%),
    radial-gradient(circle at 93.3% 75%, rgb(0 255 0 / 50%), transparent 70.71%)
      beige;
  border-radius: 50%;
}
```

Using conic gradients

The **`conic-gradient()`** CSS function creates an image consisting of a gradient with color transitions rotated around a center point (rather than radiating from the center). Example conic gradients include pie charts and color wheels, but they can also be used for creating checker boards and other interesting effects.

The conic-gradient syntax is similar to the radial-gradient syntax, but the color-stops are placed around a gradient arc, the circumference of a circle, rather than on the gradient line emerging from the center of the gradient, and the color-stops are percentages or degrees: absolute lengths are not valid.

In a radial gradient, the colors transition from the center of an ellipse, outward, in all directions. With conic gradients, the colors transition as if spun around the center of a circle, starting at the top and going clockwise. Similar to radial gradients, you can position the center of the gradient. Similar to linear gradients, you can change the gradient angle.

A basic conic gradient

As with linear and radial gradients, all you need to create a conic gradient are two colors. By default, the center of the gradient is at the 50% 50% mark, with the start of the gradient facing up:

```
<div class="simple-conic"></div>
```

```
div {
  width: 120px;
  height: 120px;
}
```

```
.simple-conic {
  background: conic-gradient(red, blue);
}
```

Positioning the conic center

Like radial gradients, you can position the center of the conic gradient with keyterms, percentage, or absolute lengths, with the keyword "at"

```
<div class="conic-gradient"></div>
```

```
div {
  width: 120px;
  height: 120px;
}
```

```
.conic-gradient {
  background: conic-gradient(at 0% 30%, red 10%, yellow 30%, dodgerblue 50%);
}
```

Changing the angle

By default, the different color stops you specify are spaced equidistantly around the circle. You can position the starting angle of the conic gradient using the "from" keyword at the beginning followed by an angle or a length, and you can specify different positions for the colors stops by including an angle or length after them.

```
<div class="conic-gradient"></div>
```

```
div {
  width: 120px;
  height: 120px;
}
```

```
.conic-gradient {
  background: conic-gradient(from 45deg, red, orange 50%, yellow 85%, green);
}
```

Using repeating gradients

The `linear-gradient()`, `radial-gradient()`, and `conic-gradient()` functions don't support automatically repeated color stops. However, the `repeating-linear-gradient()`, `repeating-radial-gradient()`, and `repeating-conic-gradient()` functions are available to offer this functionality.

The size of the gradient line or arc that repeats is the length between the first color stop value and the last color stop length value. If the first color stop just has a color and no color stop length, the value defaults to 0. If the last color stop has just a color and no color stop length, the value defaults to 100%. If neither is declared, the gradient line is 100% meaning the linear and conic gradients will not repeat and the radial gradient will only repeat if the radius of the gradient is smaller than the length between the center of the gradient and the farthest corner. If the first color stop is declared, and the value is greater than 0, the gradient will repeat, as the size of the line or arc is the difference between the first color stop and last color stop is less than 100% or 360 degrees.

Repeating linear gradients

This example uses `repeating-linear-gradient()` to create a gradient that progresses repeatedly in a straight line. The colors get cycled over again as the gradient repeats. In this case the gradient line is 10px long.

```
<div class="repeating-linear"></div>
```

```
div {
  width: 120px;
  height: 120px;
}
```

```
.repeating-linear {
  background: repeating-linear-gradient(
    -45deg,
    red,
    red 5px,
    blue 5px,
    blue 10px
  );
}
```

Multiple repeating linear gradients

Similar to regular linear and radial gradients, you can include multiple gradients, one on top of the other. This only makes sense if the gradients are partially transparent allowing subsequent gradients to show through the transparent areas, or if you include different background-sizes, optionally with different background-position property values, for each gradient image. We are using transparency.

In this case the gradient lines are 300px, 230px, and 300px long.

```
<div class="multi-repeating-linear"></div>
```

```
div {
  width: 600px;
  height: 400px;
}
```

```
.multi-repeating-linear {
  background:
    repeating-linear-gradient(
      190deg,
      rgb(255 0 0 / 50%) 40px,
      rgb(255 153 0 / 50%) 80px,
      rgb(255 255 0 / 50%) 120px,
      rgb(0 255 0 / 50%) 160px,
      rgb(0 0 255 / 50%) 200px,
      rgb(75 0 130 / 50%) 240px,
      rgb(238 130 238 / 50%) 280px,
      rgb(255 0 0 / 50%) 300px
    ),
    repeating-linear-gradient(
      -190deg,
      rgb(255 0 0 / 50%) 30px,
      rgb(255 153 0 / 50%) 60px,
      rgb(255 255 0 / 50%) 90px,
      rgb(0 255 0 / 50%) 120px,
      rgb(0 0 255 / 50%) 150px,
      rgb(75 0 130 / 50%) 180px,
      rgb(238 130 238 / 50%) 210px,
      rgb(255 0 0 / 50%) 230px
    ),
    repeating-linear-gradient(
      23deg,
      red 50px,
      orange 100px,
      yellow 150px,
      green 200px,
      blue 250px,
      indigo 300px,
      violet 350px,
      red 370px
    );
}
```

Plaid gradient

To create plaid we include several overlapping gradients with transparency. We use the multiple position color stop syntax:

```
<div class="plaid-gradient"></div>
```

```
div {
  width: 200px;
  height: 200px;
}
```

```
.plaid-gradient {
  background:
    repeating-linear-gradient(
      90deg,
      transparent 0 50px,
      rgb(255 127 0 / 25%) 50px 56px,
      transparent 56px 63px,
      rgb(255 127 0 / 25%) 63px 69px,
      transparent 69px 116px,
```

```
      rgb(255 206 0 / 25%) 116px 166px
    ),
    repeating-linear-gradient(
      0deg,
      transparent 0 50px,
      rgb(255 127 0 / 25%) 50px 56px,
      transparent 56px 63px,
      rgb(255 127 0 / 25%) 63px 69px,
      transparent 69px 116px,
      rgb(255 206 0 / 25%) 116px 166px
    ),
    repeating-linear-gradient(
      -45deg,
      transparent 0 5px,
      rgb(143 77 63 / 25%) 5px 10px
    ),
    repeating-linear-gradient(
      45deg,
      transparent 0 5px,
      rgb(143 77 63 / 25%) 5px 10px
    );
}
```

Repeating radial gradients

This example uses `repeating-radial-gradient()` to create a gradient that radiates repeatedly from a central point. The colors get cycled over and over as the gradient repeats.

```
<div class="repeating-radial"></div>
```

```
div {
  width: 120px;
  height: 120px;
}
```

```
.repeating-radial {
  background: repeating-radial-gradient(
    black,
    black 5px,
    white 5px,
    white 10px
  );
}
```

Multiple repeating radial gradients

```
<div class="multi-target"></div>
```

```
div {
  width: 250px;
  height: 150px;
}
```

```
.multi-target {
  background:
    repeating-radial-gradient(
        ellipse at 80% 50%,
        rgb(0 0 0 / 50%),
        rgb(0 0 0 / 50%) 15px,
        rgb(255 255 255 / 50%) 15px,
        rgb(255 255 255 / 50%) 30px
      )
      top left no-repeat,
    repeating-radial-gradient(
        ellipse at 20% 50%,
        rgb(0 0 0 / 50%),
        rgb(0 0 0 / 50%) 10px,
        rgb(255 255 255 / 50%) 10px,
        rgb(255 255 255 / 50%) 20px
      )
      top left no-repeat yellow;
  background-size:
    200px 200px,
    150px 150px;
}
```

Repeating conic gradients

This example uses `repeating-conic-gradient()` to create a gradient that rotates repeatedly around a center point. In this case, the declared color stops are repeated four times.

```
<div class="repeating-conic"></div>
```

```
div {
  width: 120px;
  height: 120px;
}
```

```
.repeating-conic {
  background: repeating-conic-gradient(
    #66ccff 0% 8.25%,
    #6633ff 8.25% 16.5%,
    #ff3399 16.5% 25%
  );
}
```

Multiple repeating conic gradients

Just like linear and radial repeating gradients, you can stack multiple conic gradients on top of each other, creating interesting effects by using different `at <position>` values so the conic gradients don't overlap at their centers and different `from <angle>` values so the repeating effects don't line up. This example overlaps three semi-transparent repeating radial gradients that each repeat their color schemes four times.

To make overlapping gradients visible, you need to ensure either that the colors of the gradients on the top of the stack are partially transparent or use the `background-blend-mode` CSS property.

```
<div class="multi-repeating-conic"></div>
```

```
div {
  width: 250px;
  height: 250px;
}
```

```
.multi-repeating-conic {
  background:
    repeating-conic-gradient(
      from 0deg at 80% 50%,
      #5691f580 0% 8.25%,
      #b338ff80 8.25% 16.5%,
      #f8305880 16.5% 25%
    ),
    repeating-conic-gradient(
      from 15deg at 50% 50%,
      #e856f580 0% 8.25%,
      #ff384c80 8.25% 16.5%,
      #e7f83080 16.5% 25%
    ),
    repeating-conic-gradient(
      from 0deg at 20% 50%,
      #f58356ff 0% 8.25%,
      #caff38ff 8.25% 16.5%,
      #30f88aff 16.5% 25%
    );
}
```

Using the CSS object-view-box property

The `object-view-box` property can be used to define a viewbox within replaced elements, enabling the display of just a section of the replaced content. The subsection of the element displayed can be presented as zoomed-in, zoomed-out, or at original size, while maintaining the content's intrinsic aspect ratio. In this guide, we examine this property, comparing it to the similar `object-fit` property, and explore its functionality through zooming in and out, as well as panning across an element.

Intrinsic size, extrinsic size, and <code>object-fit</code>

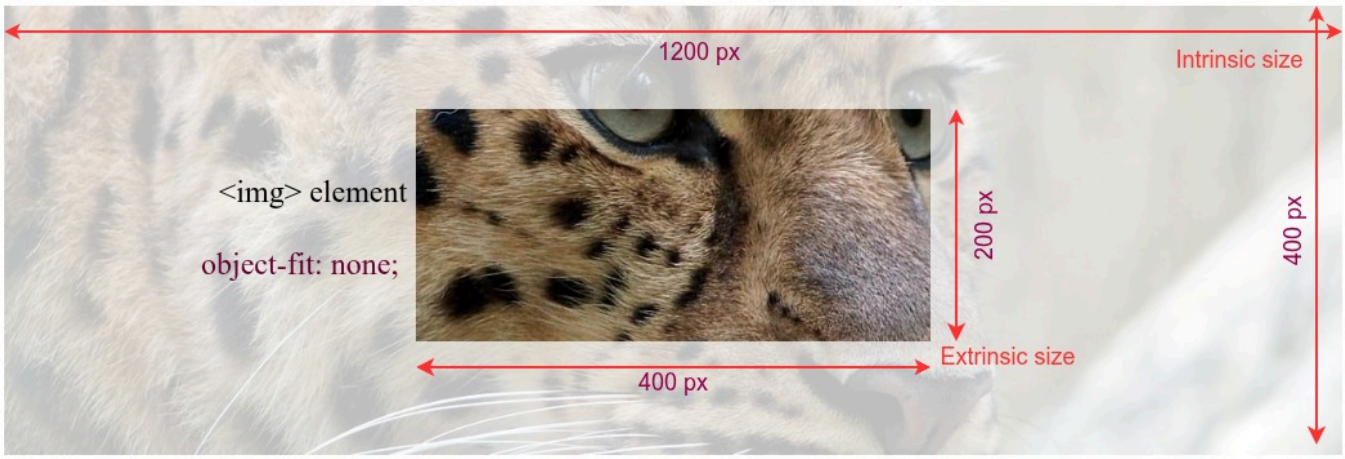
Every replaced elements has two sizes; an extrinsic size and an intrinsic size.

The extrinsic size is the dimension of the HTML element in which the content is rendered based on the box and visual formatting models. The box model and visual formatting model determine the size of rendered elements based on content, HTML attributes, CSS applied to the elements and their ancestors, and the viewport size.

The intrinsic size is the actual size of the content itself; the size the element is when no styles are applied and without any layout constraints. While the intrinsic and extrinsic sizes don't have to be the same, it is generally important to maintain a replaced element's intrinsic aspect ratio.

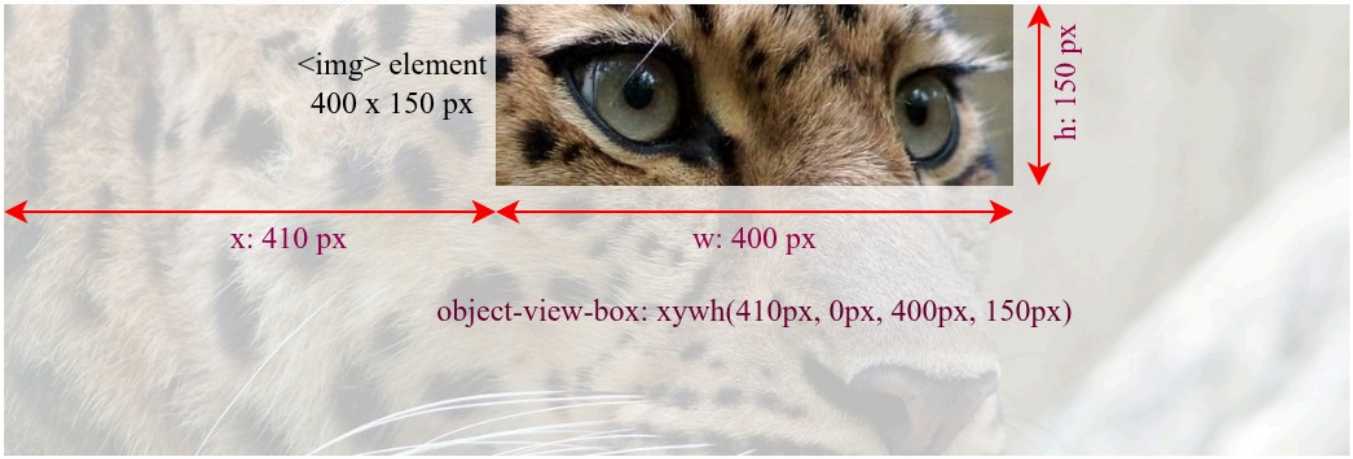
<code>object-view-box</code> versus <code>object-fit</code>

CSS has many sizing properties. When it comes to sizing replaced elements, the `object-fit` property enables us to control, to some extent, how replaced elements are rendered within a defined box. For example, in the following screenshot, a 1200 x 400 image is displayed using an `<img>` element. The `<img>` element is sized to 400 x 200. The image content is positioned using `object-fit: none;` declaration.



The `object-view-box` property is more flexible than the `object-fit` property, and it is capable of doing more things. For example, it can be used to crop, zoom, and pan images. The property sets the viewable area (viewbox), which defines what part of the content to show and how to fit it inside the extrinsic size. The viewbox value contains a rectangle and its position relative to the intrinsic area of the content, but the *physical size of the view box remains equal to the extrinsic size*. The viewbox marks the area in the content to be displayed, and then the content area is transformed to match the extrinsic dimensions fitting into the HTML element.

In the following image, we have the same leopard picture in a 400 x 150 image element. However, this time we have used `object-view-box` property to crop the portion of the picture showing the leopard's eyes.



In this case, as the dimensions of the `<img>` element and the viewbox defined by the `object-view-box` property are the same, i.e., 400 x 150 pixels, the aspect ratios of both are the same, and the replaced element is neither scaled nor distorted.

Maintaining the same aspect ratio prevents image distortion. With `object-view-box`, we can accomplish various image operations while having different extrinsic and view box sizes, without distorting the replaced element as it scales up and down.

Zooming in and out

Reducing the viewbox size, the area of the replaced element that is displayed, increases the zoom-in effect, because smaller content is stretched to fit the HTML element's dimensions. Decreasing it gives it a zoom-out effect.

This example demonstrates using the `object-view-box` property to zoom a section of a replaced element in and out, within a statically sized HTML element. In this case, the eye of the leopard, within a very large image, serves as the focal point of the zoom effect.

HTML

We include an `<img>` element and a `range` `<input>` element, with an associated `<label>`. The natural dimensions, or intrinsic size, of the original leopard image are `1244px` wide by `416px` tall, with an aspect ratio of `3:1`.

```
<img
  src="https://mdn.github.io/shared-assets/images/examples/leopard.jpg"
  alt="leopard" />
<p>
  <label for="box-size">Zoom-in: </label>
  <input type="range" id="box-size" min="115" max="380" value="150" />
</p>
<output></output>
```

CSS

We define a `--box-size` custom property, which is used as the height and width in the `xywh()` function, creating a square viewbox with an aspect ratio of `1:1`. The view box's offset point, the focal point in our zoom effect, is set at `500px` for the `x` coordinate and `30px` for the `y` coordinate, which corresponds to the top-left corner of the leopard's right eye.

```
input {
  width: 350px;
}

output {
  text-align: center;
  background-color: #dedede;
  font-family: monospace;
  padding: 5px;
  display: block;
}

@supports not (object-view-box: none) {
  body::before {
    content: "Your browser does not support the 'object-view-box' property.";
    color: black;
    background-color: #ffcd33;
    display: block;
    width: 100%;
    text-align: center;
  }
}
```

```
img {
  width: 350px;
  height: 350px;
  border: 2px solid red;

  --box-size: 150px;
  object-view-box: xywh(500px 30px var(--box-size) var(--box-size));
}
```

JavaScript

We add an event listener to the slider that updates the value of the `--box-size` custom property when the user interacts with it. To increase the zoom-in effect when the slider is moved to the right, the slider's value is inverted by subtracting it from `500px`, as reducing the view box size increases the zoom-in effect.

```
const img = document.querySelector("img");
const zoom = document.getElementById("box-size");
const output = document.querySelector("output");
```

```
function update() {
  const size = 500 - zoom.value;
  img.style.setProperty("--box-size", `${size}px`);
  output.innerText = `object-view-box: xywh(500px 30px ${size}px ${size}px);`;
}

zoom.addEventListener("input", update);
update();
```

Result

Move the slider to the right to increase the zoom-in effect and left to reduce it. The slider only affects the dimensions of the view box, while the x and y values, the origin point of the viewbox, remain constant. The size of the `<img>` element also remains constant.

Panning an image

We can create a panning effect by changing the coordinates of the view box window, the `x` and `y` components of the `xywh()` function, while keeping the size of the visible section constant. For example, by keeping the view box dimensions constant and changing only the horizontal position - the `x` parameter - we can create a horizontal panning effect.

```
<img
  src="https://mdn.github.io/shared-assets/images/examples/leopard.jpg"
  alt="leopard" />
<p>
  <label for="position">Left offset: </label>
  <input type="range" id="position" min="0" max="900" value="450" />
</p>
<output></output>
```

```
input {
  width: 350px;
}

@supports not (object-view-box: none) {
  body::before {
    content: "Your browser does not support the 'object-view-box' property.";
    color: black;
    background-color: #ffcd33;
    display: block;
    width: 100%;
    text-align: center;
  }
}
output {
  text-align: center;
  background-color: #dedede;
  font-family: monospace;
  padding: 5px;
  display: block;
}

img {
  width: 350px;
  height: 350px;

  --x-position: 0;
  object-view-box: xywh(var(--x-position) 30px 350px 350px);
}
```

```
const img = document.querySelector("img");
const position = document.getElementById("position");
const output = document.querySelector("output");

function update() {
  img.style.setProperty("--x-position", `${position.value}px`);
  output.innerText = `xywh(${position.value}px 30px 350px 350px);`;
}

position.addEventListener("input", update);
update();
```

Move the slider. Note how increasing and decreasing the `x` value of the `xywh()` function creates a panning effect.

CSS inline layout

The **CSS inline layout** module defines the block-axis alignment and sizing of inline-level content and adds a special layout mode for drop-caps. It describes the CSS formatting model for a flow of elements and text inside a container to be wrapped across multiple lines.

Reference

Properties

- `alignment-baseline`
- `baseline-shift`
- `baseline-source`
- `dominant-baseline`
- `initial-letter`
- `line-height`
- `text-box-edge`
- `text-box-trim`

- `text-box` shorthand
- `vertical-align`

The specification also defines the `initial-letter-align`, `initial-letter-wrap`, `inline-sizing`, and `line-fit-edge` properties, which are not yet supported by any browser.

Data types

- `<text-edge>`

Glossary terms

- baseline
- leading

Inline formatting context

This guide explains the inline formatting context.

Core concepts

The inline formatting context is part of the visual rendering of a web page. Inline boxes are laid out one after the other, in the direction sentences run in the writing mode in use:

- In a horizontal writing mode, boxes are laid out horizontally, starting on the left.
- In a vertical writing mode they would be laid out vertically starting at the top.

In the example below, the two `<div>` elements with the black borders are part of a block formatting context, while inside each box, the words participate in an inline formatting context. The words in the horizontal writing mode run horizontally, while words in the vertical writing mode run vertically.

```
<div class="example horizontal">One Two Three</div>
<div class="example vertical">Four Five Six</div>
```

```
body {
  font: 1.2em sans-serif;
}
.example {
  border: 5px solid black;
  margin: 20px;
}

.horizontal {
  writing-mode: horizontal-tb;
}
.vertical {
  writing-mode: vertical-rl;
}
```

Boxes forming a line are contained by a rectangular area called a line box. This box will be large enough to contain all of the inline boxes in that line; when there is no more room in the inline direction another line will be created. Therefore, a paragraph is a set of inline line boxes, stacked in the block direction.

When an inline box is split, margins, borders, and padding have no visual effect where the split occurs. In the next example there is a `<span>` element wrapping a set of words wrapping onto two lines. The border on the `<span>` breaks at the wrapping point.

```
<div class="example">
  Before that night—
  <span
    >a memorable night, as it was to prove— hundreds of millions of people</span
  >
  had watched the rising smoke-wreaths of their fires without drawing any
  special inspiration from the fact.
</div>
```

```
body {
  font: 1.2em sans-serif;
}
.example {
  border: 5px solid black;
  margin: 20px;
}

span {
  border: 5px solid rebeccapurple;
}
```

Margins, borders, and padding in the inline direction are respected. In the example below you can see how the margin, border, and padding on the inline `<span>` element are added.

```
<div class="example horizontal">One <span>Two</span> Three</div>
```

```
<div class="example vertical">Four <span>Five</span> Six</div>
```

```
body {
  font: 1.2em sans-serif;
}

.example {
  border: 5px solid black;
  margin: 20px;
}

span {
  border: 5px solid rebeccapurple;
  padding-inline-start: 20px;
  padding-inline-end: 40px;
  margin-inline-start: 30px;
  margin-inline-end: 10px;
}
.horizontal {
  writing-mode: horizontal-tb;
}

.vertical {
  writing-mode: vertical-rl;
}
```

> **Note:** I am using the logical, flow-relative properties — `padding-inline-start` rather than `padding-left` — so that they work in the inline dimension whether the text is horizontal or vertical. Read more about these properties in Logical Properties and Values.

Alignment in the block direction

Inline boxes may be aligned in the block direction in different ways, using the `vertical-align` property, which will align on the block axis in vertical writing modes (therefore not vertically at all!). In the example below the large text is making the line box of the first sentence larger, therefore the `vertical-align` property can be used to align the inline boxes either side of it. I have used the value `top`, try changing it to `middle`, `bottom`, or `baseline`.

```
<div class="example horizontal">
  Before that night—<span>a memorable night</span>, as it was to prove—hundreds
  of millions of people had watched the rising smoke-wreaths of their fires
  without drawing any special inspiration from the fact.
</div>

<div class="example vertical">
  Before that night—<span>a memorable night</span>, as it was to prove—hundreds
  of millions of people had watched the rising smoke-wreaths of their fires
  without drawing any special inspiration from the fact.
</div>
```

```
body {
  font: 1.2em sans-serif;
}

span {
  font-size: 200%;
  vertical-align: top;
}

.example {
  border: 5px solid black;
  margin: 20px;
  inline-size: 400px;
}

.horizontal {
  writing-mode: horizontal-tb;
}

.vertical {
  writing-mode: vertical-rl;
}
```

Alignment in the inline direction

If there is additional space in the inline direction, the `text-align` property can be used to align the inline boxes within their line box. Try changing the value of `text-align` below to `end`.

```
<div class="example horizontal">One Two Three</div>
<div class="example vertical">Four Five Six</div>
```

```
body {
  font: 1.2em sans-serif;
}

.example {
  border: 5px solid black;
  margin: 20px;
}

.horizontal {
  writing-mode: horizontal-tb;
}

.vertical {
  writing-mode: vertical-rl;
}
```

```
.example {
  text-align: center;
```

```
  inline-size: 250px;
}
```

Effect of floats

Line boxes usually have the same size in the inline direction, therefore the same width if working in a horizontal writing mode, or height if working in a vertical writing mode. If there is a `float` within the same block formatting context however, the float will cause the line boxes that wrap the float to become shorter.

```
<div class="box">
  <div class="float">I am a floated box!</div>
  <p>I am content inside the container.</p>
</div>
```

```
body {
  font: 1.2em sans-serif;
}

.box {
  background-color: rgb(224 206 247);
  border: 5px solid rebeccapurple;
}

.float {
  float: left;
  width: 250px;
  height: 150px;
  background-color: white;
  border: 1px solid black;
  padding: 10px;
}
```

CSS lists and counters

The **CSS lists and counters** module enables styling and positioning of list item bullets and manipulating their values with a combination of strings, counters, and other features.

A list item's marker, whether a bullet symbol or ordinal counter, is its defining feature. List items are not limited to `<li>` elements nested within `<ol>` or `<ul>` elements. Rather, list items are any element with `display: list-item` set.

This module defines CSS features to set and reset a list's counters, set which counter-styles or symbols to use as its markers, and position those markers. It also provides developers with the ability to create customized markers.

Reference

Properties

- `counter-increment`
- `counter-reset`
- `counter-set`
- `list-style-image`
- `list-style-type`
- `list-style-position`
- `list-style` shorthand

There is also a `marker-side` property, which is yet to be fully defined or implemented.

Pseudo-elements

- `::marker`

Functions

- `counter()`
- `counters()`

Data types

- `<counter>`
- `<counter-name>`
- `<counter-style>`

Guides

Consistent list indentation

One of the most common style changes made to lists is a change in the indentation distance—that is, how far the list items are pushed over to the right. This article will help you understand indenting list items so that list item markers are visible.

To understand why this is the case, and more importantly how to avoid the problem altogether, it's necessary to examine the details of list construction.

Creating a list

Stand-alone list item

First, we consider the pure list item, not nested in a list of items. When using the HTML `<li>` element, the browser sets the `display` value to `list-item`. Whether list items not nested in a list are provided a marker (otherwise known as a "bullet") depends on the browser. We can remove that bullet with `list-style-type: none`.

```
li {
  border: 1px dashed red;
}
li:nth-of-type(n + 4) {
  list-style-type: none;
}
```

```
li {
  width: 15em;
}
```

```
<p>Default bullets depend on the browser:</p>
<li>A list item</li>
<li>A list item</li>
<li>A list item</li>
<p>These list items have their bullets removed:</p>
<li>A list item</li>
<li>A list item</li>
<li>A list item</li>
```

That dotted red border represents the outer edges of the content area of each list item. At this point, the list items have no padding or borders.

Nested list items

Now we wrap these in a parent element; in this case, we'll wrap them in an unordered list (i.e., `<ul>`). According to the CSS box model, the list items' boxes must be displayed within the parent element's content area.

```
ul {
  border: 1px dashed blue;
}
li {
  border: 1px dashed red;
  list-style-type: none;
}
```

```
body {
  width: 15em;
}
```

```
<ul>
  <li>A list item</li>
  <li>A list item</li>
  <li>A list item</li>
</ul>
```

The dotted blue border shows us the edges of the `<ul>` element's content area. That parent comes with both margin and padding. Browsers set the following default styles on unordered lists:

```
ul {
  /* user-agent styles */
  display: block;
  list-style-type: disc;
  margin-block-start: 1em;
  margin-block-end: 1em;
  padding-inline-start: 40px;
}
```

Default bullet position

Now we put the list item markers back in. Since this is an unordered list, the list items inherit `list-style-type: disc;` browser styles, which are filled-circle "bullets," from their `<ul>` parent.

```
li {
  border: 1px dashed red;
}
ul {
  border: 1px dotted blue;
}
ul:last-of-type {
  list-style-position: inside;
}
```

```
ul {
  width: 15em;
}
```

```
<p>These default to <code>list-style-position: outside</code>.</p>
<ul>
  <li>A list item</li>
  <li>A list item</li>
  <li>A list item</li>
</ul>
<p>These have <code>list-style-position: inside</code> set.</p>
<ul>
  <li>A list item</li>
  <li>A list item</li>
  <li>A list item</li>
</ul>
```

Visually, the markers are *outside* the content area of the `<ul>`, but that's not the important part here. What's key is that the markers are placed outside the "principal box" of the `<li>` elements, not the `<ul>`. They're sort of like appendages to the list items, hanging outside the content-area of the `<li>` but still attached to the `<li>`.

This is why, in every modern browser, markers are placed outside any border set for an `<li>` element when the value of `list-style-position` defaults to or is explicitly set to `outside`. When we changed it to `inside`, the markers were brought inside the `<li>`'s content, as though they're an inline box placed at the very beginning of the `<li>`.

Default indentation

As noted above, all browsers provide the `<ul>` parent both margin and padding. While user agents CSS differ somewhat, they all include:

```
ul,
ol {
  /* user-agent styles */
  display: block;
  list-style-type: disc;
  margin-block-start: 1em;
  margin-block-end: 1em;
  padding-inline-start: 40px;
}
ol {
  list-style-type: decimal;
}
li {
  display: list-item;
  text-align: match-parent;
}
::marker {
  unicode-bidi: isolate;
  font-variant-numeric: tabular-nums;
  text-transform: none;
}
```

All browsers set `padding-inline-start` to 40 pixels for the `<ul>` element by default. In left-to-right languages, like English, this is the left *padding*. Any padding set in the author style sheets (that's your stylesheet) takes precedence.

If you want to be explicit, set the following in your style sheets to ensure, unless otherwise overridden, the list items in the main content area of your document, contained in the `<main>` section, are properly indented:

```
:where(main ol, main ul) {
  margin-inline-start: 0;
  padding-inline-start: 40px;
}
```

And always nest your `<li>` elements in a `<ul>` or `<ol>`.

CSS logical properties and values

The **CSS logical properties and values** module defines logical properties and values that can control layout through logical rather than physical direction and dimension mappings. Logical properties define direction-relative equivalents to their corresponding physical properties.

The start of a line is not always the left side of a line. Different writing systems operate in various directions. For example:

- English and Portuguese are written from left to right with new lines added below the previous ones.
- Hebrew and Arabic are right-to-left languages with new lines again being added below the previous ones.
- In some writing modes, the text lines are vertical, written from top to bottom. Chinese, Vietnamese, Korean, and Japanese are traditionally written vertically, from top to bottom, with each new vertical line added to the left of the previous one.
- Traditional Mongolian is also a top-to-bottom language, but new lines are to the right of previous ones.

The logical properties defined in this module enable defining properties relative to the content's writing direction, rather than a physical direction. This means content translated into languages with different writing modes will be rendered as intended.

Logical properties and values use the abstract terms *block* and *inline* to describe the direction in which they flow. The physical meaning of these terms depends on the writing mode.

The **block dimension** is perpendicular to the flow of text within a line, i.e., the vertical dimension in horizontal writing modes, and the horizontal dimension in vertical writing modes. For standard English text, it is the vertical dimension.

The **inline dimension** is parallel to the flow of text within a line, i.e., the horizontal dimension in horizontal writing modes, and the vertical dimension in vertical writing modes. For standard English text, it is the horizontal dimension.

CSS was initially designed with only physical coordinates. The logical properties and values module defines flow–relative equivalents for many values and properties. Properties that once only accepted physical values (`top`, `bottom`, `left`, `right`) now also accept flow-relative logical values (`block-start`, `block-end`, `inline-start`, `inline-end`).

Basic concepts of logical properties and values

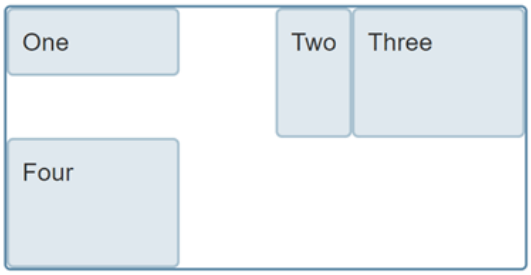
The CSS logical properties and values module defines flow-relative mappings for many of the physical properties and values in CSS. This article discusses this module, and explains flow relative values and properties.

Why are logical properties useful

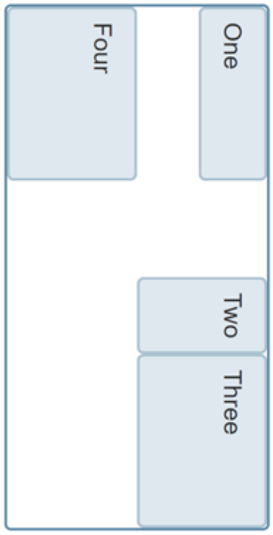
CSS 2.1 and earlier had sized things according to the physical dimensions of the screen. Therefore we describe boxes as having a `width` and `height`, position items from the `top` and `left`, assign borders, margin, and padding to the `top`, `right`, `bottom`, `left`, etc. The Logical properties and values module defines mappings for these physical properties and values to their logical, or flow relative, counterparts — e.g., `start` and `end` as opposed to `left` and `right`/`top` and `bottom`.

These mappings are very useful for sites that get translated into languages with a different writing mode than the original layout. For example, with a CSS grid layout, if the grid container has a width applied with the `align-self` and `justify-self` properties used to align the grid items, as these properties are flow relative, the `justify-self: start` aligns the item to the start on the inline dimension, and `align-self: start` does the same on the block dimension.



If the writing mode of this component is changed to `vertical-rl` using the `writing-mode` property, the alignment continues to work in the same way. The inline dimension will run vertically and the block dimension horizontally. The grid doesn't look the same, however, as the width assigned to the container is a horizontal measure, a measure tied to the physical and not the logical or flow relative running of the text.

If instead of the `width` property, the logical property `inline-size` is used, the component will work the same way no matter which writing mode it is displayed using.



You can try this out in the live example below. Change `writing-mode` from `vertical-rl` to `horizontal-tb` on `.grid` to see how the different properties change the layout.

```
<div class="grid">
  <div>One</div>
  <div>Two</div>
  <div>Three</div>
  <div>Four</div>
</div>
```

```
body {
  font: 1.2em / 1.5 sans-serif;
}

.grid {
  display: grid;
  grid-template-columns: repeat(3, 1fr);
  grid-auto-rows: minmax(100px, auto);
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
}

.grid > * {
  border-radius: 5px;
  border: 2px solid rgb(96 139 168 / 0.4);
  background-color: rgb(96 139 168 / 0.2);
  padding: 10px;
}

.grid :nth-child(1) {
  align-self: start;
}

.grid :nth-child(2) {
  justify-self: end;
}
```

```
.grid {
  writing-mode: vertical-rl;
  inline-size: 400px;
}
```

When working with a site in a writing mode other than a horizontal, top-to-bottom one, or when using writing modes for creative reasons, being able to relate to the flow of the content makes a lot of sense.

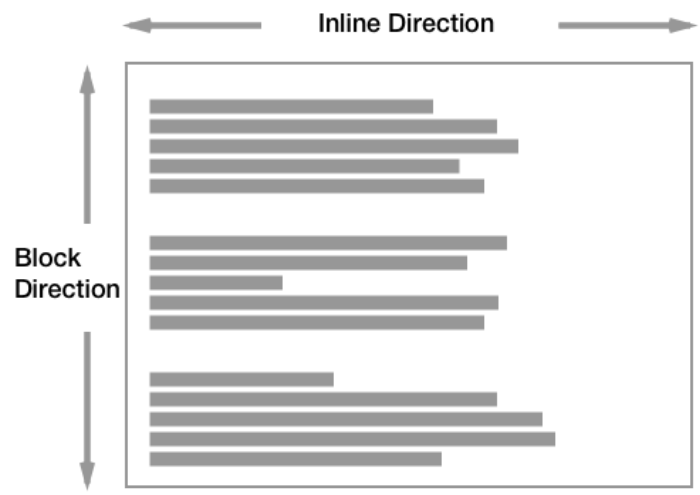
Block and inline dimensions

A key concept of working with flow relative properties and values is the two dimensions of block and inline. CSS layout methods such as flexbox and grid layout use the concepts of `block` and `inline` rather than `right` and `left`/`top` and `bottom` when aligning items.

The `inline` dimension is the dimension along which a line of text runs in the writing mode in use. Therefore, in an English document with the text running horizontally left-to-right, or an Arabic document with the text running horizontally right-to-left, the inline dimension is *horizontal*. Switch to a vertical writing mode (e.g., a Japanese document) and the inline dimension is now *vertical*, as lines in that writing mode run vertically.

The block dimension is the other dimension, and the direction in which blocks — such as paragraphs — display one after the other. In English and Arabic, these run vertically, whereas in any vertical writing mode these run horizontally.

The below diagram shows the inline and block directions in a horizontal writing mode:



This diagram shows block and inline in a vertical writing mode:

Logical properties for floating and positioning

The CSS logical properties and values module contains logical mappings for the physical values of `float` and `clear`, and also for the positioning properties used with positioned layout. This guide takes a look at how to use these.

Mapped properties and values

The table below details the logical properties and values discussed in this guide along with their physical properties and values mappings. They assume a horizontal `writing-mode`, with a left-to-right direction.

Logical property or value	Physical property or value
`float`: inline-start	`float`: left
`float`: inline-end	`float`: right
`clear`: inline-start	`clear`: left
`clear`: inline-end	`clear`: right
`inset-inline-start`	`left`
`inset-inline-end`	`right`
`inset-block-start`	`top`
`inset-block-end`	`bottom`
`text-align`: start	`text-align`: left
`text-align`: end	`text-align`: right

In addition to these mapped properties, there are some additional shorthand properties made possible by being able to address block and inline dimensions. These have no mapping to physical properties, aside from the `inset` property.

Logical property	Purpose
`inset-inline`	Sets both of the above inset values for the inline dimension simultaneously.
`inset-block`	Sets both of the above inset values for the block dimension simultaneously.
`inset`	Sets all four inset values simultaneously with physical mapping of multi-value.

Float and clear example

The physical values used with the `float` and `clear` properties are `left`, `right` and `both`. The CSS logical properties and values module defines the values `inline-start` and `inline-end` as mappings for `left` and `right`.

In the example below, the first box is floated with `float: left`, and the second with `float: inline-start`. If you apply `direction: rtl` to the `.inner` selector, the left-floated box always stays on the left, whereas the `inline-start`-floated item follows the `direction` of the text. You can combine this with `writing-mode: vertical-rl` to see the difference of block layout in combination with `direction` values.

```
<div class="container">
  <div class="inner">
    <div class="physical box"></div>
    Turnip greens yarrow ricebean rutabaga endive cauliflower sea lettuce
    kohlrabi amaranth water spinach avocado daikon napa cabbage asparagus winter
    purslane kale.
  </div>
  <div class="inner">
    <div class="logical box"></div>
    Turnip greens yarrow ricebean rutabaga endive cauliflower sea lettuce
    kohlrabi amaranth water spinach avocado daikon napa cabbage asparagus winter
    purslane kale.
  </div>
</div>
```

```
body {
  font: 1.2em / 1.5 sans-serif;
}
.container {
  display: flex;
}

.box {
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
  background-color: rgb(96 139 168 / 0.2);
  padding: 10px;
  margin: 10px;
  width: 100px;
  height: 100px;
}
```

```
.inner {
  /* direction: rtl; */
  /* writing-mode: vertical-rl; */
}

.physical {
  float: left;
}

.logical {
  float: inline-start;
}
```

Example: Inset properties for positioned layout

CSS positioning generally allows us to position an element in a manner relative to its containing block — we essentially inset the item relative to where it would fall based on normal flow. To position an element relative to the viewport, use the physical properties `top`, `right`, `bottom` and `left`. When you want the positioning to relate to the flow of text in your writing mode, use `inset-block-start`, `inset-block-end`, `inset-inline-start` and `inset-inline-end` instead.

These properties take a length or a percentage as a value, and relate to the user's screen dimensions.

In the below example, the `inset-block-start` and `inset-inline-end` properties are used to position the blue box using absolute positioning inside the area with the gray dotted border, which has `position: relative`. Change the `writing-mode` property to `vertical-rl`, or add `direction: rtl`, and see how the flow relative box stays with the text direction.

```
<div class="container">
  <div class="inner">
    <div class="physical box"></div>
  </div>
  <div class="inner">
    <div class="logical box"></div>
  </div>
</div>
```

```
.container {
  display: flex;
}

.inner {
  width: 200px;
  height: 200px;
  position: relative;
  border: 2px dotted grey;
}

.box {
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
  background-color: rgb(96 139 168 / 0.2);
  padding: 10px;
  width: 100px;
```

```
  height: 100px;
}
```

```
.inner {
  writing-mode: horizontal-tb;
}

.physical {
  position: absolute;
  top: 20px;
  right: 0;
}

.logical {
  position: absolute;
  inset-block-start: 20px;
  inset-inline-end: 0;
}
```

New two- and four-value shorthands

As with other properties in the module, we have shorthand properties which give the ability to set two or four values at once.

- `inset` — sets all four sides together with physical mapping.
- `inset-inline` — sets both logical inline insets.
- `inset-block` — sets both logical block insets.

Example: Logical values for text-align

The `text-align` property has logical values that relate to text direction — rather than using `left` and `right` you can use `start` and `end`. In the below example, `text-align: right` is set in the first block and `text-align: end` in the second.

If you change the value of `direction` to `rtl`, you will see that the alignment stays to the right for the first block, but goes to the logical end on the left in the second.

```
<div class="container">
  <div class="inner physical">Aligned text</div>
  <div class="inner logical">Aligned text</div>
</div>
```

```
body {
  font: 1.2em / 1.5 sans-serif;
}

.container {
  display: flex;
}

.inner {
  width: 200px;
  border: 2px dotted grey;
  padding: 10px;
}
```

```
.inner {
  direction: ltr;
}

.physical {
  text-align: right;
}

.logical {
  text-align: end;
}
```

This works more consistently when using box alignment that uses start and end rather than physical directions for alignment.

Logical properties for margins, borders, and padding

The CSS logical properties and values module defines flow-relative mappings for the various margin, border, and padding properties and their shorthands. In this guide, we take a look at these.

If you look at the logical properties and values module, you may notice the list of module properties is very long. This is mostly because there are four longhand values each for margin, border, and padding side, plus all the shorthand values.

Mappings for margins, borders, and padding

The module details mappings for each logical value to a physical counterpart. The table below maps these values for when the `writing-mode` is `horizontal-tb` — with a left to right direction. The inline direction therefore runs horizontally — left to right — and `margin-inline-start` would be equivalent to `margin-left`.

If you were using a `horizontal-tb` writing mode with a right-to-left text direction then `margin-inline-start` would be the same as `margin-right`, and in a vertical writing mode it would be the same as using `margin-top`.

Logical property	Physical property
`border-block-end`	`border-bottom`
`border-block-end-color`	`border-bottom-color`
`border-block-end-style`	`border-bottom-style`
`border-block-end-width`	`border-bottom-width`
`border-block-start`	`border-top`
`border-block-start-color`	`border-top-color`
`border-block-start-style`	`border-top-style`
`border-block-start-width`	`border-top-width`
`border-inline-end`	`border-right`

Logical property	Physical property
`border-inline-end-color`	`border-right-color`
`border-inline-end-style`	`border-right-style`
`border-inline-end-width`	`border-right-width`
`border-inline-start`	`border-left`
`border-inline-start-color`	`border-left-color`
`border-inline-start-style`	`border-left-style`
`border-inline-start-width`	`border-left-width`
`border-start-start-radius`	`border-top-left-radius`
`border-end-start-radius`	`border-bottom-left-radius`
`border-start-end-radius`	`border-top-right-radius`
`border-end-end-radius`	`border-bottom-right-radius`
`margin-block-end`	`margin-bottom`
`margin-block-start`	`margin-top`
`margin-inline-end`	`margin-right`
`margin-inline-start`	`margin-left`
`padding-block-end`	`padding-bottom`
`padding-block-start`	`padding-top`
`padding-inline-end`	`padding-right`
`padding-inline-start`	`padding-left`

There are also some additional shorthands, made possible because we can target both block or both inline edges of the box simultaneously. These shorthands have no physical equivalent.

Property	Purpose
`border-block`	Sets `border-color`, `border-style`, and `border-width` for both block borders.
`border-block-color`	Sets `border-color` for both block borders.
`border-block-style`	Sets `border-style` for both block borders.
`border-block-width`	Sets `border-width` for both block borders.
`border-inline`	Sets `border-color`, `-style`, and `-width` for both inline borders.
`border-inline-color`	Sets `border-color` for both inline borders.
`border-inline-style`	Sets `border-style` for both inline borders.
`border-inline-width`	Sets `border-width` for both inline borders.
`margin-block`	Sets all the block `margin`s.
`margin-inline`	Sets all the inline `margin`s.
`padding-block`	Sets the block `padding`.
`padding-inline`	Sets the inline `padding`.

Margin examples

The mapped margin properties of `margin-inline-start`, `margin-inline-end`, `margin-block-start`, and `margin-inline-end` can be used instead of their physical counterparts.

This example has two boxes with different sized margins to each edge. An extra container with a border has been included to make the margin more apparent.

One box uses physical properties and the other logical properties. Try changing the `direction` property to `rtl` to cause the boxes to display in a right-to-left direction; the margins on the first box will stay in the same place, while the margins on the inline dimension of the second box will switch.

Also try changing the `writing-mode` from `horizontal-tb` to `vertical-rl`. Notice how the margins stay in the same place for the first box, but switch around to follow the text direction in the second.

```
<div class="container">
  <div class="inner">
    <div class="physical box">
      margin-top: 5px<br />
      margin-right: 0<br />
      margin-bottom: 2em<br />
      margin-left: 50px
    </div>
  </div>
  <div class="inner">
    <div class="logical box">
      margin-block-start: 5px<br />
      margin-inline-end: 0<br />
      margin-block-end: 2em<br />
      margin-inline-start: 50px
    </div>
  </div>
</div>
```

```
body {
  font: 1.2em / 1.5 sans-serif;
}
.container {
  display: flex;
}
.inner {
  border: 2px dotted grey;
}
.box {
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
```

```
  background-color: rgb(96 139 168 / 0.2);
  padding: 10px;
  width: 220px;
  height: 220px;
}
```

```
.box {
  writing-mode: horizontal-tb;
  direction: ltr;
}

.physical {
  margin-top: 5px;
  margin-right: 0;
  margin-bottom: 2em;
  margin-left: 50px;
}

.logical {
  margin-block-start: 5px;
  margin-inline-end: 0;
  margin-block-end: 2em;
  margin-inline-start: 50px;
}
```

Margin shorthands

There are shorthands available to target either both the inline sides or both the block sides, `margin-inline` and `margin-block` respectively. Each accepts two values. The first value will apply to the start of that dimension, the second to the end. If only one value is set, it is applied to both.

In a horizontal writing mode this CSS would apply a `5px` margin to the top of the box and a `10px` margin to the bottom.

```
.box {
  margin-block: 5px 10px;
}
```

Padding examples

The mapped padding properties of `padding-inline-start`, `padding-inline-end`, `padding-block-start`, and `padding-inline-end` can be used instead of their physical counterparts.

In this example, there are two boxes. One has physical padding properties set and the other uses logical padding properties. With a `writing-mode` of `horizontal-tb`, both boxes should appear the same.

Try changing the `direction` property to `rtl` to cause the boxes to display in a right-to-left direction. The padding on the first box will stay in the same place, whereas the padding on the inline dimension of the second box will switch.

You can also try changing the `writing-mode` from `horizontal-tb` to `vertical-rl`. Again, notice how the padding stays in the same place for the first box, but switches around to follow the text direction in the second.

```
<div class="container">
  <div class="physical box">
    padding-top: 5px<br />
    padding-right: 0<br />
    padding-bottom: 2em<br />
    padding-left: 50px
  </div>

  <div class="logical box">
    padding-block-start: 5px<br />
    padding-inline-end: 0<br />
    padding-block-end: 2em<br />
    padding-inline-start: 50px
  </div>
</div>
```

```
body {
  font: 1.2em / 1.5 sans-serif;
}

.container {
  display: flex;
}
.box {
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
  background-color: rgb(96 139 168 / 0.2);
  margin: 10px;
  width: 220px;
  height: 220px;
}
```

```
.box {
  writing-mode: horizontal-tb;
  direction: ltr;
}

.physical {
  padding-top: 5px;
  padding-right: 0;
  padding-bottom: 2em;
  padding-left: 50px;
}

.logical {
  padding-block-start: 5px;
  padding-inline-end: 0;
  padding-block-end: 2em;
  padding-inline-start: 50px;
}
```

Padding shorthands

As with margin, there are two-value shorthands for padding — `padding-inline` and `padding-block` — which allow you to set the padding of the two inline, and two block dimensions, respectively.

In a horizontal `writing-mode`, this CSS would apply `5px` of padding to the top of the box and `10px` of padding to the bottom:

```
.box {
  padding-block: 5px 10px;
}
```

Border examples

The border properties are the main reason that this module seems to have so many properties, as it provides longhand logical properties for the color, width, and style of the border on each side of a box, along with the shorthand to set all three at once for each side. As with margin and padding, there is a mapped version of each physical property.

The demo below uses some longhands and three shorthand values. As with the other demos, try changing the `direction` property to `rtl` to cause the boxes to display in a right-to-left direction, or changing the `writing-mode` from `horizontal-tb` to `vertical-rl`.

```
<div class="container">
  <div class="physical box">Borders using physical properties.</div>
  <div class="logical box">Borders using logical properties.</div>
</div>
```

```
body {
  font: 1.2em / 1.5 sans-serif;
}

.container {
  display: flex;
}
.box {
  border-radius: 5px;
  background-color: rgb(96 139 168 / 0.2);
  margin: 10px;
  width: 220px;
  height: 220px;
}
```

```
.box {
  writing-mode: horizontal-tb;
  direction: ltr;
}

.physical {
  border-top: 2px solid hotpink;
  border-right-style: dotted;
  border-right-color: goldenrod;
  border-right-width: 5px;
  border-bottom: 4px double black;
  border-left: none;
}

.logical {
  border-block-start: 2px solid hotpink;
  border-inline-end-style: dotted;
  border-inline-end-color: goldenrod;
  border-inline-end-width: 5px;
  border-block-end: 4px double black;
  border-inline-start: none;
}
```

Border shorthands

There are two-value shorthands to set the width, style, and color of the block or inline dimension, and shorthands to set all three values in the block or inline dimension. The below code, in a horizontal writing mode, would give you a `2px green solid` border on the top and bottom of the box, and a `4px dotted purple` border on the left and right.

```
.box {
  border-block: 2px solid green;
  border-inline-width: 4px;
  border-inline-style: dotted;
  border-inline-color: rebeccapurple;
}
```

Flow relative border-radius properties

The module has flow-relative equivalents for the `border-radius` longhands. The below example, in a horizontal `writing-mode`, would set the top-right border radius to `1em`, the bottom-right to `0`, the bottom-left to `20px` and the top-left to `40px`.

```
.box {
  border-end-start-radius: 1em;
  border-end-end-radius: 0;
  border-start-end-radius: 20px;
  border-start-start-radius: 40px;
}
```

Indicating logical values for the 4-value shorthand syntax

The specification makes a suggestion for the four-value shorthands such as the `margin` property, however the final decision on how this should be indicated is as yet unresolved, and is discussed in this issue.

Using any four-value shorthand such as `margin`, `padding`, or `border` will currently use the physical versions, so if following the flow of the document is important, use the longhand properties for the time being.

Logical properties for sizing

In this guide, we will explain the flow-relative mappings between physical dimension properties and logical properties used for sizing elements on our pages.

When specifying the size of an item, the CSS logical properties and values module gives you the ability to indicate sizing as it relates to the flow of text (inline and block) rather than physical sizing which relates to the physical dimensions of horizontal and vertical (e.g., left and right). While these flow relative mappings may well become the default for many of us, in a design you may well use both physical and logical sizing. You might want some features to always relate to the physical dimensions whatever the writing mode.

Mappings for dimensions

The table below provides mappings between logical and physical properties. These mappings assume that you are in a `horizontal-tb` writing mode, such as English or Arabic, in which case `width` would be mapped to `inline-size`.

If you were in a vertical writing mode then `inline-size` would be mapped to `height`.

Logical Property	Physical Property
`inline-size`	`width`
`block-size`	`height`
`min-inline-size`	`min-width`
`min-block-size`	`min-height`
`max-inline-size`	`max-width`
`max-block-size`	`max-height`

Width and height example

The logical mappings for `width` and `height` are `inline-size`, which sets the length in the inline dimension and `block-size`, which sets the length in the block dimension. When working in English, replacing `width` with `inline-size` and `height` with `block-size` will give the same layout.

In the live example below, the `writing-mode` is set to `horizontal-tb`. Change it to `vertical-rl` and you will see that the first example — which uses `width` and `height` — remains the same size in each dimension, despite the text becoming vertical. The second example — which uses `inline-size` and `block-size` — will follow the text direction as if the entire block has rotated.

```
<div class="container">
  <div class="physical box">I have a width of 200px and a height of 100px.</div>

  <div class="logical box">
    I have an inline-size of 200px and a block-size of 100px.
  </div>
</div>
```

```
body {
  font: 1.2em / 1.5 sans-serif;
}
.container {
  display: flex;
}
.box {
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
  background-color: rgb(96 139 168 / 0.2);
  padding: 10px;
  margin: 10px;
}
```

```
.box {
  writing-mode: horizontal-tb;
}

.physical {
  width: 200px;
  height: 100px;
}

.logical {
  inline-size: 200px;
  block-size: 100px;
}
```

Min-width and min-height example

There are also mappings for `min-width` and `min-height` — these are `min-inline-size` and `min-block-size`. These work in the same way as the `inline-size` and `block-size` properties, but setting a minimum rather than a fixed size.

Try changing the example below to `vertical-rl`, as with the first example, to see the effect it has. I am using `min-height` in the first example and `min-block-size` in the second.

```
<div class="container">
  <div class="physical box">
    I have a width of 200px and a min-height of 5em.
  </div>

  <div class="logical box">
    I have an inline-size of 200px and a min-block-size of 5em.
  </div>
</div>
```

```
body {
  font: 1.2em / 1.5 sans-serif;
}
.container {
  display: flex;
}
.box {
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
  background-color: rgb(96 139 168 / 0.2);
  padding: 10px;
  margin: 10px;
}
```

```
.box {
  writing-mode: horizontal-tb;
}

.physical {
```

```
  width: 200px;
  min-height: 5em;
}

.logical {
  inline-size: 200px;
  min-block-size: 5em;
}
```

Max-width and max-height example

Finally you can use `max-inline-size` and `max-block-size` as logical replacements for `max-width` and `max-height`. Try playing with the below example in the same way as before.

```
<div class="container">
  <div class="physical box">I have a max-width of 200px.</div>

  <div class="logical box">I have a max-inline-size of 200px.</div>
</div>
```

```
body {
  font: 1.2em / 1.5 sans-serif;
}
.container {
  display: flex;
}
.box {
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
  background-color: rgb(96 139 168 / 0.2);
  padding: 10px;
  margin: 10px;
}
```

```
.box {
  writing-mode: horizontal-tb;
}

.physical {
  max-width: 200px;
}

.logical {
  max-inline-size: 200px;
}
```

Logical keywords for resize

The `resize` property sets whether or not an item can be resized and has physical values of `horizontal` and `vertical`. The `resize` property also has logical keyword values. Using `resize: inline` allows resizing in the inline dimension and `resize: block` allow resizing in the block dimension.

The keyword value of `both` for the resize property works whether you are thinking physically or logically. It sets both dimensions at once. Try playing with the below example.

```
<div class="container">
  <div class="physical box">
    I have a width of 200px and a height of 100px. I can be resized
    horizontally.
  </div>

  <div class="logical box">
    I have an inline-size of 200px and a block-size of 100px. I can be resized
    in the inline direction.
  </div>
</div>
```

```
body {
  font: 1.2em / 1.5 sans-serif;
}
.container {
  display: flex;
}
.box {
  border: 2px solid rgb(96 139 168);
  border-radius: 5px;
  background-color: rgb(96 139 168 / 0.2);
  padding: 10px;
  margin: 10px;
}
```

```
.box {
  writing-mode: horizontal-tb;
  overflow: scroll;
}

  width: 200px;
  height: 100px;
  resize: horizontal;
}

.logical {
  inline-size: 200px;
  block-size: 100px;
  resize: inline;
}
```

CSS masking

The **CSS masking** module defines masking and clipping, two different graphical operations that are used to partially or fully hide portions of visual elements.

Clipping involves defining a closed vector path, shape, or polygon as a **clipping path**. Everything inside the clipping path region remains visible while everything outside is hidden, or "clipped out". The `clip-path` property specifies a `<basic-shape>` or references an SVG `<clipPath>` element to be used as a clipping path.

CSS **masking** properties are used to apply a mask to an element or its border. A graphical object is then painted onto the background or border, completely or partially masking out parts of the element or its border, depending on the opacity or luminance of the mask.

The image used as the mask is specified by the `mask-image` or `mask-border-source` properties. The specified mask can be an `<image>`, a `<gradient>`, or an SVG `<mask>` element. The mask can be sized and positioned similarly to background and border images.

Clipping and masking in CSS behaves the same way as it does with SVG: First, the element is styled without filter effects, masking, clipping, and opacity. Then, any effects are applied to the element in the following order: filter effects, clipping, masking, and opacity.

While masking provides more control and options, clipping can perform better if a basic shape is all that's required — they are easier to interpolate.

Introduction to CSS clipping

CSS clipping enables you to define visible portions of an element while hiding other parts, effectively "clipping" its content within a specific shape or area. With clipping, elements aren't limited to being rendered as rectangles and can be designed in visually engaging ways. This guide explores the `clip-path` property along with some examples.

CSS clipping

Clipping is a CSS technique used to clip (hide) sections of an element, displaying only the area of the element located within a developer-defined path. Clips areas are created by vector paths; anything in the path is visible while areas outside the path are hidden.

The <code>clip-path</code> property

The `clip-path` property applies clipping. The value it accepts is a vector path defining the area of the element that should remain visible. The path can be defined using boxes, a reference to an SVG `<clipPath>`, or CSS shapes and paths. In the following example, we clip a blue square `<div>`, creating a diamond, using the `polygon()` function as the clipping path:

```
<div class="diamond"></div>
```

```
.diamond {
  height: 200px;
  width: 200px;
  background-color: blue;

  clip-path: polygon(0 50%, 50% 100%, 100% 50%, 50% 0);
}
```

With the `clip-path` property, you can make complex shapes by clipping an element to a `<basic-shape>` or to an SVG source. You can animate and transition `clip-path` shapes if the declared states have the same number of vector points.

Values of the <code>clip-path</code> property

To visually clip an element, the `clip-path` property is set to either a `<geometry-box>`, a `url` to a `<clipPath>` clip source, or a `<basic-shape>` created with shape function.

Geometry boxes

The `clip-path` hides everything outside of the clipped region. The most basic clipping is done via a geometry box. You can clip an element based on its margin, border, padding, or content. The effects of these visual box values can be achieved via other CSS properties, such as setting the `border-color` to transparent and the `background-origin` to the desired visual box. We're looking at these values mostly because these values are used in conjunction with the shape functions, which we'll look at later, to define the origin of the shape clip path.

Understanding the reference box used by CSS shapes is important when using `clip-path`, especially with basic shapes, as the reference box defines a shape's coordinate system.

Visual box values

This live example demonstrates the `clip-path` property's different visual box values on an element, while comparing it to the CSS `background-origin` property. We've applied a `border`, a `background-color`, a `background-image`, and `padding` to the `<blockquote>`. Select a radio button to update the `--value` to a different `<geometry-box>` value, which updates the `background-origin` and the `clip-path` resolved values.

```
body {
  display: flex;
  flex-flow: row wrap;
  place-content: center;
}
blockquote {
  float: left;
  font-size: 1.2rem;
}
q {
  color: white;
  font-family: sans-serif;
  display: block;
  margin-bottom: 0.5em;
}
p {
  margin: 0;
  line-height: 1.6;
}

body {
  --value: initial;
}
body:has([value="border-box"]:checked) {
  --value: border-box;
}
body:has([value="padding-box"]:checked) {
  --value: padding-box;
}
body:has([value="content-box"]:checked) {
  --value: content-box;
}
body:has([type="checkbox"]:checked) blockquote {
  border-radius: 70px;
}
```

```
blockquote {
  width: 210px;
  padding: 20px;
  margin: 20px;
  border: 20px dashed #dedede;
```

```
  background-color: #ededed;
  background-image: linear-gradient(rebeccapurple, magenta);
  background-repeat: no-repeat;
}

.clippath {
  background-origin: var(--value);
  clip-path: var(--value);
}

.box-model {
  background-origin: var(--value);
}
```

```
<blockquote class="clippath">
  <q
    >I've learned that people will forget what you said, people will forget what
    you did, but people will never forget how you made them feel.</q
  >
  <cite>&mdash; Maya Angelou</cite>
</blockquote>
<blockquote class="box-model">
  <q
    >I've learned that people will forget what you said, people will forget what
    you did, but people will never forget how you made them feel.</q
  >
  <cite>&mdash; Maya Angelou</cite>
</blockquote>

<fieldset>
  <legend>Select the geometry box value:</legend>
  <p>
    <label
      ><input type="radio" name="gb" value="border-box" /> border-box</label
    >
  </p>
  <p>
    <label
      ><input type="radio" name="gb" value="padding-box" /> padding-box</label
    >
  </p>
  <p>
    <label
      ><input type="radio" name="gb" value="content-box" /> content-box</label
    >
  </p>
  <p>
    <label
      ><input type="radio" name="gb" value="initial" checked /> initial</label
    >
  </p>
</fieldset>
<p>
  <label><input type="checkbox" /> Change the border radius</label>
</p>
```

When a `<geometry>` box is specified in combination with a `<basic-shape>`, the value defines the reference box for the basic shape. If specified by itself, it causes the edges of the specified box, including any corner shaping (such as a `border-radius`), to be the clipping path.

Shape origin

The previous example may make you think that the `<geometry-box>` values are useless, as you can use `background-origin` instead. And you can. But when clipping using basic shapes, the `<geometry-box>`, when included along with a `<basic-shape>` as the `clip-path` value, defines the reference box for, or origin of, that shape. We can combine the two previous examples to demonstrate this.

```
<blockquote class="clippath">
  <q
    >I've learned that people will forget what you said, people will forget what
    you did, but people will never forget how you made them feel.</q
  >
  <cite>&mdash; Maya Angelou</cite>
</blockquote>
<fieldset>
  <legend>Select the origin of the clip path shape:</legend>
  <p>
    <label
      ><input type="radio" name="gb" value="border-box" checked />
      border-box</label
    >
  </p>
  <p>
    <label
      ><input type="radio" name="gb" value="padding-box" /> padding-box</label
    >
  </p>
  <p>
    <label
      ><input type="radio" name="gb" value="content-box" /> content-box</label
    >
  </p>
</fieldset>
```

```
blockquote {
  width: 210px;
  padding: 20px;
  margin: 20px;
  border: 20px dashed #dedede;
  background-color: #ededed;
  background-image: linear-gradient(rebeccapurple, magenta);
  background-repeat: no-repeat;
  background-origin: border-box;
```

```
  clip-path: var(--value) polygon(0 50%, 50% 100%, 100% 50%, 50% 0);
}
```

```
blockquote {
  font-size: 1.2rem;
}
q {
  color: white;
  font-family: sans-serif;
  display: block;
  margin-bottom: 0.5em;
}
p {
  margin: 0;
  line-height: 1.6;
}

body {
  --value: "";
}
body:has([value="border-box"]:checked) {
  --value: border-box;
}
body:has([value="padding-box"]:checked) {
  --value: padding-box;
}
body:has([value="content-box"]:checked) {
  --value: content-box;
}
```

For another example, see `clip-path` shapes and geometry boxes.

Even values like `clip-path: margin-box` can be useful. In addition to creative visuals made by placing the clip-path's edge at the margin-box edge, any computed value for `clip-path`, other than `none`, results in the creation of a new stacking context the same way that CSS `opacity` does for values other than `1`.

Clipping to basic shapes

The `clip-path` property's support of `<basic-shape>` values provides a powerful way to shape elements. The various shape function enable defining precise clipping regions, effectively sculpting elements into unique forms. The basic shape functions, include:

- `circle()`
- `ellipse()`
- `inset()`
- `path()`
- `polygon()`
- `rect()`
- `shape()`
- `xywh()`

The size and position of these shapes are defined by the `<geometry-box>` value, which defaults to border-box being used as the reference box if the `clip-path` value includes a shape without the `<geometry-box>` component value.

Some of these functions appear to only provide basic predefined clipping options. They may appear to replicate effects you can create with `border-radius`, but if you toggled the `border-radius` property in the previous example, you may have noticed the power of CSS clipping. Shapes provide even more control. For example, `inset()` enables clipping a rectangle with precise margins. The real power and control comes with `path()`, `shape()`, and even `polygon()`, which allows for custom multi-point shapes.

Creating polygons

With `polygon()`, by defining pairs of coordinates, each of which represents a vertex of the shape. you can create intricate forms like stars or abstract figures. The coordinates define vector points connected by straight lines.

Here we use the `polygon()` function to create a star:

```
<div class="star"></div>
```

```
.star {
  width: 200px;
  height: 200px;
  background: linear-gradient(rebeccapurple, magenta) blue;
  clip-path: polygon(
    50% 0%,
    61% 35%,
    100% 35%,
    68% 57%,
    79% 91%,
    50% 70%,
    21% 91%,
    32% 57%,
    0% 35%,
    39% 35%,
    50% 0%
  );
}
```

Animation

Clipped shapes can be animated and transitioned by declaring the same number of vector points for the different states.

```
<div class="star"></div>
```

```
.star {
  width: 200px;
  height: 200px;
  background: linear-gradient(rebeccapurple, magenta) blue;
  clip-path: polygon(
    50% 0%,
    61% 35%,
    100% 35%,
```

```
    68% 57%,
    79% 91%,
    50% 70%,
    21% 91%,
    32% 57%,
    0% 35%,
    39% 35%,
    50% 0%
  );
}
```

```
@keyframes morphStar {
  from {
    clip-path: polygon(
      50% 0%,
      61% 35%,
      100% 35%,
      68% 57%,
      79% 91%,
      50% 70%,
      21% 91%,
      32% 57%,
      0% 35%,
      39% 35%,
      50% 0%
    );
  }
  to {
    clip-path: polygon(
      50% 10%,
      65% 30%,
      90% 20%,
      75% 60%,
      85% 95%,
      50% 80%,
      15% 95%,
      25% 60%,
      10% 20%,
      35% 30%,
      50% 10%
    );
  }
}

.star {
  animation: morphStar alternate 3s infinite ease-in-out;
}
```

The <code>path()</code> function

The `path()` function enables drawing shapes using SVG commands. The function accepts the equivalent of the SVG `d` attribute as the function's parameter.

The star from the previous example can be created using `path()`:

```
<div class="star"></div>
```

```
.star {
  width: 200px;
  height: 200px;
  background: linear-gradient(rebeccapurple, magenta) blue;
  clip-path: path(
    "M100,0 L122,70 L200,70 L136,114 L158,182 L100,140 L42,182 L64,114 L0,70 L78,70 L100,0 Z"
  );
}
```

Curved lines

With `path()`, we are not limited to straight lines. In this example, we use the `path()` function to create a heart:

```
<div class="heart"></div>
```

```
.heart {
  width: 200px;
  height: 200px;
  background: linear-gradient(rebeccapurple, magenta) blue;
  clip-path: path(
    "M20,70 A40,40,0,0,1,100,70 A40,40,0,0,1,180,70 Q180,130,100,190 Q20,130,20,70 Z"
  );
}
```

SVG as source

Instead of passing an SVG `d` attribute string as the `path()` function argument, the value of the `clip-path` property can reference the SVG `<clipPath>` element directly.

```
<div class="heart"></div>
<svg height="0" width="0">
  <clipPath id="heart">
    <path
      d="M20,70 A40,40,0,0,1,100,70 A40,40,0,0,1,180,70 Q180,130,100,190 Q20,130,20,70 Z" />
  </clipPath>
</svg>
```

The `id` of the `<clipPath>` is the parameter of the `url()` function.

```
.heart {
  width: 200px;
  height: 200px;
  background: linear-gradient(rebeccapurple, magenta) blue;
```

```
  clip-path: url("#heart");
}
```

Shape function

The SVG path syntax is not the most intuitive. For this reason, CSS also offers a `shape()` function. The `shape()` function also takes path drawing directive, but with a syntax that is more human readable. We can recreate the heart with more declarative CSS:

```
.heart {
  clip-path: shape(
    from 20px 70px,
    arc to 100px 70px of 1% cw,
    arc to 180px 70px of 1% cw,
    curve to 100px 190px with 180px 130px,
    curve to 20px 70px with 20px 130px
  );
}
```

The `shape()` function is more robust in that it accepts CSS values and units (`path()` is limited to coordinates), including using CSS math functions like `calc()`. By using variables, we can create shapes (and boxes) of many different sizes:

```
:root {
  --m: 10;
}
.heart {
  width: calc(20px * var(--m));
  height: calc(20px * var(--m));
  display: inline-block;
  background: linear-gradient(rebeccapurple, magenta) blue;
  clip-path: border-box
    shape(
      from calc(2px * var(--m)) calc(7px * var(--m)),
      arc to calc(10px * var(--m)) calc(7px * var(--m)) of 1% cw,
      arc to calc(18px * var(--m)) calc(7px * var(--m)) of 1% cw,
      curve to calc(10px * var(--m)) calc(19px * var(--m)) with
        calc(18px * var(--m)) calc(13px * var(--m)),
      curve to calc(2px * var(--m)) calc(7px * var(--m)) with
        calc(2px * var(--m)) calc(13px * var(--m))
    );
}
.small {
  --m: 4;
}

.medium {
  --m: 8;
}

.large {
  --m: 12;
}
```

```
<div class="heart small"></div>
<div class="heart medium"></div>
<div class="heart large"></div>
```

Wrapping text around your clipped shapes

Clipped elements are still rectangular boxed. Clipping means your element doesn't look like a box; but it is still a box. To wrap inline content around the non-rectangular (or rectangular) shapes you define, use the `shape-outside` property. By default, inline content wraps around its margin box; `shape-outside` provides a way to customize this wrapping, making it possible to wrap text around the elements you've clipped, following the clip path you replicated rather than the element's rectangular box.

The content includes two elements to be clipped and the content that will be shaped around them.

```
<div class="leftTriangle"></div>
<div class="rightTriangle"></div>
<blockquote>
  <q>
    I've learned that people will forget what you said, people will forget what
    you did, but people will never forget how you made them feel.</q
  >
  <cite>&mdash; Maya Angelou</cite>
</blockquote>
```

```
:root {
  --m: 10;
  font-size: calc(3px * var(--m));
}
div {
  width: calc(0.75em * var(--m));
  height: calc(0.75em * var(--m));
  display: inline-block;
  background: linear-gradient(rebeccapurple, magenta) blue;
}
cite {
  display: block;
  text-align: right;
}
```

In addition to applying the same shape for both the `clip-shape` and `shape-outside` properties, the clipped element has to be floated so that the clipped element is on the same line as the content.

```
.leftTriangle {
  clip-path: polygon(0 0, 0 100%, 100% 0);
  shape-outside: polygon(0 0, 0 100%, 100% 0);
  float: left;
}
.rightTriangle {
  clip-path: polygon(100% 0, 100% 100%, 0 100%);
  shape-outside: polygon(100% 0, 100% 100%, 0 100%);
```

```
  float: right;
}
```

Introduction to CSS masking

CSS masking enables you to reveal or hide parts of an element selectively by applying one or more mask images to it. These mask images can be gradients, images, or SVG sources. Unlike CSS clipping, which either fully shows or hides areas of an element based on the shape of a single path, masking allows for nuanced transparency and blending effects based on the alpha transparency and, optionally, luminance of the mask images.

This guide introduces the concept of masking, the various mask image types, and how the luminance and alpha-transparency of the mask impact the portions of the element that are masked (made visible), versus the portions that are clipped (or hidden).

What is masking in CSS?

In CSS, masks can be used to define areas of an element that are visible and other areas that are hidden. Mask layers, defined by one or more `mask-image` sources, determine the areas of an element that should be visible and at what opacity.

> **Note:** Multiple CSS masking property values can be set using the `mask` shorthand property.

With `alpha` masks, the opacity of the masked element matches the opacity of the mask applied. In CSS, masking is the opposite of a masquerade mask, where the face is hidden wherever the mask is opaque. In CSS, the areas of the element where its mask is fully opaque will be fully opaque and visible. Wherever the mask is fully transparent, the element will be fully hidden. Areas of the element that are masked by partially opaque mask areas will be partially opaque, matching the mask's opacity.

With alpha masks, the color of the mask is irrelevant. Only the opacity of the mask matters. With luminance masks, the brightness of the mask colors is taken into account when determining the opacity of the masked element. The brighter and more opaque the color, the more opaque the element. The darker and more transparent the color, the less opaque the mask will be.

Masks can be defined using CSS gradients, raster images (such as PNGs), and SVG `<mask>` elements. In this guide, we introduce the various mask image types as we discuss opaqueness and transparency, luminance, and masking versus CSS clipping.

Each mask layer consists of a `mask-image`, which is positioned relative to an origin box. The mask images can be sized, repeated, and clipped. In cases where multiple mask images are declared, the way the mask layers are composited, or combined, can be set. These are discussed in the masking properties guide.

> **Note:** All examples will be using the following image as the underlying element upon which masks will be applied:
>
>

Opaqueness versus transparency

```
<img
  src="https://mdn.github.io/shared-assets/images/examples/progress-pride-flag.jpg"
  alt="Pride flag"
  class="applied-mask" />
<div class="mask-source"></div>
```

```
body {
  display: flex;
  gap: 20px;
  padding: 15px;
  background-image:
    linear-gradient(to right, transparent 50%, rgb(0 0 0 / 0.05) 50%),
    linear-gradient(to bottom, transparent 50%, rgb(0 0 0 / 0.05) 50%);
  background-size: 20px 20px;
}
div,
svg,
img {
  width: 220px;
  aspect-ratio: 1;
}
```

With alpha masks, the visible areas of an element are defined by the alpha-transparency of the mask applied to it. Wherever the mask is fully opaque, the element will be visible. At every pixel where the mask is fully transparent, the element too will be fully hidden. Areas of the element that are masked by a partially opaque section of a mask will be partially opaque, matching the opacity of the mask applied to it.

With gradients

To demonstrate this, let's look at an example using a `conic-gradient()` as the `mask-image`. CSS gradients, including conic gradients, can be used to create smooth transitions between visible and hidden areas.

In this case, the top-right corner of the mask is fully opaque, the top-left quadrant is fully transparent, and the bottom half has a smooth transition between opaque and transparent.

```
.applied-mask {
  mask-image: conic-gradient(black 90deg, transparent 270deg);
}
.mask-source {
  background: conic-gradient(black 90deg, transparent 270deg);
}
```

Note how the element on which the mask is applied has a fully visible top-right corner, the top-left quarter is hidden, and the bottom half transitions smoothly from visible to transparent, reflecting the visibility of the applied mask image.

With alpha masks, the color of the mask doesn't matter, only the transparency. In this example, we have a striped gradient with fully opaque red, semi-opaque red, and fully transparent stripes.

```
.applied-mask {
  mask-image: repeating-linear-gradient(
    to bottom right,
    red 0 20px,
    #ff000055 20px 40px,
    transparent 40px 60px
  );
}
.mask-source {
  background: repeating-linear-gradient(
    to bottom right,
    red 0 20px,
    #ff000055 20px 40px,
    transparent 40px 60px
  );
}
```

Note how the fully opaque mask areas reveal fully opaque element pixels, semi-transparent mask areas create semi-transparent areas, and fully transparent mask areas hide the associated areas completely.

With imported images

The previous two examples used gradients as masks and background images. The mask image doesn't have to be a CSS image. It can be an external image or an SVG.

In this case we use an external PNG. The image contains a colorful heart with a transparent background.

```
.applied-mask {
  mask-image: url("https://mdn.github.io/shared-assets/images/examples/colorful-heart.png");
  mask-size: 220px 220px;
}
.mask-source {
  background: url("https://mdn.github.io/shared-assets/images/examples/colorful-heart.png");
  background-size: 220px 220px;
}
```

Note how the transparent mask areas crop the element; the only parts of the element that are visible are the areas where the mask is opaque. The color of the mask itself doesn't matter.

Alpha transparency versus luminance

The `mask-mode` property's default value — `match-source` — sets the mode to either `alpha` or `luminance`, depending on the value. The `match-source` value resolves to `alpha` for all mask sources other than SVG `<mask>` elements. If the mask source is a `<mask>` element, `match-source` resolves to the `<mask>`'s `mask-type` property value, if set. Otherwise, it resolves to the value of the SVG `mask-type` attribute set on the `<mask>` element. If that is not explicitly set either, `match-source` will resolve to `luminance`.

If `mask-mode` resolves to `luminance`, or we explicitly set it to `luminance`, the colors of the mask will affect the mask opacity. In the previous demo, the `mask-mode` was not set, so the value defaulted to `match-source`. As the colorful heart image is a transparent PNG, `match-source` resolves to `alpha`. By explicitly setting this property, we can control the mode. In this demo, we change the `mask-mode` to `luminance`.

```
.applied-mask {
  mask-mode: luminance;
}
```

When applying `mask-mode: luminance` to the same mask as in the previous example, the areas of the element where the mask is **lightest** are more opaque, while **darker** areas are less opaque.

The opacity of a luminance mask is determined by the `R`, `G`, `B`, and `A` values of an RGB color using the formula:

`((0.2125 * R) + (0.7154 * G) + (0.0721 * B)) * A`

For example, the newest `<named-color>` is `rebeccapurple`, which is `#663399`. While one might assume the lightness might be equivalent to the L of the `hsl()` color function, it's not that simple. The value `#663399` is equivalent to `rgb(40% 20% 60% / 1)` and `hsl(270 50% 40% / 1)`, but the brightness value is `27.134%`, not `40%`.

`((0.2125 * 0.4) + (0.7154 * 0.2) + (0.0721 * 0.6)) * 1 = 0.27134`

White has a brightness value of `100%`.

`((0.2125 * 1) + (0.7154 * 1) + (0.0721 * 1)) * 1 = 1`

Black's brightness is `0%`.

`((0.2125 * 0) + (0.7154 * 0) + (0.0721 * 0)) * 1 = 0`

We'll demonstrate this by adding white (`rgb(100% 100% 100%)`) with a lightness of `100%` at `27.234%` opacity to a `rebeccapurple`, `white`, and `black` linear gradient, which we'll then use to mask our image. This white resolves to the same opacity value:

`((0.2125 * 1) + (0.7154 * 1) + (0.0721 * 1)) * 0.27134 = 0.27134`

```
.applied-mask {
  mask-image: repeating-linear-gradient(
    to bottom left,
    rebeccapurple 0 20px,
    rgb(100% 100% 100% / 0.27134) 20px 40px,
    black 40px 45px,
    white 45px 50px
  );
  mask-mode: luminance;
}
.mask-source {
  background: repeating-linear-gradient(
    to bottom left,
    rebeccapurple 0 20px,
```

```
    rgb(100% 100% 100% / 0.27134) 20px 40px,
    black 40px 45px,
    white 45px 50px
  );
}
```

```
:has(:checked) .applied-mask {
  mask-mode: alpha;
}
```

```
<label><input type="checkbox" /><code>mask-mode: alpha;</code></label>
```

The areas with a `white` mask are fully opaque. The areas with a `black` mask are fully transparent. The areas with a `rebeccapurple` mask and the areas with a `27.1234%` opaque white mask are both `27.1234%` opaque.

If you toggle the `mask-mode` to `alpha`, the color of the gradient no longer matters. The entire element will be opaque except the areas covered by the semi-opaque white.

The `mask-mode` property enables using raster images without alpha transparency, such as JPEGs, as mask images. A JPEG is made up of opaque pixels. Using a JPEG as a mask with its default `alpha` mask mode would hide the entire element. The `luminance` value of `mask-mode`, on the other hand, clips the element where the mask is black (has no lightness), is fully opaque where the mask is opaque white (100% lightness), with other areas being semi-transparent based on the lightness of the mask area masking it.

In this example, we have a white moon against a black night sky.

```
.applied-mask {
  mask-image: url("https://mdn.github.io/shared-assets/images/examples/moon.jpg");
  mask-mode: luminance;
  mask-size: 220px;
}
.mask-source {
  background: url("https://mdn.github.io/shared-assets/images/examples/moon.jpg");
  background-size: 220px;
}
```

The element is clipped and not visible where the sky is black. The image is most visible where the moon is at it's lightest.

In this case, if you toggle the `mask-mode` to `alpha`, the entire element will be visible as the entire mask is opaque.

SVG <code><mask></code> as mask source

A mask can be any type of CSS `<image>` or a `<mask-source>`. A `<mask-source>` is a `<url>` reference to an SVG `<mask>` element. This is similar to clipping with the CSS `clip-path` property, in which case the "mask" is an SVG `<clipPath>` element instead (with `clip-path`, the luminance of the path doesn't matter).

In this example, we define an SVG with a `<mask>` element, an identical `<clipPath>` element, and an identical `<path>` element so you can view the mask and clip path source.

```
<img
  src="https://mdn.github.io/shared-assets/images/examples/progress-pride-flag.jpg"
  alt="Pride flag"
  class="applied-mask" />
<svg class="mask-source">
  <mask id="mask-heart">
    <path
      d="M20,70 A40,40,0,0,1,100,70 A40,40,0,0,1,180,70 Q180,130,100,190 Q20,130,20,70 Z"
      fill="rgb(255 0 0 / 0.5)"
      stroke="rgb(255 255 255 / 1)"
      stroke-width="20" />
  </mask>
  <clippath id="clip-heart">
    <path
      d="M20,70 A40,40,0,0,1,100,70 A40,40,0,0,1,180,70 Q180,130,100,190 Q20,130,20,70 Z"
      fill="rgb(255 0 0 / 0.5)"
      stroke="rgb(255 255 255 / 1)"
      stroke-width="20" />
  </clippath>
  <path
    d="M20,70 A40,40,0,0,1,100,70 A40,40,0,0,1,180,70 Q180,130,100,190 Q20,130,20,70 Z"
    fill="rgb(255 0 0 / 0.5)"
    stroke="rgb(255 255 255 / 1)"
    stroke-width="20" />
</svg>
<img
  src="https://mdn.github.io/shared-assets/images/examples/progress-pride-flag.jpg"
  alt="Pride flag"
  class="applied-clip" />
```

```
.applied-mask {
  mask-image: url("#mask-heart");
}
.applied-clip {
  clip-path: url("#clip-heart");
}
```

```
:has(:checked) .applied-mask {
  mask-mode: alpha;
}
body {
  flex-flow: row wrap;
}
```

```
<label><input type="checkbox" /><code>mask-mode: alpha;</code></label>
```

Because the image source is a `<mask>`, and the mask has neither the `mask-type` CSS property nor the `mask-type` SVG attribute set, the `mask-type` defaults to `alpha`, so the default of `mask-mode: match-source` resolves to `luminance`. This is because, for mask sources that are SVG `<mask>` elements, the `mask-type` defaults to `luminance` unless the `mask-type` attribute is explicitly set to `alpha`.

As we haven't set the `mask-type` attribute or CSS property on our mask, the `mask-mode` property default of `match-source` resolves to `luminance`. Toggle the checkbox to set the `mask-mode` value to `alpha` or allow it to default to `match-source`.

This example also demonstrated the difference between masking and clipping in CSS. You'll note that luminance and alpha-transparency are relevant to masking but not to clipping. Masking can be used to control the opacity of an element, while clipping shows everything inside the clipping path and fully hides the parts of the element outside the clip path. Clipped areas are completely invisible, whereas masked areas can be partially or fully visible.

If all you need are shapes, clipping may suffice. But if you need fading, variable opacity, or even control of position and size (which we'll discuss in a separate guide), masking is more suitable.

CSS mask properties

CSS masking is a technique that enables you to define visible portions of an element by applying a mask, which selectively reveals or hides parts of the element based on the alpha channels, and optionally colors, of the applied mask images.

The introductory guide to masking introduces the different types of mask images and their modes. The guide to declaring multiple masks discusses the mask layers and the `mask` shorthand property, providing a brief introduction to the shorthand's component properties. In this guide, we explore these component properties in greater detail and look at how they interact. We also explain how, in cases where multiple mask images are declared, the mask layers are composited, or combined.

CSS masks are composed of one or more mask layers, with a mask layer created for every value in the comma-separated list of `mask` or `mask-image` values, whether the values are images, mask sources, or the keyword `none`. Every `mask-image` is positioned relative to an origin box. The mask images can be sized, repeated, and clipped, then composited together with previous layers to create the final visual mask on the element.

The <code>mask-image</code> property

The minimum requirement to create a mask is a `mask-image` property set to a value other than `none`. The keyword `none` within a list of mask sources creates a mask layer. However, if `none` is the only value of the `mask-image` property, no masking occurs.

The mask image can be a CSS gradient, an imported image (such as a PNG, SVG, etc.), or an SVG `<mask>` element.

In this example, we create five mask layers, including an imported image, two gradients, a layer with no image, and an SVG `<mask>` source as the mask image.

```
.masked-element {
  mask-image:
    url("alphaImage.png"), linear-gradient(to right, black, transparent),
    radial-gradient(circle, white 50%, transparent 75%), none, url("#svg-mask");
}
```

Because one of the mask images is specified as `none`, only four mask images are applied to the `.masked-element` element, while creating five mask layers.

The importance of <code>none</code>

The `none` layer generally has no visual effect (see the `mask-composite` property for how it impacts the applied mask), but as each value in a comma-separated list of `mask-*` values applies to a separate mask layer, the `none` value serves an important purpose even when it doesn't change the composited mask.

This fourth layer in our five-layer structure will match the fourth value of any other comma-separated `mask-*` property values. As previously mentioned, the number of layers is determined by the number of comma-separated values in the `mask-image` property value, even if a value is `none`. Each `mask-*` value is matched up with the `mask-image` values, in order. If the number of values in a `mask-*` property differs from the number of mask layers, any excess values are ignored, or, if the property has fewer values than the number of mask layers, the values are repeated.

If a `mask-*` property has a single value, this value applies to all the layers. If we have five values, the fourth value applies to the `none` layer, with the last value being applied to the `<mask>` source layer. If there are two comma-separated values, the first value will apply to all the odd layers only, including that `<mask>` source layer. For example, each `mask-*` property may have a different number of values:

```
.masked-element {
  mask-image:
    url("alphaImage.png"), linear-gradient(to right, black, transparent),
    radial-gradient(circle, white 50%, transparent 75%), none, url("#svg-mask");
  mask-repeat: repeat-x, repeat-y;
  mask-position:
    center,
    top left,
    bottom right;
}
```

In this case, every odd layer will be repeated along the x-axis while every even layer is repeated along the y-axis. The first and fourth layer images will be centered, while the second and fifth will be positioned in the top left corner. The `none` means the fifth layer's `#svg-mask` image will be repeated along the x-axis starting at the top left corner.

Learn more about mask layers and the `none` keyword.

The <code>mask-mode</code> property

The `mask-mode` property can be used to set the mode of each mask layer to either `alpha` or `luminance`, or allow it to default to the source's mode by setting the value to `match-source`, which is the default. While most `mask-*` properties have an analogous `background-*` property (`mask-image` is analogous to the `background-image` property, for example), `mask-mode` and `mask-composite` have no analogous `background` property.

Mask types: <code>alpha</code> and <code>luminance</code>

Each mask is either an `alpha` or a `luminance` mask.

With `alpha` masks, the alpha-transparency of each mask pixel is important. Wherever the mask is opaque, the corresponding parts of the element will be visible. Wherever the mask is transparent, the corresponding parts of the element will be hidden. Wherever the mask is semi-opaque, the element will be equally semi-opaque. The color of the mask doesn't matter, just the alpha-transparency of the colors.

With `luminance` masks, both the brightness of mask's colors and the alpha channel determine the opaqueness of the masked areas.

> **Note:** All subsequent examples use the following image as a `background-image` on an element to which masks will be applied:

This example demonstrates the difference between `alpha` and `luminance` masks. The masks are the same, but in the `alpha` mask, only the alpha-transparency of the gradient mask colors matter. In the `luminance` example, the R, G, B, and A all matter.

Two containers contain images, while the last is empty but is included to display the gradient we will be using as our `mask-image`.

```
<div class="alpha">
  <img
    src="https://mdn.github.io/shared-assets/images/examples/progress-pride-flag.jpg"
    alt="Pride flag" />
</div>
<div class="luminance">
  <img
    src="https://mdn.github.io/shared-assets/images/examples/progress-pride-flag.jpg"
    alt="Pride flag" />
</div>
<div class="gradient"></div>
```

```
body {
  display: flex;
  gap: 20px;
  padding: 15px;
  background-image: conic-gradient(
    transparent 90deg,
    rgb(0 0 0 / 0.05) 90deg 180deg,
    transparent 180deg 270deg,
    rgb(0 0 0 / 0.05) 270deg
  );
  background-size: 30px 30px;
}
div,
svg,
img {
  width: 220px;
  aspect-ratio: 1;
}
div {
  border: 1px solid black;
}
```

We declare a `repeating-linear-gradient` with red, transparent, and semi-transparent red diagonal stripes. This gradient is used as our mask and, for the last container, as the background image:

```
img {
  mask-image: repeating-linear-gradient(
    to bottom right,
    red 0 20px,
    #ff000055 20px 40px,
    transparent 40px 60px
  );
}
.gradient {
  background: repeating-linear-gradient(
    to bottom right,
    red 0 20px,
    #ff000055 20px 40px,
    transparent 40px 60px
  );
}
```

We set different values for the `mask-mode` property for each image:

```
.alpha img {
  mask-mode: alpha;
}

.luminance img {
  mask-mode: luminance;
}
```

In the `alpha` case, only the transparency of the gradient's colors matter. Where the gradient is opaque red, the image is opaque. Where the gradient is transparent, the image is hidden. Where the gradient is 50% opaque, the image is 50% opaque. In the `luminance` case, the color's brightness matters! See Alpha transparency versus luminance to learn about the equation that uses the color's R, G, B, and A channels to determine the opacity of the mask.

The <code>mask-mode</code> default value: <code>match-source</code>

The default value of the `mask-mode` property is `match-source`. This value sets the `mask-mode` to match the mask's mode type. The `match-source` value resolves to `alpha` for every mask except masks where the mask source is an SVG `<mask>` element.

When an SVG `<mask>` element is used as the mask source, the `match-source` value resolves to the value of the `<mask>` element's `mask-type` property. If the `<mask>` element (not the "masked element") doesn't have the CSS `mask-type` property defined, this property defaults to the value of the SVG `mask-type` attribute, if present. If that is omitted as well, the `match-source` value will resolve to `luminance`.

Continuing with the `masked-element` example, if we don't explicitly set the `mask-mode` property, it will default to `match-source` for each layer, as if we had set the following:

```
.masked-element {
  mask-image:
    url("alphaImage.png"), linear-gradient(to right, black, transparent),
    radial-gradient(circle, white 50%, transparent 75%), none, url("#svg-mask");
  mask-mode: match-source;
}
```

or, using the `mask` shorthand:

```
.masked-element {
  mask:
    url("alphaImage.png") match-source,
    linear-gradient(to right, black, transparent) match-source,
    radial-gradient(circle, white 50%, transparent 75%) match-source,
    none match-source,
    url("#svg-mask") match-source;
}
```

The first mask layer, `url("alphaImage.png")`, references an image. As this isn't a `<mask>` element within an `<svg>`, the `mask-mode` resolves to `alpha`, with the opaque parts of this image making the corresponding parts of the element visible, while the transparent or semi-transparent parts are invisible or partially visible.

The `linear-gradient(to right, black, transparent)` is the second mask layer and `radial-gradient(circle, white 50%, transparent 75%)` is the third. Again, these aren't `<mask>` elements, so the `match-source` value resolves to `alpha`. The masking effect of these layers is determined by the opaqueness of the gradient mask by default.

The fourth mask layer has `none` declared, meaning the mask for this layer is transparent black. The `.masked-element` class sets `mask-mode: match-source;`. Had `mask-mode` instead been a comma-separated list of five different values, the fourth value would have applied to this `none` layer, allowing the fifth value to apply to the fifth layer.

The fifth mask layer is comprised of an SVG `<mask>` element that has `svg-mask` as its `id`. While the default mask mode of the other layers is `alpha`, the default mask type of SVG `<mask>` elements is the `mask-type` value, or, if not set, the `mask-type` attribute. If that isn't defined either, the value defaults to `luminance`. In other words, the masking effect of the `<mask>` is determined by both the brightness and transparency of the `<mask>` element's colors.

If we don't declare the `mask-mode` property at all, and allow it to default to `match-source` for each mask layer, the result in this `.masked-element` case would resolve to:

```
.masked-element {
  mask-image:
    url("alphaImage.png"), linear-gradient(to right, black, transparent),
    radial-gradient(circle, white 50%, transparent 75%), none, url("#svg-mask");
  mask-mode: alpha, alpha, alpha, match-source, luminance;
}
```

or, using the `mask` shorthand:

```
.masked-element {
  mask:
    url("alphaImage.png") alpha,
    linear-gradient(to right, black, transparent) alpha,
    radial-gradient(circle, white 50%, transparent 75%) alpha,
    none match-source,
    url("#svg-mask") luminance;
}
```

The <code>mask-position</code> property

Analogous to the `background-position` property, the `mask-position` property sets the initial position of the mask image relative to the mask layer's origin box, defined by the `mask-origin` property. The syntax follows the `background-position`'s `<position>` syntax, with the value being one, two, or four `<position>` values, defining one to two relative or absolute position offsets.

One-value syntax

If only one keyword value is specified, that value specifies the mask origin edge against which the mask will be placed with the other dimension being `center`.

If only one `<length-percentage>` value is specified, this specifies the X coordinate relative to the left edge of the mask origin, with the Y coordinate set to `50%`.

If two keyword values are specified, the order of the value doesn't matter, but the value cannot include two vertical or two horizontal axis values; `left right` and `top bottom` are both invalid.

Two-value syntax

If two values are present, including one keyword and one `<length-percentage>` value, the order only matters if the keyword is `center`:

- If the keyword is `left` or `right`, it defines the X coordinate relative to the left edge, and the value defines the Y coordinate relative to the top edge.
- Similarly, a `top` or `bottom` keyword defines the Y coordinate positioning the element against the top or bottom edge, respectively, with the other value defining the X value relative to the left edge of the mask origin box.
- When one value is the `center` keyword and the other is a `<length-percentage>`, the first value defines the horizontal position and the second value defines the vertical position.

If two values are present and both are `<length-percentage>` values, the order again matters; the first value defines the horizontal positioning as an offset from the left edge of the mask-positioning area while the second value defines the vertical position as an offset from the top edge of the mask-positioning area.

Four-value syntax

Mask positions can also be relative to corners other than the top left. The four-value syntax enables offsetting the mask from any corner. The value includes two `<length-percentage>` offsets, each preceded by the origin side for that offset. Whether you declare the horizontal or vertical pair first doesn't matter, but you must declare the origin-side keyword (`left`, `right`, `top`, `bottom`, `x-start`, `x-end`, `y-start`, `y-end`, `block-start`, `block-end`, `inline-start`, or `inline-end`) before the offset `<length-percentage>` in each pair, and the two origin-sides can't be from the same axis.

In the two `<length-percentage>` syntax, the origin sides are `top` and `left`, in that order. For example, `mask-position: 10px 20px` is the equivalent of `mask-position: left 10px top 20px`. When offsetting from the top and left, the offset sides aren't required, but the order matters. With the four value syntax, you can use `mask-position` to offset the mask image from any edge combinations, such as `left 10px bottom 20px`, and the order of the sides doesn't matter, as the offset edge is defined by the keyword preceding it rather than the declaration order.

Percentage values

When offsetting using percentage values, the mask's dimension is subtracted from the element's dimension, just as is done with percentage offsets with `background-position`.

Positioning repeating mask images

The `mask-position` property defines the initial position of the mask image. By "initial position", if the mask repeats, the browser places the first mask image in the position defined by the `mask-position` property, thus defining the placement of the mask repetitions.

In this example, we set the position of the first image to `bottom right`, meaning the first mask will be placed at the bottom right edge of the mask origin box. Because mask images repeat by default, the repeating masks will be positioned against the first placed mask's top and left sides.

```
<div class="keywords">
  <img
    src="https://mdn.github.io/shared-assets/images/examples/progress-pride-flag.jpg"
    alt="Pride flag" />
</div>
<div class="twoValue">
  <img
    src="https://mdn.github.io/shared-assets/images/examples/progress-pride-flag.jpg"
    alt="Pride flag" />
</div>
<div class="fourValue">
  <img
    src="https://mdn.github.io/shared-assets/images/examples/progress-pride-flag.jpg"
    alt="Pride flag" />
</div>
```

```
div,
img {
  width: calc(30vw - 20px);
}
```

```
img {
  mask-image: url("https://mdn.github.io/shared-assets/images/examples/mask-star.svg");
}
.keywords img {
  mask-position: bottom right;
}
.twoValue img {
  mask-position: -20px -10px;
}
.fourValue img {
  mask-position: right -20px bottom -10px;
}
```

```
div::before {
  content: 'class="' attr(class) '"';
  display: block;
  text-align: center;
  font-family: monospace;
}
body {
  flex-flow: row wrap;
}
```

The `mask-position` defines the position of the first mask image's placement. This demo shows where the first image is placed:

```
img {
  mask-repeat: no-repeat;
}
```

Because the default value for the `mask-repeat` property is `repeat`, the images are repeated along the X and Y axes, based on the position of that first mask:

The two-value example defines the top and left offsets of the original mask. The four-value example combines the previous two previous examples, position the first mask using the same offsets as the second image, but from the same edges as demonstrated in the first image.

In the first image, the first star to be placed is the one on the bottom right, with the repeated stars above and to the left. Because of this positioning, the initial star is not clipped, but the top-most and left-most stars are.

If we don't explicitly set the `mask-position` property, it will default to `0% 0%` for each layer, with the top-left corner of the mask abutting the top-left corner of the mask origin box. Continuing with the `masked-element` example, it is as if we had set the following:

```
.masked-element {
  mask-image:
    url("alphaImage.png"), linear-gradient(to right, black, transparent),
    radial-gradient(circle, white 50%, transparent 75%), none, url("#svg-mask");
  mask-mode: match-source;
  mask-position: 0% 0%;
}
```

or, expanding on the example using the `mask` shorthand:

```
.masked-element {
  mask:
    url("alphaImage.png") 0% 0% match-source,
    linear-gradient(to right, black, transparent) 0% 0% match-source,
    radial-gradient(circle, white 50%, transparent 75%) 0% 0% match-source,
    none 0% 0% match-source,
    url("#svg-mask") 0% 0% match-source;
}
```

The <code>mask-origin</code> property

When an element has padding, a border, or both, the `mask-origin` property defines which of these box edge values acts as the mask origin box, or the *mask positioning area*, within which a mask image is positioned, for that layer. The `mask-origin` property is analogous to the `background-origin` property, but with a different initial value and SVG-only values.

HTML elements can have masks contained within their content border box, padding box, or content box. For example, if the `mask-position` is `top left`, is that relative to the border's outer edge, the padding's outer edge, or the content's outer edge?

In the `mask-position` masking example, the position defined was relative to the border-box (the default behavior), although it is worth noting that the `<img>` had no border or padding set, therefore the content-box, padding-box, and border-box origins would all be the same in this case.

```
<div class="border-box">
  <img
    src="https://mdn.github.io/shared-assets/images/examples/progress-pride-flag.jpg"
    alt="Pride flag" />
</div>
<fieldset>
```

```
  <legend>Set the <code>mask-origin</code> value</legend>
  <label
    ><input type="radio" name="origin" id="origin_border-box" checked />
    border-box</label
  >
  <label
    ><input type="radio" name="origin" id="origin_padding-box" />
    padding-box</label
  >
  <label
    ><input type="radio" name="origin" id="origin_content-box" />
    content-box</label
  >
</fieldset>
```

```
div {
  all: unset;
}
legend {
  align-self: baseline;
}
label {
  display: block;
}
```

In this example, the `mask-position` places the initial mask in the top left corner of the `<img>` element that has a large border and padding, with a green background color to enable seeing the star masking on the padding area.

```
img {
  mask-image: url("https://mdn.github.io/shared-assets/images/examples/mask-star.svg");
  mask-position: top left;
  padding: 15px;
  border: 15px solid;
  background-color: green;
}
:has(#origin_border-box:checked) img {
  mask-origin: border-box;
}
:has(#origin_padding-box:checked) img {
  mask-origin: padding-box;
}
:has(#origin_content-box:checked) img {
  mask-origin: content-box;
}
```

Change the value of the `mask-origin` property by changing the selected radio button, looking at the position of the top left star mask as you do so.

The default value is `border-box`. With this value, the initial mask is placed at the border's top-left edge and is not clipped. When the initial mask is placed at the outer or inner edge of the padding, there is room above it and to the left; these repeating masks are clipped.

Continuing with the `masked-element` example, if we don't explicitly set the `mask-origin` property, it will default to `border-box` for each layer, as if we had set the following:

```
.masked-element {
  mask-image:
    url("alphaImage.png"), linear-gradient(to right, black, transparent),
    radial-gradient(circle, white 50%, transparent 75%), none, url("#svg-mask");
  mask-mode: match-source;
  mask-position: 0% 0%;
  mask-origin: border-box;
}
```

or, expanding on the example using the `mask` shorthand:

```
.masked-element {
  mask:
    url("alphaImage.png") 0% 0% border-box match-source,
    linear-gradient(to right, black, transparent) 0% 0% border-box match-source,
    radial-gradient(circle, white 50%, transparent 75%) 0% 0% border-box
      match-source,
    none 0% 0% border-box match-source,
    url("#svg-mask") 0% 0% border-box match-source;
}
```

For SVG elements, which don't have the associated CSS layout boxes, a mask can be contained inside the SVG element's fill, stroke, or view box.

The <code>mask-clip</code> property

The `mask-clip` property determines the area of the element that will be affected by a mask, effectively clipping the element at the defined box edge. It is analogous to the `background-clip` property, but with some different values.

Because the `mask-clip` property accepts all the `mask-origin` values and both have the same `border-box` default value, the two properties may seem similar, but they serve very different purposes. While `mask-origin` determines where a mask image will be positioned, the `mask-clip` property causes the original element to have its content clipped to the specified box. It is important to understand them both: if the `mask-origin` causes the `mask-position` to place the mask image outside the clipping area, the mask will be clipped.

The `mask-clip` property accepts all the `mask-origin` values, as well as its own `no-clip` value. The `no-clip` value sets the painted content not to be clipped. You can still cause the mask image to be clipped by positioning it outside of the border content area using `mask-position` values that are less than zero or resolve to greater than 100%.

Setting the `mask-clip` and `mask-origin` to different values can cause the mask layer image to be clipped. For example, if an element with a border and padding has `mask-clip` set to `content-box` and `mask-origin` set to `border-box`, and the `mask-position` is set to the `top left` edge, the mask layer image will be clipped at the top-left edge.

The next example adds clipping options to the previous example to demonstrate the different non-SVG `mask-clip` values and to show how they impact the different `mask-origin` values.

```
<div class="border-box">
  <img
    src="https://mdn.github.io/shared-assets/images/examples/progress-pride-flag.jpg"
    alt="Pride flag" />
</div>
<fieldset>
  <legend>Set the <code>mask-clip</code> value</legend>
```

```
  <label
    ><input type="radio" name="clip" id="clip_border-box" checked />
    border-box</label
  >
  <label
    ><input type="radio" name="clip" id="clip_padding-box" /> padding-box</label
  >
  <label
    ><input type="radio" name="clip" id="clip_content-box" /> content-box</label
  >

  <label><input type="radio" name="clip" id="clip_no-clip" /> no-clip</label>
</fieldset>
<fieldset>
  <legend>Set the <code>mask-origin</code> value</legend>
  <label
    ><input type="radio" name="origin" id="origin_border-box" checked />
    border-box</label
  >
  <label
    ><input type="radio" name="origin" id="origin_padding-box" />
    padding-box</label
  >
  <label
    ><input type="radio" name="origin" id="origin_content-box" />
    content-box</label
  >
</fieldset>
```

```
:has(#clip_border-box:checked) img {
  mask-clip: border-box;
}
:has(#clip_padding-box:checked) img {
  mask-clip: padding-box;
}
:has(#clip_content-box:checked) img {
  mask-clip: content-box;
}
```

The first mask is placed at the top-left edge of the mask origin container, then repeated. If the origin box is the `border-box` and the clipping region is the `content-box`, the top and left areas of the mask origin container will be clipped. Generally, you will want the `mask-clip` to be the same as the `mask-origin`.

Continuing with the `masked-element` example, if we don't explicitly set the `mask-clip` property, it will default to `border-box` for each layer, as if we had set the following:

```
.masked-element {
  mask-image:
    url("alphaImage.png"), linear-gradient(to right, black, transparent),
    radial-gradient(circle, white 50%, transparent 75%), none, url("#svg-mask");
  mask-mode: match-source;
  mask-position: 0% 0%;
  mask-origin: border-box;
  mask-clip: border-box;
}
```

or, expanding on the example using the `mask` shorthand:

```
.masked-element {
  mask:
    url("alphaImage.png") 0% 0% border-box border-box match-source,
    linear-gradient(to right, black, transparent) 0% 0% border-box border-box
      match-source,
    radial-gradient(circle, white 50%, transparent 75%) 0% 0% border-box
      border-box match-source,
    none 0% 0% border-box border-box match-source,
    url("#svg-mask") 0% 0% border-box border-box match-source;
}
```

In the `mask` shorthand, if only one `<geometry-box>` value is given, it sets both the `mask-origin` and `mask-clip` property values. If two `<geometry-box>` values are present, the first defines the `mask-origin` and the second defines the `mask-clip`.

For mask layer images that do not reference an SVG `<mask>` element, the `mask-clip` property defines whether the mask painting area, or the area affected by the mask, is the border, padding, or content box. The painted content of the element will be restricted to this area.

When the mask layer's `mask-image` source is a `<mask>`, the `mask-clip` property has no effect. Rather, the `<mask>` element's `x`, `y`, `width`, `height`, and `maskUnits` attributes determine the mask painting area.

The <code>mask-size</code> property

The `mask-size` property is used to size mask layers. This property is analogous to the `background-size` property, taking the same values. When sizing your masks, remember that areas of the element not covered by the mask images are hidden.

There are three ways to declare a `mask-size`:

- the `cover` or `contain` keyword,
- one length, percentage, or the keyword `auto`, or
- two values that are a combination of lengths, percentages, and the keyword `auto`.

The mask image can be left to its natural size, stretched, or constrained to fit the available space. The aspect ratio of the mask image is maintained by default, but declaring two `<length-percentage>` values can distort the mask image if the ratio of the two values is not the same as the original image (`mask-repeat: round` is the other property/value pair that may distort the mask image).

If the `mask-size` is set to `contain`, the mask image will be the largest size it can be while being fully contained within the mask positioning area. In this case, the mask image is not clipped, but rather, it is fully contained.

When set to `cover`, the mask image will be the smallest size it can be to fully cover the entire mask-positioning area, with the mask being clipped if the mask's aspect ratio differs from the aspect ratio of the mask-positioning area.

In other words, With `cover` and `contain`, at least one dimension of the mask will be the same size as the mask-positioning area's same dimension; the mask image either grows or shrinks so that either the width is the same width as the mask positioning area or the mask image's height is equal to the mask positioning area's height.

With `cover`, `contain`, and `<percentage>` values, the size is relative to the origin box. In our star-mask and flag image example, the aspect ratio of both the mask image and the `<img>` are `1:1`, meaning in this case `cover`, `contain`, and `100%` will all produce the same sized mask. This example demonstrates how, when `mask-size` is set to `cover`, `contain` or a `<percentage>` value, the actual size of the mask may differ depending on the value of the `mask-origin` property:

```
<div class="border-box">
  <img
    src="https://mdn.github.io/shared-assets/images/examples/progress-pride-flag.jpg"
    alt="Pride flag" />
</div>
<fieldset>
  <legend>Set the <code>mask-origin</code> value</legend>
  <label
    ><input type="radio" name="origin" id="border-box" checked />
    border-box</label
  >
  <label
    ><input type="radio" name="origin" id="padding-box" /> padding-box</label
  >
  <label
    ><input type="radio" name="origin" id="content-box" /> content-box</label
  >
</fieldset>
```

```
img {
  mask-image: url("https://mdn.github.io/shared-assets/images/examples/mask-star.svg");
  mask-position: top left;
  padding: 15px;
  border: 15px solid;
  background-color: green;
}
```

```
img {
  mask-size: 100%;
}
:has(#border-box:checked) img {
  mask-origin: border-box;
}
:has(#padding-box:checked) img {
  mask-origin: padding-box;
}
:has(#content-box:checked) img {
  mask-origin: content-box;
}
```

Change the value of the `mask-origin` property to see how the different values impact the mask size:

This example included one `<percentage>` value. When one `<length-percentage>` value is specified, it defines only the mask width, with the height defaulting to `auto`, which maintains the aspect ratio. When two values are specified, the first defines the mask width and the second defines its height.

The default value of `mask-size` is `auto`, rendering the mask at its intrinsic size, the size at which the mask would be displayed if no CSS were applied. The underlying aspect ratio of the mask image is maintained if you set a single `<length-percentage>` value, or two values in the same ratio as the aspect ratio. If you declare two values not in the same ratio as the aspect ratio, the mask image is distorted.

Like with all longhand components of shorthand property, if the `mask` shorthand property is set and the value of the `mask-size` property is not defined within any mask layer, the `mask-size` value is reset to its initial value of `auto` for those mask layers.

If the image has no intrinsic proportion, for example in the case of a CSS gradient, the default `auto` is the entirety of the mask positioning area as set by the `mask-origin` property.

Continuing with the `masked-element` example, if we don't explicitly set the `mask-size` property, it will default to `auto` for each layer, as if we had set the following:

```
.masked-element {
  mask-image:
    url("alphaImage.png"), linear-gradient(to right, black, transparent),
    radial-gradient(circle, white 50%, transparent 75%), none, url("#svg-mask");
  mask-mode: match-source;
  mask-position: 0% 0%;
  mask-origin: border-box;
  mask-clip: border-box;
  mask-size: auto;
}
```

or, expanding on the example using the `mask` shorthand, with the `mask-size` component going after the `mask-position` value, separated by a forward slash (/):

```
.masked-element {
  mask:
    url("alphaImage.png") 0% 0% / auto border-box border-box match-source,
    linear-gradient(to right, black, transparent) 0% 0% / auto border-box
      border-box match-source,
    radial-gradient(circle, white 50%, transparent 75%) 0% 0% / auto border-box
      border-box match-source,
    none 0% 0% / auto border-box border-box match-source,
    url("#svg-mask") 0% 0% / auto border-box border-box match-source;
}
```

The <code>mask-repeat</code> property

The `mask-repeat` property defines how mask images are repeated, or tiled, after the initial mask image has been sized and positioned. The `mask-repeat` property defines if and how that mask image is repeated along the horizontal and vertical axes. In most of the previous examples, you may have noticed the star mask repeated along the X and Y axes. This is because `repeat` is the default value.

The `mask-repeat` property is analogous to the `background-repeat` property, accepting the same `<repeat-style>` values. As is the case with `background-repeat`, the first (and possibly only) mask-image repetition is positioned by the `*-position` property and sized by the `*-size` property. The positions of the repeated background or mask images are based on this initial image instance.

Continuing with the `masked-element` example, if we don't explicitly set the `mask-repeat` property, it will default to `repeat` for each layer, as if we had set the following:

```
.masked-element {
  mask-image:
    url("alphaImage.png"), linear-gradient(to right, black, transparent),
    radial-gradient(circle, white 50%, transparent 75%), none, url("#svg-mask");
  mask-mode: match-source;
```

```
  mask-position: 0% 0%;
  mask-origin: border-box;
  mask-clip: border-box;
  mask-size: auto;
  mask-repeat: repeat;
}
```

or, expanding on the example using the `mask` shorthand:

```
.masked-element {
  mask:
    url("alphaImage.png") 0% 0% / auto repeat border-box border-box match-source,
    linear-gradient(to right, black, transparent) 0% 0% / auto repeat border-box
      border-box match-source,
    radial-gradient(circle, white 50%, transparent 75%) 0% 0% / auto repeat
      border-box border-box match-source,
    none 0% 0% / auto repeat border-box border-box match-source,
    url("#svg-mask") 0% 0% / auto repeat border-box border-box match-source;
}
```

The <code>mask-composite</code> property

The `mask` shorthand includes the `mask-composite` property, which defines how multiple masks are combined to create the final mask effect. Each value in the comma-separated list of values determines whether the browser should `add`, `subtract`, `intersect`, or `exclude` the associated mask layer from or to the mask layers below it. Similar to `mask-mode`, and the other `mask-*` properties, there is no property in the `background` shorthand that is analogous.

```
<div class="add">
  <img
    src="https://mdn.github.io/shared-assets/images/examples/progress-pride-flag.jpg"
    alt="Pride flag" />
</div>
<div class="subtract">
  <img
    src="https://mdn.github.io/shared-assets/images/examples/progress-pride-flag.jpg"
    alt="Pride flag" />
</div>
<div class="intersect">
  <img
    src="https://mdn.github.io/shared-assets/images/examples/progress-pride-flag.jpg"
    alt="Pride flag" />
</div>
<div class="exclude">
  <img
    src="https://mdn.github.io/shared-assets/images/examples/progress-pride-flag.jpg"
    alt="Pride flag" />
</div>
```

In this example, we include two `mask-image` values, including the star and the gradient from the previous examples as mask images:

```
img {
  mask-image:
    repeating-linear-gradient(
      to bottom right,
      red 0 20px,
      #ff000055 20px 40px,
      transparent 40px 60px
    ),
    url("https://mdn.github.io/shared-assets/images/examples/mask-star.svg");
}
```

We set a different `mask-composite` value for each image:

```
.add img {
  mask-composite: add;
}
.subtract img {
  mask-composite: subtract;
}
.intersect img {
  mask-composite: intersect;
}
.exclude img {
  mask-composite: exclude;
}
```

```
div::before {
  content: "mask-composite: " attr(class);
  display: block;
  text-align: center;
  font-family: monospace;
}
body {
  flex-flow: row wrap;
}
```

The semi-transparent star mask is added to, subtracted from, intersected with, or excluded from the striped mask, depending on the `mask-composite` value.

The `mask-composite` property is only relevant in cases with two or more mask layers. This reads "mask layers", not "mask images" because, if `none` is included, the transparent black mask is composited. A `none` value can have a profound effect on masking in the case of `subtract` and `intersect`. For example, if the `mask-mode` resolves to `luminance`, subtracting a black mask will remove the entire mask (the element will be hidden). Similarly, if `none` is the last layer with `mask-composite: intersect` set for that layer, the entire element will be hidden. Here, we add a third layer, with `none`, to the previous example:

```
img {
  mask-image:
    url("https://mdn.github.io/shared-assets/images/examples/mask-star.svg"),
    repeating-linear-gradient(
      to bottom right,
      red 0 20px,
      #ff000055 20px 40px,
```

```
      transparent 40px 60px
    ),
    none;
}
```

Note how the `intersect` example excludes everything because the transparent black mask doesn't intersect anything.

If we reverse the order of the mask layers, we can also get very different results:

```
<div class="subtract">
  <img
    class="gradientFirst"
    src="https://mdn.github.io/shared-assets/images/examples/progress-pride-flag.jpg"
    alt="Pride flag" />
</div>
<div class="subtract">
  <img
    class="starFirst"
    src="https://mdn.github.io/shared-assets/images/examples/progress-pride-flag.jpg"
    alt="Pride flag" />
</div>
```

```
.gradientFirst {
  mask-image:
    repeating-linear-gradient(
      to bottom right,
      red 0 20px,
      #ff000055 20px 40px,
      transparent 40px 60px
    ),
    url("https://mdn.github.io/shared-assets/images/examples/mask-star.svg");
}
.starFirst {
  mask-image:
    url("https://mdn.github.io/shared-assets/images/examples/mask-star.svg"),
    repeating-linear-gradient(
      to bottom right,
      red 0 20px,
      #ff000055 20px 40px,
      transparent 40px 60px
    );
}
```

In the first example, the stars are subtracted from the stripes. In the second, the stripes are subtracted from the stars.

Like all the other `mask` component properties, `mask-composite` takes a comma-separated list of values. Because the property effects how masks are combined, this property is only relevant for multiple mask layers and the number of used values is one less than the number of mask layers.

The last pair of masks is composited first. The previous mask image is then composited with the previous composition.

Continuing with the `masked-element` example, if we don't explicitly set the `mask-composite` property, it will default to `add` for each layer, as if we had set the following:

```
.masked-element {
  mask-image:
    url("alphaImage.png"), linear-gradient(to right, black, transparent),
    radial-gradient(circle, white 50%, transparent 75%), none, url("#svg-mask");
  mask-mode: match-source;
  mask-position: 0% 0%;
  mask-origin: border-box;
  mask-clip: border-box;
  mask-size: auto;
  mask-repeat: repeat;
  mask-composite: add;
}
```

In this case, the `<mask>` element will be composited with the `none` layer. Then the radial gradient will be composited with the result of the previous composition, and so on.

Like we saw with all the other component properties, we could have used the `mask` shorthand:

```
.masked-element {
  mask:
    url("alphaImage.png") 0% 0% / auto repeat border-box border-box add
      match-source,
    linear-gradient(to right, black, transparent) 0% 0% / auto repeat border-box
      border-box add match-source,
    radial-gradient(circle, white 50%, transparent 75%) 0% 0% / auto repeat
      border-box border-box add match-source,
    none 0% 0% / auto repeat border-box border-box add match-source,
    url("#svg-mask") 0% 0% / auto repeat border-box border-box add match-source;
}
```

Declaring multiple masks

CSS masking is a technique that enables you to use images as masks to define which sections of an element are fully visible or semi-opaque. The CSS mask selectively reveals or hides parts of the element based on the alpha channel and in some cases the brightness of the colors of the applied mask images.

CSS masks are the opposite of masks worn at masquerade (masked) balls. At a masked ball, a wearer's face is hidden wherever the mask is opaque and visible wherever you can see through the mask. In CSS, the areas where the composited mask layers are fully opaque reveal the element, while transparent areas hide it.

CSS masks are made up of one or more mask layers. In this guide, we discuss the concept of mask layers and how to declare multiple mask layers using the `mask` shorthand property.

Understanding mask layers

You can apply CSS masking to all HTML elements and most SVG elements. A mask can consist of one or more composited mask layers. You define multiple layers using comma-separated values in the `mask` shorthand property or the `mask-image` property–even a value set to `none` counts as a layer.

Each mask layer can contain a mask image, which is positioned relative to the mask's origin box. The image can be sized, repeated, and clipped. If you include more than one mask image, you can define the way the mask layers are composited or combined. (These features are briefly introduced in this guide. For more details and examples, see the masking properties guide.)

Syntax for multiple mask layers

The `mask` shorthand property accepts a comma-separated list of mask layers. The syntax for each layer can include the following values:

```
<image> <position> / <size> <repeat> <origin> <clip> <composite> <mode>
```

All the components in a mask layer are optional. However, if you omit the `mask-image` value, it defaults to a transparent black image, which hides the element in that layer completely.

The `mask` shorthand declaration sets values for all the `mask-*` properties. Any component not declared within a layer will default to its initial value. The `mask` property also resets all the `mask-border-*` properties to their initial values. A `mask` declaration that only includes a `mask-image` value implicitly sets the following:

```
mask-mode: match-source;
mask-position: 0% 0%;
mask-size: auto;
mask-repeat: repeat;
mask-origin: border-box;
mask-clip: border-box;
mask-composite: add;

mask-border-source: none;
mask-border-mode: alpha;
mask-border-outset: 0;
mask-border-repeat: stretch;
mask-border-slice: 0;
mask-border-width: auto;
```

Defining mask layers with <code>mask-image</code>

As long as a comma-separated `mask-image` property declaration includes at least one value other than `none`, a mask layer is created for every value in the declaration, even for the `none` values. This behavior applies whether you're using the `mask-image` property or the `mask` shorthand. These mask images can be gradients, images, or SVG sources. You can define them using a CSS gradient, a raster image (such as PNGs), or an SVG `<mask>` element.

```
.gradient-mask {
  mask-image: linear-gradient(to right, black, transparent);
}

.raster-mask {
  mask-image: url("alphaImage.png");
}

.mask-element-mask {
  mask-image: url("#svg-mask");
}
```

The introductory guide to masking introduces the different types of mask images and their modes.

The `mask-image` property is analogous to the `background-image` property. Just as with the `background-image` property, to include multiple mask images, the image values are separated by commas.

```
.multiple-gradient-mask {
  mask-image:
    linear-gradient(to right, black, transparent),
    radial-gradient(circle, white 50%, transparent 75%);
}
```

Each mask image in a multiple-image declaration creates a mask layer. All the examples in this section create one mask layer, except the `multiple-gradient-mask` declaration, which creates two.

Mask layers and the <code>none</code> keyword

If `none` is the only value of the `mask-image` property, no mask layers are created and no masking occurs.

```
.no-masks {
  mask-image: none;
}
```

Similarly, when using the `mask` shorthand, if no `mask-image` value is present other than `none`, no masking occurs. If any of the following are declared, no mask layers are created and nothing is hidden:

```
mask: none;
mask: none 100px 100px no-repeat;
mask: 100px 100px no-repeat;
```

Otherwise, as long as there is a `mask-image` declared that isn't set to `none`, a mask layer is created for every value in the comma-separated list of values, even when the `mask-image` value is omitted from a value in the comma-separated list or is explicitly set to `none`. In other words, a layer is created for each valid comma-separated value, unless the entire property resolves to `none`.

```
.masked-element {
  mask-image:
    url("alphaImage.png"), linear-gradient(to right, black, transparent),
    radial-gradient(circle, white 50%, transparent 75%), none, url("#svg-mask");
}
```

The keyword `none` within a list of mask sources creates a mask layer, albeit a transparent black image layer. Any elements with the class `masked-element` will have five mask layers:

We can also create the layers using the `mask` shorthand:

```
.masked-element {
  mask:
    url("alphaImage.png"), linear-gradient(to right, black, transparent),
    radial-gradient(circle, white 50%, transparent 75%), none, url("#svg-mask");
}
```

If a value in the comma-separated list of values is an empty image, fails to download, references a `<mask>` element that doesn't exist, or otherwise cannot be displayed (or is set to `none`), it still counts as a mask image layer, rendering a transparent black mask image that has no visual effect. If all of the values do this, the element will be fully hidden.

No masking occurs if the entire property resolves to `none`, which makes the element fully visible. On the other hand, if the value includes multiple layers and at least one is not `none`, the `none` layers don't reveal any part of the element (or don't make any part of the element visible). In this example, the value doesn't resolve to `none`; but because all non-`none` images are invalid, masking occurs, and the element will be fully hidden.

A computed value other than `none` creates a CSS stacking context.

How mask layers affect <code>mask-*</code> properties

The number of mask layers matters when you're also using individual `mask-*` properties after or with more specificity than a `mask` declaration.

The `mask-*` properties include:

- `mask-mode`: Sets the mode of each mask layer to either `alpha` or `luminance`, or allows it to default to the source's mode by setting the value to `match-source`. The default is `match-source`.
- `mask-position`: Analogous to the `background-position` property with syntax that follows the `background-position`'s `<position>` syntax, it sets the initial position of the mask image relative to the mask layer's origin box, defined by the `mask-origin` property. You can specify one, two, or four `<position>` values. The default `0% 0%` positions the top-left corner of the mask at the top-left corner of the mask origin box.
- `mask-origin`: Analogous to the `background-origin` property, it specifies the *mask positioning area*, which is the mask origin box area within which a mask image is positioned. For example, if the `mask-position` is `top left`, this property defines whether that is relative to the border's outer edge, the padding's outer edge, or the content's outer edge.
- `mask-clip`: Analogous to the `background-clip` property, it determines the area of the element affected by a mask. It defines whether the mask painting area is the border, padding, or content box, restricting the painted content of the element to this area. If the mask layer's `mask-image` source is an SVG `<mask>` element, the `mask-clip` property has no effect.
- `mask-size`: Analogous to the `background-size` property, this is used to size the mask layer. Values can be a single keyword (`cover`, `contain`, or `auto`), a single length or percentage, or two space-separated values–each of which may be a length, percentage, or `auto`. The default is `auto`.
- `mask-repeat`: Analogous to the `background-repeat` property, this defines how the mask layer image is tiled after it has been sized and positioned.
- `mask-composite`: Defines how a mask is combined with the mask layers below it. Each mask layer is either added to, subtracted from, included with, or excluded from the previously composited mask layers below it. Similar to `mask-mode`, there is no analogous `background-*` property.

Each `mask-*` value in a comma-separated list of `mask` component properties applies to a separate mask layer. As stated earlier, an element can have multiple mask layers applied — the number of layers is determined by the number of comma-separated values in the `mask-image` or `mask` properties. Each `mask-*` value is matched with a mask layer, in order. If the number of values in the `mask-*` property is greater than the number of mask layers, any excess values are ignored. If the mask component property has fewer values than the number of mask layers, the `mask-*` values are repeated.

To learn more about these individual properties, see CSS mask properties.

Order of shorthand component properties

For the most part, the order of the properties is flexible, but there are a few quirks and exceptions.

Ordering rules for <code>mask-origin</code> and <code>mask-clip</code>

The `mask-origin` value, listed in the syntax as `<origin>`, comes before the `mask-clip` values, listed in the syntax as `<clip>`.

```
<image> <position> / <size> <repeat> <origin> <clip> <composite> <mode>
```

Both accept `<geometry-box>` keywords. In addition, `mask-clip` also accepts `no-clip`. Because of this, the order of these two matters when you want to set `mask-clip` to any value other than `no-clip`.

- If one `<geometry-box>` value is present along with the `no-clip` keyword, then the `<geometry-box>` sets the `mask-origin` value, and `mask-clip` is set to `no-clip`. In this case, the order doesn't matter.
- If only one `<geometry-box>` value is present and there is no `no-clip` keyword, both the `mask-origin` and `mask-clip` components are set to that value. As there is only one value, again the ordering doesn't matter.
- If two `<geometry-box>` values are present, the first sets the `mask-origin` component and the second sets the `mask-clip` component. In this case, the order is very important.

Setting the incorrect order for the `mask-origin` and `mask-clip` values may affect the appearance, but will not cause the declaration to fail.

Ordering rules for <code>mask-size</code> and <code>mask-position</code>

You may have noticed a slash between `mask-position` and `mask-size`, listed in the syntax as `<position>` and `<size>`. Both properties accept similar values.

```
<image> <position> / <size> <repeat> <origin> <clip> <composite> <mode>
```

In this case, the order is very important. If only one or a pair of `<length-percentage>` values are present, it will define the position of the image rather than the size. Including both a position and a size in a mask layer without including the slash between the two will invalidate the entire declaration.

```
mask:
  url("star.svg") bottom 2em right 4em / auto 2vw no-repeat padding-box
    content-box luminance,
  url("circle.svg") 100px 100px / 50% repeat-x border-box padding-box alpha;
```

If a single pair of `<length-percentage>` values is present, it sets the `mask-position` property, and the `mask-size` will be `auto`. If a layer includes both a `mask-size` and a `mask-position`, the `mask-size` property value must come after the `mask-position` property value and the values must be separated by a forward slash (`/`). The slash is required even if the `mask-size` is set to a value that is not a valid `mask-position` value.

```
mask: url("star.svg") contain;
mask: url("star.svg") 10px 10px cover;
mask: url("star.svg") top right 100px 100px;
```

```
mask: url("star.svg") 10px 10px / cover;
mask: url("star.svg") top 100px right 100px;
mask: url("star.svg") top right / 100px 100px;
```

To include a `mask-size` in a mask layer using the `mask` shorthand, you must include a `mask-position` value with a slash immediately before it.

> **Warning:** If you include a size in a mask layer but forget the slash after the position, the entire declaration will become invalid.

CSS media queries

The **CSS media queries** module enables testing and querying of viewport values and browser or device features, to conditionally apply CSS styles based on the current user environment. Media queries are used in the CSS `@media` rule and other contexts and languages such as HTML and JavaScript.

Media queries are a key component of responsive design. They enable conditional setting of CSS styles depending on the presence or value of device characteristics. It's common to use a media query based on viewport size to set appropriate layouts on devices with different screen sizes — for example three columns on a wide screen or a single column on a narrow screen.

Other common examples include increasing the font size and hiding navigation menus when printing a page, adjusting the padding between paragraphs when a page is viewed in portrait or landscape mode, or increasing the size of buttons to provide a larger hit area on touchscreens.

In CSS, use the `@media` at-rule to conditionally apply part of a style sheet based on the result of a media query. To conditionally apply an entire style sheet, use `@import`.

When designing reusable HTML components, you may also use container queries, which allow you to apply styles based on the size of a containing element rather than the viewport or other device characteristics.

Printing

There may be times in which your website or application would like to improve the user's experience when printing content. There are several possible scenarios:

- You wish to adjust layout to take advantage of the size and shape of the paper.
- You wish to use different styles to enhance the appearance of your content on paper.
- You wish to use higher resolution images for a better result.
- You want to adjust the user experience of printing, such as presenting a specially-formatted version of your content before printing begins.

There may be other cases in which you want to manage the printing process, but these are some of the most common scenarios. This article provides tips and techniques for helping your web content print better.

Using a print style sheet

Add the following to your `<head>` tag.

```
<link href="/path/to/print.css" media="print" rel="stylesheet" />
```

Using media queries and @page to control printed content

You can use the CSS `@media` at-rule to set different styles for your webpage when it is printed on paper or as a PDF versus when it is displayed on the screen. The `print` media type sets the styles for printed media; these styles will only be used for printed content.

Add this at the end of your stylesheet. Note that specificity and precedence rules still apply:

```
@media print {
  /* All your print styles go here */
  #header,
  #footer,
  #nav {
    display: none !important;
  }
}
```

You can also use the `@page` at-rule to modify different aspects of printed pages including the page's dimensions, orientation, and margins. The `@page` at-rule can be used to target all pages in a print-out or just a specific subset of pages

Detecting print requests

Browsers send `beforeprint` and `afterprint` events to determine when printing may have occurred. You can use this to adjust the user interface presented during printing (for example displaying or hiding user interface elements during the print process).

Examples

Here are some common examples.

Automatically close the window when finished

The following example will close the window after the user has printed its contents:

```
window.addEventListener("afterprint", () => self.close);
```

Print an external page without opening it

If you want to be able to print an external page without opening it, you can utilize a hidden `<iframe>` (see: HTMLIFrameElement), automatically removing it after the user prints its contents. The following is a possible example which will print a file named `externalPage.html`:

HTML

```
<button id="print_external">Print external page!</button>
```

JavaScript

```
function setPrint() {
  const closePrint = () => {
    document.body.removeChild(this);
  };
  this.contentWindow.onbeforeunload = closePrint;
  this.contentWindow.onafterprint = closePrint;
  this.contentWindow.print();
}

document.getElementById("print_external").addEventListener("click", () => {
  const hideFrame = document.createElement("iframe");
  hideFrame.onload = setPrint;
  hideFrame.style.display = "none"; // hide iframe
  hideFrame.src = "external-page.html";
  document.body.appendChild(hideFrame);
});
```

Testing media queries programmatically

The DOM provides features that can test the results of a media query programmatically, via the `MediaQueryList` interface and its methods and properties. Once you've created a `MediaQueryList` object, you can check the result of the query or receive notifications when the result changes.

Creating a media query list

Before you can evaluate the results of a media query, you need to create the `MediaQueryList` object representing the query. To do this, use the `window.matchMedia` method.

For example, to set up a query list that determines if the device is in landscape or portrait orientation:

```
const mediaQueryList = window.matchMedia("(orientation: portrait)");
```

Checking the result of a query

Once you've created your media query list, you can check the result of the query by looking at the value of its `matches` property:

```
if (mediaQueryList.matches) {
  /* The viewport is currently in portrait orientation */
} else {
  /* The viewport is not currently in portrait orientation, therefore landscape */
}
```

Receiving query notifications

If you need to be aware of changes to the evaluated result of the query on an ongoing basis, it's more efficient to register a listener than to poll the query's result. To do this, call the `addEventListener()` method on the `MediaQueryList` object, with a callback function to invoke when the media query status changes (e.g., the media query test goes from `true` to `false`):

```
// Create the query list.
const mediaQueryList = window.matchMedia("(orientation: portrait)");

// Define a callback function for the event listener.
function handleOrientationChange(mql) {
  // …
}

// Run the orientation change handler once.
handleOrientationChange(mediaQueryList);

// Add the callback function as a listener to the query list.
mediaQueryList.addEventListener("change", handleOrientationChange);
```

This code creates the orientation-testing media query list and adds an event listener to it. After defining the listener, we also call the listener directly. This makes our listener perform adjustments based on the current device orientation; otherwise, our code might assume the device is in portrait mode at startup, even if it's actually in landscape mode.

The `handleOrientationChange()` function would look at the result of the query and handle whatever we need to do on an orientation change:

```
function handleOrientationChange(evt) {
  if (evt.matches) {
    /* The viewport is currently in portrait orientation */
  } else {
    /* The viewport is currently in landscape orientation */
  }
}
```

Above, we define the parameter as `evt` — an event object of type `MediaQueryListEvent` that also includes the `media` and `matches` properties, so you can query these features of the `MediaQueryList` by directly accessing it, or accessing the event object.

Ending query notifications

To stop receiving notifications about changes to the value of your media query, call `removeEventListener()` on the `MediaQueryList`, passing it the name of the previously-defined callback function:

```
mediaQueryList.removeEventListener("change", handleOrientationChange);
```

Using media queries

Media queries allow you to apply CSS styles depending on a device's media type (such as print vs. screen) or other features or characteristics such as screen resolution or orientation, aspect ratio, browser viewport width or height, user preferences such as preferring reduced motion, data usage, or transparency.

Media queries are used for the following:

- To conditionally apply styles with the CSS `@media`, `@custom-media` and `@import` at-rules.
- To target specific media for the `<style>`, `<link>`, `<source>`, and other HTML elements with the `media=` or `sizes=` attributes.
- To test and monitor media states using the `Window.matchMedia()` and `EventTarget.addEventListener()` methods.

> **Note:** The examples on this page use CSS's `@media` for illustrative purposes, but the basic syntax remains the same for all types of media queries.

Syntax

A media query is composed of an optional *media type* and any number of *media feature* expressions, which may optionally be combined in various ways using *logical operators*. Media queries are case-insensitive.

- Media types define the broad category of device for which the media query applies: `all`, `print`, `screen`.

  The type is optional (assumed to be `all`) except when using the `only` logical operator.

- Media features describe a specific characteristic of the user agent, output device, or environment:

  - `any-hover`
  - `any-pointer`
  - `aspect-ratio`
  - `color`
  - `color-gamut`
  - `color-index`
  - `device-aspect-ratio`
  - `device-height`
  - `device-posture`
  - `device-width`
  - `display-mode`
  - `dynamic-range`
  - `forced-colors`
  - `grid`
  - `height`
  - `hover`
  - `inverted-colors`
  - `monochrome`
  - `orientation`
  - `overflow-block`
  - `overflow-inline`
  - `pointer`
  - `prefers-color-scheme`
  - `prefers-contrast`
  - `prefers-reduced-motion`
  - `prefers-reduced-transparency`
  - `resolution`
  - `scripting`
  - `update`
  - `video-dynamic-range`
  - `width`

  For example, the `hover` feature allows a query to check whether the device supports hovering over elements. Media feature expressions test for their presence or value, and are entirely optional. Each media feature expression must be surrounded by parentheses.

- Logical operators can be used to compose a complex media query: `not`, `and`, and `only`. You can also combine multiple media queries into a single rule by separating them with commas.

A media query computes to `true` when the media type (if specified) matches the device on which a document is being displayed *and* all media feature expressions compute as true. Queries involving unknown media types are always false.

> **Note:** A style sheet with a media query attached to its `<link>` tag will still download even if the query returns `false`, the download will happen but the priority of downloading will be much lower. Nevertheless, its contents will not apply unless and until the result of the query changes to `true`. You can read why this happens in Tomayac's blog Why Browsers Download Stylesheets With Non-Matching Media Queries.

Targeting media types

Media types describe the general category of a given device. Although websites are commonly designed with screens in mind, you may want to create styles that target special devices such as printers or audio-based screen readers. For example, this CSS targets printers:

```
@media print {
  /* … */
}
```

You can also target multiple devices. For instance, this `@media` rule uses two media queries to target both screen and print devices:

```
@media screen, print {
  /* … */
}
```

See media types for the list of available media types. Because media types describe devices in very broad terms, most of the originally-defined media types were deprecated, with just `screen`, `print`, and `all` remaining. To target more specific attributes, use *media features* instead.

Targeting media features

Media features describe the specific characteristics of a given user agent, output device, or environment. For instance, you can apply specific styles to widescreen monitors, computers that use mice, or devices that are being used in low-light conditions. This example applies styles when the user's *primary* input mechanism (such as a mouse) can hover over elements:

```
@media (hover: hover) {
  /* … */
}
```

Media features are either range or discrete.

Discrete features take their value from an enumerated set of possible keyword values. For example, the discrete `orientation` feature accepts either `landscape` or `portrait`.

```
@media print and (orientation: portrait) {
  /* … */
}
```

Many *range features* can be prefixed with "min-" or "max-" to express "minimum condition" or "maximum condition" constraints. For example, this CSS will apply styles only if your browser's viewport width is equal to or narrower than 1250px:

```
@media (max-width: 1250px) {
  /* … */
}
```

The following media queries are equivalent to the above example:

```
@media (width <= 1250px) {
  /* … */
}

@media (1250px >= width) {
  /* … */
}
```

With media query range features, you can either use the inclusive `min-` and `max-` prefixes or the more concise range syntax operators `<=` and `>=`.

The following media queries are equivalent:

```
@media (min-width: 30em) and (max-width: 50em) {
  /* … */
}

@media (30em <= width <= 50em) {
  /* … */
}

@media (50em >= width >= 30em) {
  /* … */
}
```

The range comparisons above are inclusive. To exclude the comparison value, use `<` and/or `>`.

```
@media (30em < width < 50em) {
  /* … */
}

@media (50em > width > 30em) {
  /* … */
}
```

If you create a media feature query without specifying a value, the nested styles will be used as long as the feature's value is not `0` or `none`. For example, this CSS will apply to any device with a color screen:

```
@media (color) {
  /* … */
}
```

If a feature doesn't apply to the device on which the browser is running, expressions involving that media feature are always false.

For more Media feature examples, please see the reference page for each specific feature.

Creating complex media queries

Sometimes you may want to create a media query that depends on multiple conditions. This is where the *logical operators* come in: `not`, `and`, and `only`. Furthermore, you can combine multiple media queries into a comma-separated list; this allows you to apply the same styles in different situations, with the contained media queries evaluated as a logical `or` composition: interpreted as if each media query were within parentheses with an `or` between them.

In the previous example, we saw the `and` operator used to group a media *type* with a media *feature*. The `and` operator can also combine multiple media features within a single media query. The `not` operator negates a media query, or a media feature when used with brackets, basically reversing their normal meanings. The `or` operator can, under certain conditions, be used to combine multiple media features within a single media query. Lastly, the `only` operator was used to prevent older browsers from applying the styles without evaluating the media feature expressions but it has no effect in modern browsers.

> **Note:** In most cases, the `all` media type is used by default when no other type is specified. However, if you use the `only` operator, you must explicitly specify a media type. You can see `only screen` or `only print` as a whole.

Combining multiple types or features

The `and` keyword combines a media feature with a media type *or* other media features. This example combines two media features to restrict styles to landscape-oriented devices with a width of at least 30 ems:

```
@media (width >= 30em) and (orientation: landscape) {
  /* … */
}
```

To limit the styles to devices with a screen, you can chain the media features to the `screen` media type:

```
@media screen and (width >= 30em) and (orientation: landscape) {
  /* … */
}
```

Testing for multiple queries

You can use a comma-separated list of media queries to apply styles when the user's device matches any one of various media types, features, or states.

The following rule contains two media queries. The block's styles will apply if either the user's device has a height of 680px or more *or* if the browser viewport is in portrait mode (the viewport height is greater than the viewport width):

```
@media (height >= 680px), screen and (orientation: portrait) {
  /* … */
}
```

In this example, if the user is printing to a PDF and the page height is 800px, the media query returns true because the first query component — which tests whether the viewport has a height of `680px` or more — is true. Likewise, if a user is on a smartphone in portrait mode with a viewport height of 480px, the media query returns true because the second query component is true.

In a comma-separated list of media queries, the individual media queries end at the comma or, in the case of the last media query in the list, at the opening bracket ({).

Inverting a query's meaning

The `not` keyword inverts the meaning of a single media query. For example, the CSS styles in this media query will apply to everything *except* printed media:

```
@media not print {
  /* … */
}
```

The `not` negates only the media query it is applied to. The `not`, without parenthesis, negates all the features within the media query in which it is contained. This means, in a comma-separated list of media queries, each `not` applies to the single query it is contained within, applying to *all* the features within that single query. In this example, the `not` applies to the first media query `screen and (color)`, which concludes at the first comma:

```
@media not screen and (color), print and (color) {
  /* … */
}
```

Because the query starts with a media type `screen`, you *cannot* wrap `screen and (color)` with parentheses. On the other hand, if your media query consists of features only, then you *must* parenthesize the query:

```
@media not ((width > 1000px) and (color)), print and (color) {
  /* … */
}
```

Parentheses limit the components of the query that get negated. For example, to negate the `(width > 1000px)` query only:

```
@media (not (width > 1000px)) and (color), print and (color) {
  /* … */
}
```

`not` only negates the query to its right. In this example, we negate the `hover` media feature but not the `screen` media type:

```
@media screen and not (hover) {
  /* … */
}
```

The `not (hover)` matches if the device has no hover capability. In this case, because of its ordering, the `not` applies to `hover` but not to `screen`.

Improving compatibility with older browsers

The `only` keyword prevents older browsers that do not support media queries with media features from applying the given styles. *It has no effect on modern browsers.*

```
@media only screen and (color) {
  /* … */
}
```

Testing for multiple features with <code>or</code>

You can use `or` to test for a match among more than one feature, resolving to `true` if any of the features are true. For example, the following query tests for devices that have a monochrome display or hover capability:

```
@media (not (color)) or (hover) {
  /* … */
}
```

Note that you cannot use the `or` operator on the same level as the `and` and `not` operators. You can either separate the media features with a comma or use parenthesis to group sub-expressions of media features to clarify the order of evaluation.

For example, the following queries are both valid:

```
@media ((color) and (hover)) or (monochrome) {
  /* … */
}

/* or */
@media (color) and (hover), (monochrome) {
  /* … */
}
```

Using media queries for accessibility

CSS media queries can be used to help users with disabilities better experience your website.

Reduced Motion

Blinking and flashing animation can be problematic for people with cognitive concerns such as Attention Deficit Hyperactivity Disorder (ADHD). Additionally, certain kinds of motion can be a trigger for Vestibular disorders, epilepsy, and migraine and Scotopic sensitivity. Reducing animations or switching animation off completely based on the user's preference can also benefit users with low battery or low-end devices.

The `prefers-reduced-motion` media query enables providing an experience with fewer animations and transitions to users who have set their operating system's accessibility preferences to reduce motion. It has two possible values:

`no-preference`

Indicates that the user has made no preference known to the system.

`reduce`

Indicates that user has notified the system that they prefer an interface that minimizes the amount of movement or animation, preferably to the point where all non-essential movement is removed.

Example

This example has an annoying animation unless you turn on Reduce Motion in your accessibility preferences.

HTML

```
<div class="animation">animated box</div>
```

CSS

```
.animation {
  animation: vibrate 0.3s linear infinite both;
}

@media (prefers-reduced-motion: reduce) {
  .animation {
    animation: none;
  }
}
```

The value of `prefers-reduced-motion` is `reduce`, not "none". This preference does not mean all animations must be removed, which could be achieved with `* {animation: none !important;}`. Rather, users expect motion animation, including those triggered by user interaction, to be disabled unless the animation is essential to the functionality or the information being conveyed (see WCAG: Animation from Interactions).

CSS motion path

The **CSS motion path** module allows authors to animate any graphical object along a custom path.

The CSS transforms module provides features that enable boxes to be repositioned, rotated, scaled, and skewed relative to its laid out position, without disrupting the layout of any other elements on the page. These transforms can be animated and transitioned, but only in relatively basic ways.

The features of the CSS motion path module provide offset transforms: transforms that align a point on an element to an offset distance along an offset path, optionally rotating the transformed element to follow the path direction. This module enables powerful transform possibilities, for example:

- Positioning using polar coordinates rather than limiting transformation to the standard rectangular `transform` coordinates.
- Animating an element along a defined path.

CSS motion paths allow the definition of complex 2D spatial transitions by leveraging CSS shape functions.

For example, you can define a specific path of any shape you want with the `offset-path` property. You can then animate an element to move along that path by animating the `offset-distance` property, and rotate it at any point with the `offset-rotate` property.

Motion paths in action

```
<div id="heart">
  <div id="motion-demo"></div>
</div>
```

```
#motion-demo {
  offset-path: path(
    "M20,70 A40,40,0,0,1,100,70 A40,40,0,0,1,180,70 Q180,130,100,190 Q20,130,20,70 Z"
  );
  animation: move 3000ms infinite linear;
```

```
  width: 10px;
  height: 10px;
  background: red;
}

#heart {
  width: 200px;
  height: 200px;
  background-color: lightpink;
  clip-path: path(
    "M20,70 A40,40,0,0,1,100,70 A40,40,0,0,1,180,70 Q180,130,100,190 Q20,130,20,70 Z"
  );
}

@keyframes move {
  100% {
    offset-distance: 100%;
  }
}
```

In this example, we used CSS masking and CSS shapes to clip a container with a light pink background into a heart shape. We used a `path()` function as the value of the `clip-path` property. Its child is a `10px` by `10px` red box that is made to follow the edge of its parent. We did this by using the same `<basic-shape>` as the path, setting the box's `offset-path` property to the same `path()` function value. We used CSS animations to change the `offset-distance` from `0%` to `100%` over three seconds.

CSS multi-column layout

The **CSS multi-column layout** module lets you divide content across multiple columns. By using the properties in this module, you can define the preferred number and width of columns, the gap size between columns, and the visual appearance of the optional column dividing lines (known as column rules). You can also define how content should flow from column to column and how to break content between columns.

Multi-column layout in action

In this example, the 1967 speech from Canada's centennial, *A Lament for Confederation*, by Chief Dan George, is displayed across multiple columns, similar to the way articles are displayed in printed newspapers. If you have JavaScript enabled, controls enable changing the preferred column number and width, the width of the gap between columns, whether the title and a sample blockquote should be contained in a

single column or made to span all columns, and whether breaking within the paragraphs should be avoided.

```
<article>
  <div class="title">
    <h1>A Lament for Confederation</h1>
    <p>&mdash;Chief Dan George, 1967</p>
  </div>
  <p>
    How long have I known you, Oh Canada? A hundred years? Yes, a hundred years.
    And many, many tides more. And today, when you celebrate your hundred years,
    Oh Canada, I am sad for all the Indian people throughout the land.
  </p>
  <p>
    For I have known you when your forests were mine; when they gave me my meat
    and my clothing. I have known you in your fruits and rivers where your fish
    flashed and danced in the sun, where the waters said 'come and eat of my
    abundance.' I have known you in the freedom of your winds. And my spirit,
    like your winds, once roamed this good lands.
  </p>
  <blockquote>
    <p>
      But in long the hundred years since the white man came, I have seen that
      freedom disappear just like the salmon going mysteriously out to sea.
    </p>
  </blockquote>
  <p>
    The white man's strange customs I could not understand, pressed down upon me
    until I could no longer breathe.
  </p>
  <p>
    When I fought to protect my home and my land, I was called a savage. When I
    neither understood nor welcomed this new way of life, I was called lazy.
    When I tried to rule my people, I was stripped of my authority.
  </p>
  <p>
    My nation was ignored in your history textbooks – we were less important in
    the history of Canada than the buffalo that ranged the plains. I was
    ridiculed in your plays and motion pictures, and when I drank your
    fire-water, I got drunk – very, very drunk. And I forgot.
  </p>
  <p>
    Oh Canada, how can I celebrate with you this centenary, this hundred years?
    Shall I thank you for the reserves that are left me of my beautiful forests?
    Shall I thank you for the canned fish of my rivers? Shall I thank you for
    the loss of my pride and authority, even among my own people? For the lack
    of my will to fight back? No! I must forget what is past and gone.
  </p>
  <p>
    Oh God in heaven! Give me the courage of the olden chiefs. Let me wrestle
    with my surroundings. Let me once again, as in the days of old, dominate my
    environment. Let me humbly accept this new culture and through it rise up
    and go on.
  </p>
  <p>
    Oh god, like the thunderbird of old, I shall rise again out of the sea. I
    shall grab the instruments of the white man's success – his education, his
    skills, and with these new tools I shall build my race into the proudest
    segment of your society. And, before I follow the great chiefs who have gone
    before us, I shall see these things come to pass.
  </p>
  <p>
    I shall see our young braves and our chiefs sitting in the house of law and
    government, ruling and being ruled by the knowledge and freedoms of our
    great land. So shall we shatter the barriers of our isolation. So shall the
    next hundred years be the greatest in the proud history of our tribes and
    nations.

```

> **Note:** Multiple-column layout is closely related to paged media. Each column box is a fragment, much like each printed page is a fragment of a document. Using the properties defined in the CSS fragmentation module, you can control how content breaks between columns and pages.

Basic concepts of multi-column layouts

Multi-column layout, usually referred to as multicol layout, is a specification for laying out content into a set of column boxes much like columns in a newspaper. This guide explains how the specification works with some common use case examples.

Key properties

Multicol layout is unlike any of the other layout methods in CSS; it fragments the content, including all descendant elements, into columns. This happens in the same way that content is fragmented into pages when we work with CSS paged media by creating a print stylesheet.

In this and subsequent guides, we will be discussing the following properties defined in the CSS multi-column layout module:

- `column-width`
- `column-count`
- `columns` shorthand
- `column-rule-color`
- `column-rule-style`
- `column-rule-width`
- `column-rule` shorthand
- `column-span`
- `column-fill`
- `column-gap`
- `break-after`
- `break-before`
- `break-inside`

Defining columns

By adding the `column-count` or the `column-width` property to an element, or using the `columns` shorthand, the element becomes a *multi-column container* or *multicol container* for short. The columns are anonymous boxes; they're described as *column boxes* in the specification.

Specifying the number of columns

The `column-count` property specifies the number of columns that you would like the content to be displayed as. The browser will then assign the correct amount of space to each column box to create the requested number of columns.

In the below example, we use the `column-count` property to create three columns on the `.container` element. The content, including the children of `.container`, is then split between the three columns.

```
<div class="container">
  <p>
    Veggies es bonus vobis, proinde vos postulo essum magis kohlrabi welsh onion
    daikon amaranth tatsoi tomatillo melon azuki bean garlic.
  </p>

  <p>
    Gumbo beet greens corn soko endive gumbo gourd. Parsley shallot courgette
    tatsoi pea sprouts fava bean collard greens dandelion okra wakame tomato.
    Dandelion cucumber earthnut pea peanut soko zucchini.
  </p>

  <p>
    Turnip greens yarrow ricebean rutabaga endive cauliflower sea lettuce
    kohlrabi amaranth water spinach avocado daikon napa cabbage asparagus winter
    purslane kale. Celery potato scallion desert raisin horseradish spinach
    carrot soko.
  </p>
</div>
```

```
body {
  font: 1.2em / 1.5 sans-serif;
}

.container {
  column-count: 3;
}
```

In the above example, the content is wrapped within the paragraph `<p>` tags with the default styling. Therefore, there is a margin above each paragraph. You can see how this margin causes the first line of text to be pushed down. This is because a multicol container creates a block formatting context (BFC) because of which margins on child elements do not collapse with any margin on the container.

Specifying the width of columns

The `column-width` property is used to set the optimal width for every column box. If you declare a column width, the browser will work out how many columns of that width will fit into the multicol container and distribute any extra space equally between the columns. Therefore, the column width should be seen as minimum width because the column boxes are likely to be wider due to the additional space.

In the case of a single column with less width available than the value of `column-width`, the column box will shrink to be smaller than the declared column width.

In the example below, the `column-width` property is set to `200px`. We get as many 200-pixel columns as will fit the container, with the extra space shared equally.

```
<div class="container">
  <p>
    Veggies es bonus vobis, proinde vos postulo essum magis kohlrabi welsh onion
    daikon amaranth tatsoi tomatillo melon azuki bean garlic.
  </p>

  <p>
    Gumbo beet greens corn soko endive gumbo gourd. Parsley shallot courgette
    tatsoi pea sprouts fava bean collard greens dandelion okra wakame tomato.
    Dandelion cucumber earthnut pea peanut soko zucchini.
  </p>

  <p>
    Turnip greens yarrow ricebean rutabaga endive cauliflower sea lettuce
    kohlrabi amaranth water spinach avocado daikon napa cabbage asparagus winter
    purslane kale. Celery potato scallion desert raisin horseradish spinach
    carrot soko.
  </p>
</div>
```

```
body {
  font: 1.2em / 1.5 sans-serif;
}

.container {
  column-width: 200px;
}
```

Specifying both number and width of columns

If you specify both the properties on a multicol container, then `column-count` will act as a maximum number of columns. Therefore, the behavior as described for `column-width` will happen, until the number of columns in `column-count` is reached. After this point, no more columns will be drawn, and the extra space is distributed evenly between the existing columns, even if there is enough room for more columns of the specified `column-width` size.

When using both properties together, you may get fewer columns than specified in the value for `column-count`.

In this next example, we use `column-width` of `200px` and `column-count` of `2`. Even if there is space for more than two columns, we get two. If there is not enough space for two columns of at least 200 pixels each, we get one.

```
<div class="container">
  <p>
    Veggies es bonus vobis, proinde vos postulo essum magis kohlrabi welsh onion
    daikon amaranth tatsoi tomatillo melon azuki bean garlic.
  </p>

  <p>
    Gumbo beet greens corn soko endive gumbo gourd. Parsley shallot courgette
```

```
    tatsoi pea sprouts fava bean collard greens dandelion okra wakame tomato.
    Dandelion cucumber earthnut pea peanut soko zucchini.
  </p>

  <p>
    Turnip greens yarrow ricebean rutabaga endive cauliflower sea lettuce
    kohlrabi amaranth water spinach avocado daikon napa cabbage asparagus winter
    purslane kale. Celery potato scallion desert raisin horseradish spinach
    carrot soko. .
  </p>
</div>
```

```
body {
  font: 1.2em / 1.5 sans-serif;
}

.container {
  column-count: 2;
  column-width: 200px;
}
```

Shorthand for column properties

You can use the `columns` shorthand to set the `column-count` and `column-width` values. If you specify a length unit, the value will be used for `column-width`, and if you specify an integer, the value will be used for `column-count`. You can set both the properties, separating the two values with a space.

This CSS would give the same result as the first example, with `column-count` set to `3`.

```
.container {
  columns: 3;
}
```

This CSS would give the same result as the second example, with `column-width` of `200px`.

```
.container {
  columns: 200px;
}
```

This CSS would give the same result as the third example, with both `column-count` and `column-width` set.

```
.container {
  columns: 2 200px;
}
```

Next steps

In this guide, we've learned the basic use of multi-column layout. In the next guide, we will look at how much we can style the columns themselves.

Handling content breaks in multi-column layout

Content between column boxes in a multicol layout breaks in the same way that it breaks between pages in paged media. In both contexts, you can control where and how content breaks by using properties of the CSS fragmentation module. In this guide, we see how fragmentation works in a *multi-column container* or *multicol container* for short.

Fragmentation basics

The CSS fragmentation module provides details on how content breaks between the fragmentation containers or *fragmentainers*. The multi-column layout module, on the other hand, defines the `break-after`, `break-before`, and `break-inside` properties that provide some control within and between columns. In multicol layout, a column box is a fragment container.

A column box can contain other markup and there are many places where a break would not be ideal. For example, we would generally prefer that the caption of an image not be separated into a new column away from the image it refers to. Also, ending a column with a heading looks strange. The multicol fragmentation properties give us ways to exercise some control over this.

There are various places we might want to control our breaks:

- Breaks inside boxes, for example inside a figure element.
- Breaks before and after boxes, which would include our heading example above.
- Breaks between lines.

Breaks inside boxes

To control breaks inside boxes use the `break-inside` property. This property takes values of:

- `auto`
- `avoid`
- `avoid-page`
- `avoid-column`
- `avoid-region`

In the example below, we have applied break-inside to the figure element to prevent the caption from becoming separated from the image.

```
<div class="container">
  <figure>
    <img
      alt="Multiple hot air balloons in a clear sky, a crowd of spectators gather in the foreground."
      src="https://mdn.github.io/shared-assets/images/examples/balloons.jpg" />
    <figcaption>Balloons</figcaption>
  </figure>
  <p>
    Veggies es bonus vobis, proinde vos postulo essum magis kohlrabi welsh onion

  </p>
  <p>
    Gumbo beet greens corn soko endive gumbo gourd. Parsley shallot courgette
    tatsoi pea sprouts fava bean collard greens dandelion okra wakame tomato.
  </p>
</div>
```

```
body {
  font: 1.2em / 1.5 sans-serif;
}

img {
  max-width: 100%;
}
figure {
  margin: 0;
  break-inside: avoid;
}
figcaption {
  font-weight: bold;
  border-bottom: 2px solid #999999;
}
.container {
  column-width: 200px;
}
```

Breaks before and after boxes

The `break-before` and `break-after` properties are used to control breaks before and after elements. They take the following values when in a multicol context:

- auto
- avoid
- avoid-column
- column

In this next example, we are forcing a column break before an `h2` element.

```
<div class="container">
  <p>
    Veggies es bonus vobis, proinde vos postulo essum magis kohlrabi welsh onion
    daikon.
  </p>
  <h2>My heading</h2>
  <p>
    Gumbo beet greens corn soko endive gumbo gourd. Parsley shallot courgette
    tatsoi pea sprouts fava bean collard greens dandelion okra wakame tomato.
    Dandelion cucumber earthnut pea peanut soko zucchini.
  </p>
  <p>Turnip greens yarrow ricebean rutabaga endive cauliflower sea lettuce.</p>
</div>
```

```
body {
  font: 1.2em / 1.5 sans-serif;
}

.container {
  column-width: 250px;
}

h2 {
  break-before: column;
}
```

Breaks between lines

The `orphans` and `widows` properties, part of the CSS fragmentation module, are also useful and worth mentioning. The `orphans` property controls the number of lines left on their own at the end of a fragment. The `widows` property controls the number left on their own at the start of a fragment.

The `orphans` and `widows` properties take an `<integer>` as a value, which represents the number of lines to keep together at the end and start of a fragment, respectively. Note that these properties only work inside a block container, such as a paragraph. If the block has fewer lines in it than the number that you specify as a value, all lines will be kept together.

In the example below, we are using the `orphans` property to control the number of lines left at the bottom of a column. You can change that value to see the effect on the breaking of the content.

```
<div class="container">
  <p>
    Veggies es bonus vobis, proinde vos postulo essum magis kohlrabi welsh onion
    daikon.
  </p>
  <p>
    Gumbo beet greens corn soko endive gumbo gourd. Parsley shallot courgette
    tatsoi pea sprouts fava bean collard greens dandelion okra wakame tomato.
    Dandelion cucumber earthnut pea peanut soko zucchini.
  </p>
  <p>Turnip greens yarrow ricebean rutabaga endive cauliflower sea lettuce.</p>
</div>
```

```
body {
  font: 1.2em / 1.5 sans-serif;
}

.container {
  column-width: 250px;
  orphans: 3;
}
```

When things don't work as expected

If you have small amounts of content and are trying to control breaks on several elements, your content needs to break somewhere, so you may not always get the result you intended. To some extent, your use of fragmentation is always a suggestion to the browser, to control breaks in this way if it is possible. If the content doesn't break where you intended, the result may be untidy, but the content is still available for your users.

Handling overflow in multi-column layout

In this guide, we look at how to deal with overflow in a multi-column (*multicol*) layout, both inside the column boxes and in situations where there is more content than will fit into the container.

Overflow inside column boxes

An overflow situation happens when an item's size is larger than the column box. For example, the situation could happen when an image in a column is wider than the `column-width` value or the width of the column based on the number of columns declared with `column-count`.

In this situation, the content should visibly overflow into the next column, rather than be clipped by the column box.

```
<div class="container">
  <p>
    Veggies es bonus vobis, proinde vos postulo essum magis kohlrabi welsh onion
    daikon amaranth tatsoi tomatillo melon azuki bean garlic.
  </p>
  <img
    alt="A close-up of two hot air balloons being inflated."
    src="https://mdn.github.io/shared-assets/images/examples/balloons3.jpg" />
  <p>
    Gumbo beet greens corn soko endive gumbo gourd. Parsley shallot courgette
    tatsoi pea sprouts fava bean collard greens dandelion okra wakame tomato.
    Dandelion cucumber earthnut pea peanut soko zucchini.
  </p>
  <p>
    Turnip greens yarrow ricebean rutabaga endive cauliflower sea lettuce
    kohlrabi amaranth water spinach avocado daikon napa cabbage asparagus winter
    purslane kale. Celery potato scallion desert raisin horseradish spinach
    carrot soko.
  </p>
</div>
```

```
body {
  font: 1.2em / 1.5 sans-serif;
}

.container {
  column-width: 250px;
}
```

This example renders like so:

There are two columns of text. In the left column, there is a photo that is wider than the column. The image expands into that second column, appearing behind the text of the right column. The flow of text in the right column isn't affected by the protruding photo, but the appearance is.

If you want an image to fit the column box, setting `max-width: 100%` will prevent the image from growing beyond its container, in this case, the column box.

```
<div class="container">
  <p>
    Veggies es bonus vobis, proinde vos postulo essum magis kohlrabi welsh onion
    daikon amaranth tatsoi tomatillo melon azuki bean garlic.
  </p>
  <img
    alt="A close-up of two hot air balloons being inflated."
    src="https://mdn.github.io/shared-assets/images/examples/balloons3.jpg" />
  <p>
    Gumbo beet greens corn soko endive gumbo gourd. Parsley shallot courgette
    tatsoi pea sprouts fava bean collard greens dandelion okra wakame tomato.
    Dandelion cucumber earthnut pea peanut soko zucchini.
  </p>
  <p>
    Turnip greens yarrow ricebean rutabaga endive cauliflower sea lettuce
    kohlrabi amaranth water spinach avocado daikon napa cabbage asparagus winter
    purslane kale. Celery potato scallion desert raisin horseradish spinach
    carrot soko.
  </p>
</div>
```

```
body {
  font: 1.2em / 1.5 sans-serif;
}

.container {
  column-width: 250px;
}
img {
  max-width: 100%;
}
```

The updated rendering looks like this:

More columns than will fit

How overflowing columns are handled depends on whether the media context is fragmented, such as print, or is continuous, such as a web page.

- In fragmented media, after a fragment (for example, a page) is filled with columns, the columns will move to a new page and fill that up with columns.
- In continuous media, if a height is set on a multi-column container, columns overflow in the inline direction by default. On the web, this means that you will get a horizontal scrollbar. This behavior can be overridden by using `column-height` and `column-wrap` to enforce column wrapping.

This example shows the default continuous media overflow behavior. The multicol container has a set `height` and there is more text than space to create columns; therefore, we get columns created outside of the container.

```
<div class="container">
  <p>
    Veggies es bonus vobis, proinde vos postulo essum magis kohlrabi welsh onion
    daikon amaranth tatsoi tomatillo melon azuki bean garlic.
  </p>
  <p>
    Gumbo beet greens corn soko endive gumbo gourd. Parsley shallot courgette
    tatsoi pea sprouts fava bean collard greens dandelion okra wakame tomato.
    Dandelion cucumber earthnut pea peanut soko zucchini.
  </p>
  <p>
    Turnip greens yarrow ricebean rutabaga endive cauliflower sea lettuce
```

```
    kohlrabi amaranth water spinach avocado daikon napa cabbage asparagus winter
    purslane kale. Celery potato scallion desert raisin horseradish spinach
    carrot soko.
  </p>
</div>
```

```
body {
  font: 1.2em / 1.5 sans-serif;
}

.container {
  column-width: 200px;
  height: 180px;
  border: 2px dashed;
}
```

This example renders like so:

Scroll horizontally to see the overflowing columns.

Using vertical media queries

One issue with multicol on the web is that if the columns are taller than the viewport, the reader will need to scroll the page up and down to read, which is not a good user experience. One way to avoid this is to only apply the column properties if you know there is enough vertical space.

In the example below, we used a `height` @media query to ensure there is enough vertical space before applying the column properties.

```
<div class="container">
  <p>
    Veggies es bonus vobis, proinde vos postulo essum magis kohlrabi welsh onion
    daikon amaranth tatsoi tomatillo melon azuki bean garlic.
  </p>
  <p>
    Gumbo beet greens corn soko endive gumbo gourd. Parsley shallot courgette
    tatsoi pea sprouts fava bean collard greens dandelion okra wakame tomato.
    Dandelion cucumber earthnut pea peanut soko zucchini.
  </p>
  <p>
    Turnip greens yarrow ricebean rutabaga endive cauliflower sea lettuce
    kohlrabi amaranth water spinach avocado daikon napa cabbage asparagus winter
    purslane kale. Celery potato scallion desert raisin horseradish spinach
    carrot soko.
  </p>
</div>
```

```
body {
  font: 1.2em / 1.5 sans-serif;
}

@media (height >= 300px) {
  .container {
    column-width: 200px;
  }
}
```

This example renders like so:

Using column wrapping for multicol

The `column-height` and `column-wrap` properties can be used to set a fixed height for generated columns and force excess columns to overflow into additional rows in the block direction. In horizontal writing mode content, this results in vertically-scrolling rows of columns, rather than a horizontally scrolling single row. Let's look at an example.

The HTML contains basic text content, which we have hidden for brevity.

```
<p>
  This is a bunch of text split into three columns using the CSS
  <code>column-count</code> property with a value of <code>3</code>. It also
  includes a <code>column-height</code> value of <code>95vh</code>. The
  <code>column-wrap</code> value is set to its initial value, <code>auto</code>;
  when a <code>column-height</code> value is included,
  <code>column-wrap: auto</code> resolves to <code>wrap</code>, which allows the
  columns to wrap onto multiple rows. The text is equally distributed over the
  columns, and placed into multiple rows.
</p>

<p>
  The <code>column-height</code> and <code>column-wrap</code> properties were
  introduced in
  <a href="https://drafts.csswg.org/css-multicol-2/"
    >CSS Multi-column Layout Module Level 2</a
  >.
</p>
```

We give our content some styles. Most notably, we set the `<body>` element's `column-count` to `3`, and its `column-height` to `95vh` so that each row of columns fills up the viewport. We don't need to explicitly set `column-wrap` to `wrap`: when `column-height` is set to a `<length>` value, the initial value of `column-wrap` (`auto`) resolves to `wrap`, which is usually the behavior you'll want.

```
body {
  font-size: 1.3em;
  line-height: 1.5;
  column-count: 3;
  column-height: 95vh;
}
```

```
html {
  font-family: sans-serif;
}

body {
  width: 70%;
```

```
  margin: 0 auto;
}

p:first-of-type {
  margin-top: 0;
}
```

```
@supports not (column-height: 5em) {
  body::before {
    content: "Your browser does not support the 'column-height' property.";
    background-color: wheat;
    position: fixed;
    inset: 40% 0;
    height: fit-content;
    text-align: center;
    padding: 1rem 0;
  }
}
```

This example renders as follows:

Next steps

In the final guide in this series, we will see how fragmentation works with multicol layouts to give us control over how content breaks between columns.

Spanning and balancing columns

In this guide, we look at how to make elements span across columns inside the multi-column (*multicol*) container and how to control how the columns are filled.

Spanning the columns

To cause an item to span across columns, use the `column-span` property with a value of `all`. This will cause the element to become a *spanner*, spanning all the columns.

Any descendant element of the multicol container may be turned into a spanner, including both direct and indirect children. For example, a heading nested directly inside the container could become a spanner, as could a heading nested inside a `<section>` nested inside the multicol container.

In the example below, the `<h2>` element is set to `column-span: all` and spans all of the columns.

```
<div class="container">
  <p>
    Veggies es bonus vobis, proinde vos postulo essum magis kohlrabi welsh onion
    daikon amaranth tatsoi tomatillo melon azuki bean garlic. Gumbo beet greens
    corn soko endive gumbo gourd.
  </p>
  <h2>A heading</h2>
  <p>
    Parsley shallot courgette tatsoi pea sprouts fava bean collard greens
    dandelion okra wakame tomato. Dandelion cucumber earthnut pea peanut soko
    zucchini.
  </p>
  <p>
    Turnip greens yarrow ricebean rutabaga endive cauliflower sea lettuce
    kohlrabi amaranth water spinach avocado daikon napa cabbage asparagus winter
    purslane kale. Celery potato scallion desert raisin horseradish spinach
    carrot soko.
  </p>
</div>
```

```
body {
  font: 1.2em / 1.5 sans-serif;
}

.container {
  column-width: 250px;
}

h2 {
  column-span: all;
  background-color: #4d4e53;
  color: white;
}
```

In this second example, the heading is inside an `<article>` element, yet still spans the content as expected.

```
<div class="container">
  <p>
    Veggies es bonus vobis, proinde vos postulo essum magis kohlrabi welsh onion
    daikon amaranth tatsoi tomatillo melon azuki bean garlic. Gumbo beet greens
    corn soko endive gumbo gourd.
  </p>
  <article>
    <h2>A heading</h2>
    <p>
      Parsley shallot courgette tatsoi pea sprouts fava bean collard greens
      dandelion okra wakame tomato. Dandelion cucumber earthnut pea peanut soko
      zucchini.
    </p>
    <p>
      Turnip greens yarrow ricebean rutabaga endive cauliflower sea lettuce
      kohlrabi amaranth water spinach avocado daikon napa cabbage asparagus
      winter purslane kale. Celery potato scallion desert raisin horseradish
      spinach carrot soko.
    </p>
  </article>
</div>
```

```
body {
  font: 1.2em / 1.5 sans-serif;
}
```

```
.container {
  column-width: 250px;
}

h2 {
  column-span: all;
  background-color: #4d4e53;
  color: white;
}
```

When a spanner is introduced, it breaks the flow of columns; columns restart after the spanner, effectively creating a new set of column boxes. The content does not jump over a spanning element.

Limitations of column-span

The `column-span` can have only two values. The initial value `none` means the item does not span and remains within a column. The value `all` means the item spans all of the columns. There are no values that enable partial spanning, such as having an item span two out of three columns.

Things to watch out for

If the spanning element is inside another element with margins, padding, and a border or background color, the box may appear above the spanner with the rest of the content being displayed below. For this reason, care should be taken when setting an element to span all the columns, ensuring this scenario is accounted for.

```
<div class="container">
  <p>
    Veggies es bonus vobis, proinde vos postulo essum magis kohlrabi welsh onion
    daikon amaranth tatsoi tomatillo melon azuki bean garlic. Gumbo beet greens
    corn soko endive gumbo gourd.
  </p>
  <article>
    <h2>A heading</h2>
    <p>
      Parsley shallot courgette tatsoi pea sprouts fava bean collard greens
      dandelion okra wakame tomato. Dandelion cucumber earthnut pea peanut soko
      zucchini.
    </p>
    <p>
      Turnip greens yarrow ricebean rutabaga endive cauliflower sea lettuce
      kohlrabi amaranth water spinach avocado daikon napa cabbage asparagus
      winter purslane kale. Celery potato scallion desert raisin horseradish
      spinach carrot soko.
    </p>
  </article>
</div>
```

```
body {
  font: 1.2em / 1.5 sans-serif;
}

article {
  border: 1px solid red;
  padding: 10px;
}

.container {
  column-width: 250px;
}
h2 {
  background-color: #4d4e53;
  color: white;
  column-span: all;
}
```

Additionally, if a spanning element appears later in the content, it can cause unexpected or unwanted behavior when there is not enough content to create columns after the spanner. Use spanning carefully and test at various breakpoints to make sure you get the effect you intended.

Filling and balancing columns

A balanced set of columns is where all columns have approximately the same amount of content. Filling and balancing are relevant when the amount of content does not match the amount of space provided, such as when a `height` is declared on the container.

The initial value for `column-fill` is `balance`. The value of `balance` means all columns are as balanced as possible. In fragmented contexts, such as paged media, only the last fragment is balanced. This means that on the last page, the final set of column boxes is balanced.

The other balancing value, `balance-all`, balances all columns in fragmented contexts.

The columns in this example contain an image and some text, which are balanced. The image, which cannot break, is in the first column. The other columns are balanced, filling with equal amounts of text.

```
<div class="container">
  <img
    alt="Multiple hot air balloons in a clear sky, a crowd of spectators gather in the foreground."
    src="https://mdn.github.io/shared-assets/images/examples/balloons.jpg" />
  <p>
    Veggies es bonus vobis, proinde vos postulo essum magis kohlrabi welsh onion
    daikon amaranth tatsoi tomatillo melon azuki bean garlic.
  </p>
  <p>
    Gumbo beet greens corn soko endive gumbo gourd. Parsley shallot courgette
    tatsoi pea sprouts fava bean collard greens dandelion.
  </p>
</div>
```

```
body {
  font: 1.2em / 1.5 sans-serif;
}
h2 {
  background-color: #4d4e53;
  color: white;
}
img {
  max-width: 100%;
```

```
}
.container {
  column-width: 200px;
  column-fill: balance;
  height: 250px;
}
```

The `auto` value for `column-fill` fills a column sequentially, filling the first column in the inline-start direction, before placing content in subsequent columns, rather than balancing and filling all the columns equally. In this example, we changed `column-fill` to `auto`. The columns are filled to the height of the container, leaving empty columns at the end.

```
<div class="container">
  <img
    alt="Multiple hot air balloons in a clear sky, a crowd of spectators gather in the foreground."
    src="https://mdn.github.io/shared-assets/images/examples/balloons.jpg" />
  <p>
    Veggies es bonus vobis, proinde vos postulo essum magis kohlrabi welsh onion
    daikon amaranth tatsoi tomatillo melon azuki bean garlic.
  </p>
  <p>
    Gumbo beet greens corn soko endive gumbo gourd. Parsley shallot courgette
    tatsoi pea sprouts fava bean collard greens dandelion.
  </p>
</div>
```

```
body {
  font: 1.2em / 1.5 sans-serif;
}
h2 {
  background-color: #4d4e53;
  color: white;
}
img {
  max-width: 100%;
}

.container {
  column-width: 150px;
  column-fill: auto;
  height: 250px;
}
```

Next steps

In the next guide, you will learn how multicol handles overflow within columns and when there are more columns than can fit in the container.

Styling columns

As column boxes created inside multi-column (*multicol*) containers are anonymous boxes, styling individual columns is not possible, but we can style the gaps between the columns and the container in general. This guide explains how to change the gap and style rules between columns.

Column gaps

The gap between columns is controlled using the `column-gap` or `gap` property. The `column-gap` property is defined in the multi-column layout module. The `gap` property is defined in the box alignment module. This is a unified property to define gaps between boxes in all layouts that support gaps, including CSS grid layout and CSS flexible box layout.

The initial value of `column-gap` is `1em`, which prevents columns from running into each other. In other layout methods, `column-gap` is supported as a synonym for `gap`, but with an initial value of `0`. The keyword value `normal` sets `column-gap` to the initial value.

You can change the gap by using any `<length>` value. In the example below, the `column-gap` is set to `40px`.

```
<div class="container">
  <p>
    Veggies es bonus vobis, proinde vos postulo essum magis kohlrabi welsh onion
    daikon amaranth tatsoi tomatillo melon azuki bean garlic.
  </p>
  <p>
    Gumbo beet greens corn soko endive gumbo gourd. Parsley shallot courgette
    tatsoi pea sprouts fava bean collard greens dandelion okra wakame tomato.
    Dandelion cucumber earthnut pea peanut soko zucchini.
  </p>
  <p>
    Turnip greens yarrow ricebean rutabaga endive cauliflower sea lettuce
    kohlrabi amaranth water spinach avocado daikon napa cabbage asparagus winter
    purslane kale. Celery potato scallion desert raisin horseradish spinach
    carrot soko.
  </p>
</div>
```

```
body {
  font: 1.2em / 1.5 sans-serif;
}

.container {
  column-count: 3;
  column-gap: 40px;
}
```

The allowed value for `column-gap` is a `<length-percentage>`, meaning percentages are allowed. Percentage values for `column-gap` are calculated as a percentage of the width of the multicol container.

Column rules

The specification defines `column-rule-width`, `column-rule-style` and `column-rule-color`, providing a shorthand `column-rule`. These properties work in exactly the same way as the `border` properties: any `<line-style>` can be used as a `column-rule-style`, just as for valid `border-style`.

These properties are applied to the element, which is the multicol container, and therefore, all columns will have the same rule. Rules are only drawn between columns and not on the outer edges. Rules are also only drawn between columns that have content.

In this next example, a 5px-dotted rule with a color of `rebeccapurple` has been created using the longhand values.

```
<div class="container">
  <p>
    Veggies es bonus vobis, proinde vos postulo essum magis kohlrabi welsh onion
    daikon amaranth tatsoi tomatillo melon azuki bean garlic.
  </p>
  <p>
    Gumbo beet greens corn soko endive gumbo gourd. Parsley shallot courgette
    tatsoi pea sprouts fava bean collard greens dandelion okra wakame tomato.
    Dandelion cucumber earthnut pea peanut soko zucchini.
  </p>
  <p>
    Turnip greens yarrow ricebean rutabaga endive cauliflower sea lettuce
    kohlrabi amaranth water spinach avocado daikon napa cabbage asparagus winter
    purslane kale. Celery potato scallion desert raisin horseradish spinach
    carrot soko.
  </p>
</div>
```

```
body {
  font: 1.2em / 1.5 sans-serif;
}

.container {
  column-count: 3;
  column-rule-width: 5px;
  column-rule-style: dotted;
  column-rule-color: rebeccapurple;
}
```

Note that the rule itself does not take up any space: a wide rule will not push the columns apart to make space for the rule. Instead, the rule overlays the gap.

The example below uses a very wide rule of `40px` and a `10px` gap. The rule displays under the column content. To make space on both sides of the rule, the gap would need to be increased to be larger than `40px`.

```
<div class="container">
  <p>
    Veggies es bonus vobis, proinde vos postulo essum magis kohlrabi welsh onion
    daikon amaranth tatsoi tomatillo melon azuki bean garlic.
  </p>
  <p>
    Gumbo beet greens corn soko endive gumbo gourd. Parsley shallot courgette
    tatsoi pea sprouts fava bean collard greens dandelion okra wakame tomato.
    Dandelion cucumber earthnut pea peanut soko zucchini.
  </p>
  <p>
    Turnip greens yarrow ricebean rutabaga endive cauliflower sea lettuce
    kohlrabi amaranth water spinach avocado daikon napa cabbage asparagus winter
    purslane kale. Celery potato scallion desert raisin horseradish spinach
    carrot soko.
  </p>
</div>
```

```
body {
  font: 1.2em / 1.5 sans-serif;
}

.container {
  column-count: 3;
  column-gap: 10px;
  column-rule: 40px solid rebeccapurple;
}
```

Next steps

This article details all the current ways in which column boxes can be styled. In the next guide, we will take a look at making elements inside a container span across all columns.

Using multi-column layouts

The properties defined in the **CSS multi-column layout module** extend the *block layout mode*, enabling the definition of multiple columns of text. People have trouble reading text if lines are too long. If it takes too long for the eyes to move from the end of one line to the beginning of the next, readers can lose track of which line they were on. To provide for a better user experience when reading text making use of a large screen, you should limit the width of text by using columns of text placed side by side, just as newspapers do.

Using columns

Column count and width

Two CSS properties control whether and how many columns will appear: `column-count` and `column-width`.

The `column-count` property sets the number of columns to a particular number. E.g.,

Example 1

HTML

```
<div id="col">
  <p>
    Lorem ipsum dolor sit amet, consectetur adipisicing elit, sed do eiusmod
    tempor incididunt ut labore et dolore magna aliqua.
  </p>
  <p>
    Ut enim ad minim veniam, quis nostrud exercitation ullamco laboris nisi ut
    aliquip ex ea commodo consequat.
  </p>
  <p>
    Duis aute irure dolor in reprehenderit in voluptate velit esse cillum dolore
    eu fugiat nulla pariatur.
  </p>
  <p>
    Excepteur sint occaecat cupidatat non proident, sunt in culpa qui officia
    deserunt mollit anim id est laborum.
```

```
  </p>
</div>
```

CSS

```
#col {
  column-count: 2;
}
```

Result

The content will be displayed in two columns:

The `column-width` property sets the minimum desired column width. If `column-count` is not also set, then the browser will automatically make as many columns as fit in the available width.

Example 2

HTML

```
<div id="wid">
  Lorem ipsum dolor sit amet, consectetur adipisicing elit, sed do eiusmod
  tempor incididunt ut labore et dolore magna aliqua. Ut enim ad minim veniam,
  quis nostrud exercitation ullamco laboris nisi ut aliquip ex ea commodo
  consequat. Duis aute irure dolor in reprehenderit in voluptate velit esse
  cillum dolore eu fugiat nulla pariatur. Excepteur sint occaecat cupidatat non
  proident, sunt in culpa qui officia deserunt mollit anim id est laborum
</div>
```

CSS

```
#wid {
  column-width: 100px;
}
```

Result

In a multi-column block, content automatically flows from one column into the next as needed. All HTML, CSS, and DOM functionality is supported within columns, as are editing and printing.

The columns shorthand

You can use either `column-count` or `column-width`. Because values for these properties do not overlap, it is often convenient to use the shorthand `columns`.

Example 3

In this example, the CSS declaration `column-width: 12em` is replaced by `columns: 12em`.

HTML

```
<div id="col_short">
  Lorem ipsum dolor sit amet, consectetur adipisicing elit, sed do eiusmod
  tempor incididunt ut labore et dolore magna aliqua. Ut enim ad minim veniam,
  quis nostrud exercitation ullamco laboris nisi ut aliquip ex ea commodo
  consequat. Duis aute irure dolor in reprehenderit in voluptate velit esse
  cillum dolore eu fugiat nulla pariatur. Excepteur sint occaecat cupidatat non
  proident, sunt in culpa qui officia deserunt mollit anim id est laborum
</div>
```

CSS

```
#col_short {
  columns: 12em;
}
```

Example 4

In this example, the CSS declaration `column-count: 4` is replaced by `columns: 4`.

HTML

```
<div id="columns_4">
  Lorem ipsum dolor sit amet, consectetur adipisicing elit, sed do eiusmod
  tempor incididunt ut labore et dolore magna aliqua. Ut enim ad minim veniam,
  quis nostrud exercitation ullamco laboris nisi ut aliquip ex ea commodo
  consequat. Duis aute irure dolor in reprehenderit in voluptate velit esse
  cillum dolore eu fugiat nulla pariatur. Excepteur sint occaecat cupidatat non
  proident, sunt in culpa qui officia deserunt mollit anim id est laborum
</div>
```

CSS

```
#columns_4 {
  columns: 4;
}
```

Result

Example 5

The two CSS declarations `column-width: 8em` and `column-count: 12` can be replaced by `columns: 12 8em`. The `column-count` portion of the shorthand is the maximum number of columns that will be present. The `column-width` is the minimum width each column should be.

HTML

```
<div id="columns_12">
  Lorem ipsum dolor sit amet, consectetur adipisicing elit, sed do eiusmod
  tempor incididunt ut labore et dolore magna aliqua. Ut enim ad minim veniam,
  quis nostrud exercitation ullamco laboris nisi ut aliquip ex ea commodo
  consequat. Duis aute irure dolor in reprehenderit in voluptate velit esse
  cillum dolore eu fugiat nulla pariatur. Excepteur sint occaecat cupidatat non
```

```
  proident, sunt in culpa qui officia deserunt mollit anim id est laborum
</div>
```

CSS

```
#columns_12 {
  columns: 12 8em;
}
```

Result

Assuming a default `1em` gap between columns, if the container is wider than `103ems` (12 columns * `8em` width each + 7 `1em` gaps), there will be 12 columns, each with a width of `8ems` or more. If the container is less than `103ems` wide, there will be fewer than 12 columns. If the container is less than `17ems` wide (`8em` column + `8em` column + `1em` gap), the content will be displayed as a single column with no column gap.

Height balancing

CSS columns require that the column heights must be balanced: that is, the browser automatically sets the maximum column height so that the heights of the content in each column are approximately equal. Firefox does this.

However, in some situations it is also useful to set the maximum height of the columns explicitly, and then lay out content starting at the first column and creating as many columns as necessary, possibly overflowing to the right. Therefore, if the height is constrained, by setting the CSS `height` or `max-height` properties on a multi-column block, each column is allowed to grow to that height and no further before adding new column. This mode is also much more efficient for layout.

Column Gaps

There is a gap between columns. The recommended default is `1em`. This size can be changed by applying the `column-gap` property to the multi-column block:

Example 6

HTML

```
<div id="column_gap">
  Lorem ipsum dolor sit amet, consectetur adipisicing elit, sed do eiusmod
  tempor incididunt ut labore et dolore magna aliqua. Ut enim ad minim veniam,
  quis nostrud exercitation ullamco laboris nisi ut aliquip ex ea commodo
  consequat. Duis aute irure dolor in reprehenderit in voluptate velit esse
  cillum dolore eu fugiat nulla pariatur. Excepteur sint occaecat cupidatat non
  proident, sunt in culpa qui officia deserunt mollit anim id est laborum
</div>
```

CSS

```
#column_gap {
  column-count: 5;
  column-gap: 2em;
}
```

Result

Conclusion

CSS columns are a layout primitive that can help make large blocks of text easier to read when responsive content is viewed on wide viewports. Imaginative developers may find many uses for them, especially in conjunction with container queries and with the automatic height balancing feature.

CSS namespaces

The **CSS namespaces** module defines the syntax for using namespaces in CSS.

CSS isn't just for styling HTML. A stylesheet may be used to style SVG, MathML, XML, or HTML, each of which has a different namespace or a document containing multiple namespaces.

The `@namespace` at-rule defined in this module enables distinguishing between same-named elements in different namespaces. Element tag names are not unique to a single language. For example, the `<a>` element isn't limited to HTML. You may want to style the `<a>`s within your SVGs differently from the links in your HTML. You also will likely want to ensure that `querySelectorAll("a")` selects the right kind of element. Namespacing can help.

The `@namespace` rule is used for declaring a default namespace and for binding namespaces to namespace prefixes. The namespaces module also defines the syntax for using these prefixes to represent namespace-qualified names. That's it. What a name means or if the name is even valid depends on the context and host language.

CSS nesting

The **CSS nesting** module defines a syntax for nesting selectors, providing the ability to nest one style rule inside another, with the selector of the child rule relative to the selector of the parent rule.

CSS nesting is different from CSS preprocessors such as Sass in that it is parsed by the browser rather than being pre-compiled by a CSS preprocessor.

CSS nesting helps with the readability, modularity, and maintainability of CSS stylesheets. It also potentially helps reduce the size of CSS files, thereby decreasing the amount of data downloaded by users.

CSS nesting at-rules

Any at-rule whose body contains style rules can be nested inside another style rule using CSS nesting. Style rules nested inside at-rules take their nesting selector definition from the nearest ancestor style rule. Properties can be directly included inside a nested at-rule, acting as if they were nested in a `& {...}` block.

at-rules that can be nested

- `@media`
- `@supports`
- `@layer`
- `@scope`
- `@container`
- `@starting-style`

Examples

Nesting <code>@media</code> at-rule

In this example we see three blocks of CSS. The first one shows how to write typical at-rule nesting, the second is an expanded way of writing the nesting as the browser parses it, and the third one shows the non-nested equivalent.

Nested CSS

```
.foo {
  display: grid;
  @media (orientation: landscape) {
    grid-auto-flow: column;
  }
}
```

Expanded nested CSS

```
.foo {
  display: grid;
  @media (orientation: landscape) {
    & {
      grid-auto-flow: column;
    }
  }
}
```

Non-nested equivalent

```
.foo {
  display: grid;
}

@media (orientation: landscape) {
  .foo {
    grid-auto-flow: column;
  }
}
```

Multiple nested <code>@media</code> at-rules

At-rules can be nested within other at-rules. Below you can see an example of this, and how it would be written without nesting.

Nested at-rules

```
.foo {
  display: grid;
  @media (orientation: landscape) {
    grid-auto-flow: column;
    @media (width >= 1024px) {
      max-inline-size: 1024px;
    }
  }
}
```

Non-nested equivalent

```
.foo {
  display: grid;
}
@media (orientation: landscape) {
  .foo {
    grid-auto-flow: column;
  }
}
@media (orientation: landscape) and (width >= 1024px) {
  .foo {
    max-inline-size: 1024px;
  }
}
```

Nesting Cascade Layers (<code>@layer</code>)

Cascade Layers can be nested to create child-layers. These are joined with a `.` (dot).

Defining the parent & child layers

We start by defining the named cascade layers, prior to using them, without any style assignments.

```
@layer base {
  @layer support;
}
```

Assigning rules to layers with nesting

Here the `.foo` selector assigns its rules to the **base** `@layer`. The nested **support** `@layer` creates the `base.support` sub-layer, and the `&` nesting selector is used to create the rules for the `.foo .bar` selector.

```
.foo {
  @layer base {
    block-size: 100%;
    @layer support {
      & .bar {
        min-block-size: 100%;
      }
    }
  }
}
```

Equivalent without nesting

```
@layer base {
  .foo {
    block-size: 100%;
  }
}
@layer base.support {
  .foo .bar {
    min-block-size: 100%;
  }
}
```

CSS nesting and specificity

The specificity of the `&` nesting selector is calculated using the largest specificity in the associated selector list. This is identical to how specificity is calculated when using the `:is()` function.

```
<b class="foo">
  <i>Blue text</i>
```

```
</b>
```

<code>&</code> nesting syntax

```
#a, b {
  & i {
    color: blue;
  }
}

.foo i {
  color: red;
}
```

<code>:is()</code> syntax

```
:is(#a, b) {
  & i {
    color: blue;
  }
}

.foo i {
  color: red;
}
```

In this example, the id selector (`#a`) has a specificity of `1-0-0`, while the type selector (`b`) has a specificity of `0-0-1`. The `&` nesting selector and `:is()` pseudo-class both take a specificity of `1-0-0`, even though the `#a` id selector is never used.

The `.foo` class selector has a specificity of `0-1-0`. This makes the total specificity `1-0-1` for `& i` and `0-1-1` for `.foo i`, meaning that `color: blue;` wins out.

Using CSS nesting

The CSS nesting module allows you to write your stylesheets so that they are easier to read, more modular, and more maintainable. As you are not constantly repeating selectors, the file size can also be reduced.

CSS nesting is different from CSS preprocessors such as Sass in that it is parsed by the browser rather than being pre-compiled by a CSS preprocessor. Also, in CSS nesting, the specificity of the `&` nesting selector is similar to the `:is()` function; it is calculated using the highest specificity in the associated selector list.

This guide shows different ways to arrange nesting in CSS.

Child selectors

You can use CSS nesting to create child selectors of a parent, which in turn can be used to target child elements of specific parents. This can be done with or without the `&` nesting selector.

There are certain instances where using the `&` nesting selector can be necessary or helpful:

- When joining selectors together, such as using compound selectors or pseudo-classes.
- For backwards compatibility.
- As a visual indicator to aid with readability, when seeing the `&` nesting selector you know that CSS nesting is being used.

```
/* Without nesting selector */
.parent {
  /* parent styles */
  .child {
    /* child of parent styles */
  }
}

/* With nesting selector */
.parent {
  /* parent styles */
  & .child {
    /* child of parent styles */
  }
}

/* the browser will parse both of these as */
.parent {
  /* parent styles */
}
.parent .child {
  /* child of parent styles */
}
```

Examples

In these examples, one without and one with the `&` nesting selector, the `<input>` inside the `<label>` is being styled differently to the `<input>` that is a sibling of a `<label>`.

Without nesting selector

HTML

```
<form>
  <label for="name">Name:
    <input type="text" id="name" />
  </label>
  <label for="email">email:</label>
  <input type="text" id="email" />
</form>
```

CSS

```
form,
label {
  display: flex;
  flex-direction: column;
  gap: 0.5rem;
}
```

```
input {
  /* styles for input not in a label  */
  border: tomato 2px solid;
}
label {
  /* styles for label */
  font-family: system-ui;
  font-size: 1.25rem;

  input {
    /* styles for input in a label  */
    border: blue 2px dashed;
  }
}
```

Result

With nesting selector

```
<form>
  <label for="name">Name:
    <input type="text" id="name" />
  </label>
  <label for="email">email:</label>
  <input type="text" id="email" />
</form>
```

CSS

```
form,
label {
  display: flex;
  flex-direction: column;
  gap: 0.5rem;
}
```

```
input {
  /* styles for input not in a label  */
  border: tomato 2px solid;
}
label {
  /* styles for label */
  font-family: system-ui;
  font-size: 1.25rem;

  & input {
    /* styles for input in a label  */
    border: blue 2px dashed;
  }
}
```

Result

Combinators

CSS Combinators can also be used with or without the `&` nesting selector.

Example

Nesting the sibling combinator

In this example, the first paragraph after each `<h2>` is targeted with the next-sibling combinator (+) using CSS nesting.

HTML

```
<h2>Heading</h2>
<p>This is the first paragraph.</p>
<p>This is the second paragraph.</p>
```

CSS

```
h2 {
  color: tomato;
  + p {
    color: white;
    background-color: black;
  }
}
/* this code can also be written with the & nesting selector */
/*
h2 {
  color: tomato;
  & + p {
    color: white;
    background-color: black;
  }
}
*/
```

Result

Compound selectors

When using compound selectors in nested CSS you **have** to use the `&` nesting selector. This is because the browser will automatically add whitespace between selectors that do not use the `&` nesting selector.

In order to target an element with `class="a b"` the `&` nesting selector is needed otherwise the whitespace will break the compound selector.

```
.a {
  /* styles for element with class="a" */
  .b {
    /* styles for element with class="b" which is a descendant of class="a" */
  }
  &.b {
    /* styles for element with class="a b" */
  }
}

/* the browser parses this as */
.a {
  /* styles for element with class="a" */
}
.a .b {
  /* styles for element with class="b" which is a descendant of class="a" */
}
.a.b {
  /* styles for element with class="a b" */
}
```

Example

Nesting and compound selectors

In this example the `&` nesting selector is used to create compound selectors to style elements with multiple classes.

HTML

```
<div class="notices">
  <div class="notice">
    <h2 class="notice-heading">Notice</h2>
    <p>Lorem ipsum dolor sit amet consectetur adipisicing elit.</p>
  </div>
  <div class="notice warning">
    <h2 class="warning-heading">Warning</h2>
    <p>Lorem ipsum dolor sit amet consectetur adipisicing elit.</p>
  </div>
  <div class="notice success">
    <h2 class="success-heading">Success</h2>
    <p>Lorem ipsum dolor sit amet consectetur adipisicing elit.</p>
  </div>
</div>
```

CSS

Styles for the `.notices` to create a column using flexbox layout.

```
.notices {
  display: flex;
  flex-direction: column;
  gap: 0.5rem;
  width: 90%;
  margin: auto;
}
```

In the CSS code below, nesting is used to create compound selectors both with and without `&`. The top-level selector defines the basic styles for elements with `class="notice"`. The `&` nesting selector is then used to create compound selectors for elements with either `class="notice warning"` or `class="notice success"`. Additionally, the use of nesting to create compound selectors without explicitly using `&` can be seen in the selector `.notice .notice-heading::before`.

```
.notice {
  width: 90%;
  justify-content: center;
  border-radius: 1rem;
  border: black solid 2px;
  background-color: #ffc107;
  color: black;
  padding: 1rem;
  .notice-heading::before {
    /* equivalent to `.notice .notice-heading::before` */
    content: "i ";
  }
  &.warning {
    /* equivalent to `.notice.warning` */
    background-color: #d81b60;
    border-color: #d81b60;
    color: white;
    .warning-heading::before {
      /* equivalent to `.notice.warning .warning-heading::before` */
      content: "! ";
    }
  }
  &.success {
    /* equivalent to `.notice.success` */
    background-color: #004d40;
    border-color: #004d40;
    color: white;
    .success-heading::before {
      /* equivalent to `.notice.success .success-heading::before` */
      content: "✓ ";
    }
  }
}
```

Result

Appended nesting selector

The `&` nesting selector can also be appended to a nested selector which has the effect of reversing the context.

This can be useful when we have styles for a child element that change when a parent element is given a different class:

```
<div>
  <span class="foo">text</span>
</div>
```

As opposed to:

```
<div class="bar">
  <span class="foo">text</span>
</div>
```

```
.foo {
  /* .foo styles */
  .bar & {
    /* .bar .foo styles */
  }
}
```

Example

Appending nesting selector

In this example there are 3 cards, one of which is featured. The cards are all exactly the same except the featured card will have an alternative color for the heading. By appending the `&` nesting selector the style for the `.featured h2` can be nested in the style for the `h2`.

HTML

```
<div class="wrapper">
  <article class="card">
    <h2>Card 1</h2>
    <p>Lorem ipsum dolor, sit amet consectetur adipisicing elit.</p>
  </article>
  <article class="card featured">
    <h2>Card 2</h2>
    <p>Lorem ipsum dolor, sit amet consectetur adipisicing elit.</p>
  </article>
  <article class="card">
    <h2>Card 3</h2>
    <p>Lorem ipsum dolor, sit amet consectetur adipisicing elit.</p>
  </article>
</div>
```

CSS

```
.wrapper {
  display: flex;
  flex-direction: row;
  gap: 0.25rem;
  font-family: system-ui;
}
```

In the following CSS, we are creating the styles for `.card` and `.card h2`. Then, in the `h2` style block, we nest the `.featured` class with the `&` nesting selector appended which creates a style for `.card :is(.featured h2)`, which is equivalent to `:is(.card h2):is(.featured h2)`.

```
.card {
  padding: 0.5rem;
  border: 1px solid black;
  border-radius: 0.5rem;
  & h2 {
    /* equivalent to `.card h2` */
    color: slateblue;
    .featured & {
      /* equivalent to `:is(.card h2):is(.featured h2)` */
      color: tomato;
    }
  }
}
```

Result

Nested declarations rule

The nested declaration rule is that CSS rules are parsed in the order that they are written in the CSS document.

With the following CSS:

```
.foo {
  background-color: silver;
  @media screen {
    color: tomato;
  }
  color: black;
}
```

The `background-color` is parsed first and set to silver, then the `@media` rule is evaluated, and finally the `color`.

The CSSOM parses the CSS in the following way:

```
↳ CSSStyleRule
  .style
    - background-color: silver
  ↳ CSSMediaRule
```

```
    ↳ CSSNestedDeclarations
      .style (CSSStyleDeclaration, 1) =
      - color: tomato
  ↳ CSSNestedDeclarations
    .style (CSSStyleDeclaration, 1) =
      - color: black
```

Note that in order to preserve the parsing order, all the rules before nesting are handled as top-level `CSSRules`, while any top level rules after nesting are represented as `CSSNestedDeclarations`. That's why the `color-black` is inside a nested declaration even though it is a top level declaration in the original document.

> **Note:** Support for the rule was added with `CSSNestedDeclarations`. Browsers that do not support this interface may parse nested rules in the wrong order.

Concatenation (is not possible)

In CSS preprocessors such as Sass, it is possible to use nesting to join strings to create new classes. This is common in CSS methodologies such as BEM.

```
/* the following Sass syntax... */
.component {
  &__child-element {
  }
}
/* ... would become the following CSS */
.component__child-element {
}
```

> **Warning:** This is not possible in CSS nesting: when a combinator is not used, the nested selector is treated as a type selector. Allowing concatenation would break this.

In compound selectors, the type selector must come first. Writing `&Element` (a type selector) makes the CSS selector, and the entire selector block, invalid. As the type selector must come first, the compound selector must be written as `Element&`.

```
.my-class {
  element& {
  }
}

/* the browser parses this to become a compound selector */
.my-class {
}
element.my-class {
}
```

Invalid nested style rules

If a nested CSS rule is invalid then all of the enclosed styles will be ignored. This does not affect the parent or preceding rules.

In the following example, there is an invalid selector (`%` is not a valid character for selectors). The rule that includes this selector is ignored, but subsequent valid rules are not.

```
.parent {
  /* .parent styles these work fine */
  & %invalid {
    /* %invalid styles all of which are ignored */
  }
  & .valid {
    /* .parent .valid styles these work fine */
  }
}
```

CSS overflow

The **CSS overflow** module properties enable you to handle scrollable overflow in visual media.

Overflow happens when the content in an element box extends past one or more of the box's edges. **Scrollable overflow** is the content that appears outside the element box for which you might want to add a scrolling mechanism. CSS overflow properties let you control what happens when content overflows an element box, including creating carousels without JavaScript.

Painting effects that overflow the content but do not participate in the CSS box model do not affect layout. This type of overflow is also known as ink overflow. Examples of ink overflows include box shadows, border images, text decoration, overhanging glyphs, and outlines. Ink overflows do not extend the scrollable overflow region.

Overflow in action

Try the following example to see the effects of various `overflow` property values on the content overflow and scrollbars in the adjacent fixed-size box.

The example includes options to change the values for the `overflow-clip-margin` and `width` properties, as well as to programmatically scroll the content if the overflow property creates a scroll container. Select `overflow: clip` and see the effect of different `overflow-clip-margin` values. Select `overflow: hidden` or `overflow: scroll` to check out the various `ScrollLeft` and `ScrollTop` slider settings.

```
<article>
  <fieldset>
    <legend>Select options:</legend>
    <label
      ><code>overflow</code>:
      <select id="overflowValue">
        <option>hidden</option>
        <option>clip</option>
        <option>scroll</option>
        <option>auto</option>
        <option selected>visible</option>
```

```
        <option>overlay</option>
      </select>
    </label>
    <label>
      <code>overflow-clip-margin</code>:
      <input type="number" id="ocm" value="1" min="0" max="10" />
      <code>em</code>
    </label>
    <label

Creating CSS carousels

The CSS overflow module defines features enabling the creation of flexible pure-CSS carousels with browser-generated and developer-styled scroll buttons and scroll markers. This guide explains how to create a carousel using these features.

Carousel concepts

Carousels are a common feature on the web. They typically take the form of a scrolling content area containing several items, such as presentation slides, ads, headline news stories, or key product features.

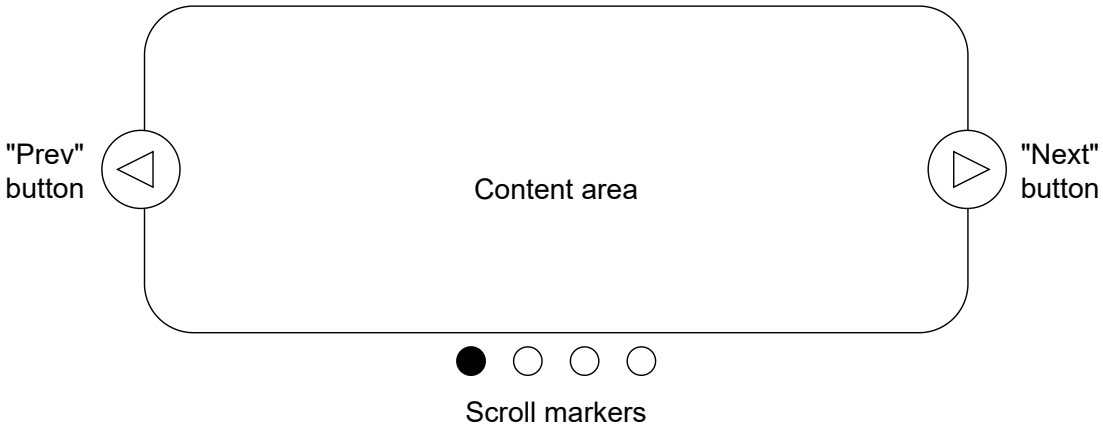
Users can move through the items by clicking or activating navigational buttons or by swiping. The navigation usually includes:

scroll buttons

> Generally "previous" and "next" buttons or links.

scroll markers

> A series of button or link icons, each representing one or more items depending on how many items are shown at each scroll position within the carousel.



A key feature of carousels is **pagination** — the items feel like separate pieces of content that are moved between rather than forming one continuous section of content. You might show one item at a time or several items on each carousel "page". When several items are visible, you might show an entirely new group of items each time the "next" or "previous" button is pressed. Alternatively, you could add a single new item to one end of the list while moving the item at the other end out of view.

Carousels can be quite brittle and challenging to implement with JavaScript. They require scripts to associate scroll markers with the items they represent while continuously updating the scroll buttons to keep them operating correctly.

Fortunately, we can create carousels with associated controls without the use of JavaScript, using CSS carousel features.

CSS carousel features

The CSS carousel features provide pseudo-elements and pseudo-classes that enable the creation of carousels using only CSS and HTML, with the browser handling most of the scrolling and link references in a flexible and consistent manner. These features are as follows:

`::scroll-button()`

Generated inside a scroll container, these pseudo-elements represent scroll buttons, which scroll the container in a specified direction.

`::scroll-marker-group`

Generated inside a scroll container; used to collect together and lay out scroll markers.

`::scroll-marker`

Generated inside the children of a scroll container ancestor or within a scroll container's columns, to represent their scroll markers. These can be selected to scroll the container to their associated child elements or column, and are collected inside the scroll container's `::scroll-marker-group` for layout purposes.

`:target-current`

Used to select the currently active scroll marker and style it. The ability to style the active scroll marker is important for both usability and accessibility.

`:target-before` and `:target-after`

Used to select and style scroll markers before and after the currently active scroll marker, respectively. They are useful for styling navigation items that come before and after the active navigation position, indicating items the user has already viewed and those that are still to come.

`::column`

Represents the individual columns generated when a container is set to display its content in multiple columns via CSS multi-column layout. The `::column` pseudo-element can be used in conjunction with `::scroll-marker` to generate a scroll marker for each column.

Carousel with single pages

Our first demo is a carousel of single pages, with each item taking up the full page. We have scroll markers as bottom navigation and scroll buttons on the sides of the page, enabling the user to move to the next and previous pages.

We'll use flexbox to lay out the carousel, scroll snapping to enforce clear pagination, and anchor positioning to position the scroll buttons and scroll markers relative to the carousel.

The HTML consists of a heading element and an unordered list, with each list item containing some sample content, along with a custom `data-` attribute (which we explain with the styling):

```
<h1>CSS carousel single item per page</h1>
<ul>
  <li data-accName="Item 1">
    <h2>Page 1</h2>
  </li>
  <li data-accName="Item 2">
    <h2>Page 2</h2>
  </li>
  <li data-accName="Item 3">
    <h2>Page 3</h2>
  </li>
  <li data-accName="Item 4">
    <h2>Page 4</h2>
  </li>
</ul>
```

Carousel layout with flexbox

We use flexbox to create a single row of items; the `<ul>` is the flex container, and the `<li>` child list items are displayed horizontally with each item taking up the full width of the carousel.

The unordered list is made to fill the full width of the viewport with a width `width` of `100vw`; it is also given a `height` of `300px`, and some `padding`. We then use flexbox to lay out the list — setting a `display` value of `flex` to cause the child list items to display in a row (due to the default `flex-direction` value of `row`), with a `gap` of `4vw` between each one.

```
* {
  box-sizing: border-box;
}

body {
  margin: 0;
  font-family: "Helvetica", "Arial", sans-serif;
}

h1 {
  text-align: center;
  font-size: 1.7rem;
}
```

```
ul {
  width: 100vw;
  height: 300px;
  padding: 20px;
  display: flex;
  gap: 4vw;
}
```

Now it's time to style the list items. The first declarations provide rudimentary styling. The important declaration is the `flex` value of `0 0 100%`, which forces each item to be as wide as the container (the `<ul>`). As a result, the content will overflow its container, and the viewport will scroll horizontally.

```
li {
  list-style-type: none;
  background-color: #eeeeee;
  border: 1px solid #dddddd;
  padding: 20px;

  flex: 0 0 100%;
}

li:nth-child(even) {
  background-color: cyan;
}
```

In addition, every even-numbered list item is given a different background-color via `:nth-child()`, so that it is easier to see the scrolling effect.

Setting up scroll snapping on the list

In this section, we will set an overflow value on the `<ul>` to turn it into a scroll container, then apply CSS scroll snapping to cause the list to snap to the center of each list item as the content is scrolled.

An `overflow-x` value of `scroll` is set on the `<ul>` so that its content will scroll horizontally within the list, rather than the entire viewport scrolling. CSS scroll snap is then used to snap to each "page" — a `scroll-snap-type` value of `x mandatory` is set to make the list into a scroll snap container. The `x` keyword causes the container's snap targets to be snapped to horizontally, while the `mandatory` keyword means that the container will always snap to a snap target at the end of a scrolling action.

```
ul {
  overflow-x: scroll;
  scroll-snap-type: x mandatory;
}
```

Next, a `scroll-snap-align` value of `center` is set on the list items so that, when the list is scrolled, it snaps to the center of each list item.

```
li {
  scroll-snap-align: center;
}
```

The code shown so far renders as follows:

Try scrolling the list by swiping or using the scrollbar to see the scroll snapping effect. No matter where you end your scroll motion, an item will always "snap" into place.

> **Note:** CSS scroll snapping is not mandatory to use the CSS carousel features. However, carousels work a lot better with scroll snapping included. Without scroll snapping, the scroll buttons and markers will be unlikely to navigate cleanly between pages, and the result will be substandard.

Creating scroll buttons

In this section we add "previous" and "next" scroll buttons to the demo to provide a tool to navigate between carousel pages. This is achieved using the `::scroll-button()` pseudo-element.

The `::scroll-button()` pseudo-elements generate buttons inside a scroll container only when their `content` properties are set to a value other than `none`. Each `::scroll-button()` represents a scroll button, the scrolling direction of which is specified by the selector's argument. You can generate up to four scroll buttons per scroll container, each scrolling the container's content towards the start or end of the block or inline axis.

You can also specify an argument of `*` to target all of the `::scroll-button()` pseudo-elements with styles.

First, all scroll buttons are targeted with some rudimentary styles, as well as styling based on different states. It is important to set `:focus` styles for keyboard users. Also, as scroll buttons are automatically set to `disabled` when no more scrolling can occur in that direction, we use the `:disabled` pseudo-class to target this state.

```
ul::scroll-button(*) {
  border: 0;
  font-size: 2rem;
  background: none;
  color: black;
  opacity: 0.7;
  cursor: pointer;
}

ul::scroll-button(*):hover,
ul::scroll-button(*):focus {
  opacity: 1;
}
```

```
ul::scroll-button(*):active {
  translate: 1px 1px;
}

ul::scroll-button(*):disabled {
  opacity: 0.2;
  cursor: unset;
}
```

> **Note:** We also set a `cursor` value of `pointer` on the scroll buttons to make it more obvious that they can be interacted with (an improvement for both general UX and cognitive accessibility), unsetting it when the scroll buttons are `:disabled`.

Next, an appropriate icon is set on the left and right scroll buttons via the `content` property, which is also what causes the scroll buttons to be generated. That icon must also have a corresponding plain text accessible name, so use the alternative text feature of the `content` property (with the caveat that this may still be insufficient to satisfy WCAG):

```
ul::scroll-button(left) {
  content: "◂" / "Previous";
}

ul::scroll-button(right) {
  content: "▸" / "Next";
}
```

> **Note:** User agents should automatically give an appropriate accessible name to generated scroll buttons so that assistive technologies can appropriately announced them and the buttons should have an implicit `role` of `button`. Providing alternative text for generated content ensures the buttons have the accessible names of "scroll left" and "scroll right" in user agents that don't natively include scroll button accessibility features.

Positioning scroll buttons

We've created the scroll buttons. Now we will position them relative to the carousel using CSS anchor positioning.

First of all, a reference `anchor-name` is set on the list. Next, each scroll button has its `position` set to `absolute`, and its `position-anchor` property set to the same reference name defined on the list, to associate the two together.

```
ul {
  anchor-name: --my-carousel;
}

ul::scroll-button(*) {
  position: absolute;
  position-anchor: --my-carousel;
}
```

To actually position each scroll button, we set values on their inset properties. We use `anchor()` functions to position the specified sides of the buttons relative to the sides of the carousel. In each case, the `calc()` function is used to add some space between the button edge and the carousel edge. For example, the right-hand edge of the left scroll button is positioned 70 pixels to the right of the carousel's left-hand edge.

```
ul::scroll-button(left) {
  right: calc(anchor(left) - 70px);
  bottom: calc(anchor(top) + 13px);
}

ul::scroll-button(right) {
  left: calc(anchor(right) - 70px);
  bottom: calc(anchor(top) + 13px);
}
```

Adding in the scroll button code, we get the following result:

Try pressing the "previous" and "next" scroll buttons to see how the pages are scrolled, respecting the scroll-snapping behavior. Also note how the "previous" button is automatically disabled when the list is scrolled to the start of the content, while the "next" button is automatically disabled when the list is scrolled to the end of the content.

Creating scroll markers

Scroll markers are a group of buttons, each one of which scrolls the carousel to a position related to one of the content pages. They provide an additional navigation tool that also indicates your progress through the carousel pages.

In this section, we will add scroll markers to the carousel, which involves three main features:

- The `scroll-marker-group` property is set on the scroll container element. It needs to be set to a non-`none` value for the `::scroll-marker-group` pseudo-element to be generated; its value specifies where the scroll marker group appears in the carousel's tab order and layout box order (but not DOM structure) — `before` puts it at the start, before the scroll buttons, while `after` puts it at the end.
- The `::scroll-marker-group` pseudo-element exists inside a scroll container, and is used to collect together, contain, and lay out scroll markers as a whole group.
- `::scroll-marker` pseudo-elements exist inside the children and `::column` fragments of a scroll container ancestor, and represent their scroll markers. These are collected inside the ancestor's `::scroll-marker-group` for layout purposes.

To begin with, the list's `scroll-marker-group` property is set to `after`, so the `::scroll-marker-group` pseudo-element is placed after the list's DOM content in the focus and layout box order; this means it comes after the scroll buttons:

```
ul {
  scroll-marker-group: after;
}
```

> **Note:** Alternatively, a scroll marker group container can be created from an existing element containing a set of `<a>` elements using `scroll-target-group`.

Next, the list's `::scroll-marker-group` pseudo-element is positioned relative to the carousel using CSS anchor positioning, similar to the scroll button's, except that it is horizontally centered on the carousel using a `justify-self` value of `anchor-center`. The group is laid out using flexbox, with a `justify-content` value of `center` and a `gap` of `20px` so that its children (the `::scroll-marker` pseudo-elements) are centered inside the `::scroll-marker-group` with a gap between each one.

```
ul::scroll-marker-group {
  position: absolute;
  position-anchor: --my-carousel;
  top: calc(anchor(bottom) - 70px);
  justify-self: anchor-center;
```

```
  display: flex;
  justify-content: center;
  gap: 20px;
}
```

Next, we handle the look and feel of the scroll markers themselves; they can be styled just like any other generated content. It is important to note that we need to set a non-`none` value for the `content` property so the scroll markers are actually generated. A value of `""` produces a blank accessible name (a WCAG SC 4.1.2 Name, Role, Value violation), so it's necessary to provide some text value. Because each scroll marker having the same name may not be useful for users, consider using `attr()` to pull the value from a custom `data-` attribute on the `<li>` (this example looks for an attribute `data-accName`). Understand this value will not be picked up by automated translation services.

We also set some rudimentary styles to make the markers appear as outlined circles while visually hiding the text content we've added:

```
li::scroll-marker {
  content: attr(data-accName);
  width: 16px;
  height: 16px;
  background-color: transparent;
  border: 2px solid black;
  border-radius: 50%;
  overflow: hidden;
  text-indent: 16px;
}
```

> **Note:** Generated content is inline by default; we can apply `width` and `height` to our scroll markers because they are being laid out as flex items.

Finally for this section, the `:target-current` pseudo-class is used to select whichever scroll marker corresponds to the currently visible "page", highlighting how far the user has scrolled through the content. In this case, we set the `background-color` to `black` so it is styled as a filled-in circle.

```
li::scroll-marker:target-current {
  background-color: black;
}
```

> **Note:** When a scroll marker group container is created on a scroll container using the `scroll-marker-group` property, the scroll container is rendered with `tablist`/`tab` semantics. You can `Tab` to it with the keyboard, then move between the different "pages" using the left and right (or up and down) cursor keys, which also changes the state of the associated scroll markers and scroll buttons as expected. The scroll markers can also be tabbed between normally, as expected.

Single page carousel final result

All of the above code combines together to create the following result:

Since the previous live example, the scroll markers have been added — try pressing them to jump straight to each page. Note how the current marker is highlighted so you can see where you are in the pagination. Also try tabbing to the scroll marker group, then use the cursor keys to cycle through each page.

You can also navigate between pages by swiping left and right, dragging the scroll bar, or pressing the scroll buttons.

Responsive carousel: multiple items per page

The second demo is a carousel with multiple items per page, which again includes scroll buttons and scroll markers for navigating through the pages. This demo is also responsive — different numbers of items appear on each page depending on the viewport width.

This demo is very similar to the Carousel with single pages demo, except that instead of using flexbox for layout, it uses CSS multi-column layout and the `::column` pseudo-element to create arbitrary columns that span the full width of the carousel and may contain multiple items.

> **Note:** There is currently no way to provide an accessible name for the scroll markers (there is no corresponding HTML element from which to draw a `data-` value as in the prior example). Using this pattern will create a WCAG SC 4.1.2 Name, Role, Value violation.

Using this approach, we can be sure that if the viewport grows or shrinks, while the item size remains constant, we'll never have a partial item displayed off the edge of the scrollport. In this case, the scroll markers are created on scroll container fragments, per-column, rather than on children, per-item.

The HTML is very similar to that of the previous demo, except that there are significantly more list items and, as multiple items will be visible at a time, we are labeling them as items rather than pages:

```
...
  <li>
    <h2>Item 1</h2>
  </li>
...
```

This demo also has very similar CSS, with the exception of the rules explained in the following sections.

```
<h1>CSS carousel multiple items per page</h1>
<ul>
  <li>
    <h2>Item 1</h2>
  </li>
  <li>
    <h2>Item 2</h2>
  </li>
  <li>
    <h2>Item 3</h2>
  </li>
  <li>
    <h2>Item 4</h2>
  </li>
  <li>
    <h2>Item 5</h2>
  </li>
  <li>
    <h2>Item 6</h2>
  </li>
  <li>
    <h2>Item 7</h2>
  </li>
```

```
  <li>
    <h2>Item 8</h2>
  </li>
  <li>
    <h2>Item 9</h2>
  </li>
  <li>
    <h2>Item 10</h2>
  </li>
  <li>
    <h2>Item 11</h2>
  </li>
  <li>
    <h2>Item 12</h2>
  </li>
  <li>
    <h2>Item 13</h2>
  </li>
  <li>
    <h2>Item 14</h2>
  </li>
  <li>
    <h2>Item 15</h2>
  </li>
</ul>
```

Carousel layout using columns

This example uses CSS multi-column layout, rather than flexbox, to layout the carousel items. The `columns` value of `1` forces each column to be the full width of the container, with the contents displaying a single column at a time. A `text-align` value of `center` is also applied, forcing the contents to align with the center of the list.

```
* {
  box-sizing: border-box;
}

body {
  margin: 0;
  font-family: "Helvetica", "Arial", sans-serif;
}

h1 {
  text-align: center;
  font-size: 1.7rem;
}
```

```
ul {
  width: 100vw;
  height: 300px;
  padding: 10px;

  overflow-x: scroll;
  scroll-snap-type: x mandatory;

  columns: 1;
  text-align: center;
}
```

We provide rudimentary box styling for the list items, then apply layout styles to allow one or more items to fit into the single content column, depending on the viewport width. The number dynamically changes as the list gets wider or narrower.

```
li {
  list-style-type: none;

  display: inline-block;
  height: 100%;
  width: 200px;

  background-color: #eeeeee;
  border: 1px solid #dddddd;
  padding: 20px;
  margin: 0 10px;

  text-align: left;
}

li:nth-child(even) {
  background-color: cyan;
}
```

The key layout properties are as follows:

- A `display` value of `inline-block` has been set to force the list items to sit alongside one another and make the list scroll horizontally.
- An absolute `width` of `200px` has been set on them to control their sizing, meaning one or more will fit in a column that grows and shrinks along with the width of the viewport.
- A `text-align` value of `left` is set on them to override the `text-align: center` set on the parent container, so the item content will be left-aligned.

The `scroll-snap-align` property is now set on the `::column` pseudo-elements — which represent the content columns generated by the `columns` property — rather than the list items. We want to snap to each complete column rather than every individual list item, showing all new items with each scroll action.

```
ul::column {
  scroll-snap-align: center;
}
```

```
ul::scroll-button(*) {
  border: 0;
  font-size: 2rem;
  background: none;
  color: black;
  opacity: 0.7;
  cursor: pointer;
```

```
}

ul::scroll-button(*):hover,
ul::scroll-button(*):focus {
  opacity: 1;
}

ul::scroll-button(*):active {
  translate: 1px 1px;
}

ul::scroll-button(*):disabled {
  opacity: 0.2;
  cursor: unset;
}

ul::scroll-button(left) {
  content: "◄";
}

ul::scroll-button(right) {
  content: "►";
}

ul {
  anchor-name: --my-carousel;
}

ul::scroll-button(*) {
  position: absolute;
  position-anchor: --my-carousel;
}

ul::scroll-button(left) {
  right: calc(anchor(left) - 70px);
  bottom: calc(anchor(top) + 13px);
}

ul::scroll-button(right) {
  left: calc(anchor(right) - 70px);
  bottom: calc(anchor(top) + 13px);
}

ul {
  scroll-marker-group: after;
}

ul::scroll-marker-group {
  position: absolute;
  position-anchor: --my-carousel;
  top: calc(anchor(bottom) - 70px);
  justify-self: anchor-center;
  display: flex;
  justify-content: center;
  gap: 20px;
}
```

Column scroll markers

The CSS for creating the scroll markers in this demo is nearly identical to the previous demo, except that the selectors are different — the scroll markers are created on the generated `::column` pseudo-elements rather than the list items. Note how we are including two pseudo-elements here to generate scroll markers on the generated columns.

```
ul::column::scroll-marker {
  content: "";
  width: 16px;
  height: 16px;
  background-color: transparent;
  border: 2px solid black;
  border-radius: 10px;
}
```

Finally, we use the `:target-current` pseudo-class to mark the active scroll marker, providing the user with an idea of where they are in the navigation. We also use the `:target-before` and `:target-after` pseudo-classes to apply some custom styling to the scroll markers before and after the active one. We also set a `transition` on the `ul::column::scroll-marker:target-current` rule so that the style changes between the different states animate smoothly.

```
ul::column::scroll-marker:target-before {
  border: 2px solid gray;
}

ul::column::scroll-marker:target-current {
  background-color: black;
  transition: all 0.7s;
}

ul::column::scroll-marker:target-after {
  border: 2px solid red;
  background-color: red;
}
```

Responsive carousel final result

The Responsive carousel is rendered as follows:

Try navigating between the different pages by swiping left and right, using the scroll bar, pressing the scroll buttons, and pressing the scroll markers. The functionality is similar to the single page flexbox example, except that now there are multiple list items in each navigated position; the scroll markers are set on column fragments, potentially containing multiple items, instead of on each item.

Also, try resizing the screen width and you'll see that the number of list items that can fit inside the list changes — and therefore the number of generated columns changes too. As the number of columns changes, the number of scroll markers dynamically updates so that each column is represented in the scroll marker group.

CSS overscroll behavior

The **CSS overscroll behavior** module provides properties to control the behavior of a scroll container when its scroll position reaches the scroll boundary. Controlling this aspect is particularly useful in scenarios where embedded scrollable areas should not trigger scrolling of the parent container.

When commenting on a blog, you might notice that if your comment exceeds the length of the provided `<textarea>`, scrolling beyond the end of the text area causes the entire blog to scroll. This is because reaching the end of a scrollable area, known as the scroll boundary, can lead to scrolling other content or the entire page. This continuous scrolling experience is called scroll chaining.

In situations where the contents of an element are larger than its container and `overflow` allows or defaults to scrolling (like in `<textarea>`), continued scrolling past the element's scrollable area will initiate scrolling in the parent element or the underlying page.

Conversely, scrolling through a website's terms and conditions and reaching the end of the content to enable a checkbox, may not force the page to scroll or bounce (as on a phone). This example shows that you can control overscroll behavior and prevent scroll chaining.

This module defines the overscroll behavior, enabling you to specify the actions when a user scrolls beyond the boundaries of a scrollable element.

CSS paged media

The **CSS paged media** module defines the properties that control the presentation of content for print or any other media that splits content into discrete pages. It allows you to set page breaks, control printable areas, and style left and right pages differently.

The CSS paged media module specifies how pages are generated and laid out to hold fragmented content in a paged presentation, including content that is printed or represented as a print preview. The module defines functionality for controlling page margins, size, orientation, and headers and footers. It extends generated content to provide functionality for generating page numbers and running headers and footers.

The process of paginating content into generated pages and controlling breaks inside elements is covered in the CSS fragmentation module.

CSS positioned layout

The **CSS positioned layout** module defines the coordinate-based positioning and offsetting schemes available in CSS and the properties used to position and stack elements on a web page. The module is best known for defining the basic positioning methods, including relative positioning, sticky positioning, absolute positioning, and fixed positioning. It also defines how positioned elements are painted and layered, clarifying stacking behavior and visual order.

The positioned layout module defines the physical, logical, and shorthand inset properties. The logical properties enable developing with internationalization and responsiveness in mind.

Like all CSS modules, this module impacts and is impacted by other modules. This module describes how positioning interacts with other layout modules such as CSS flexible box layout and CSS Grid layout. Other modules, such as CSS anchor positioning, build upon this module to enable positioning elements relative to other elements and layers.

Stacking context

Stacking context is a three-dimensional conceptualization of HTML elements along an imaginary z-axis relative to the user, who is assumed to be facing the viewport or the webpage. The stacking context determines how elements are layered on top of one another along the z-axis (think of it as the "depth" dimension on your screen). Stacking context determines the visual order of how overlapping content is rendered.

Elements within a stacking context are stacked independently from elements outside of that stacking context, ensuring elements in one stacking context don't interfere with the stacking order of elements in another. Each stacking context is completely independent of its siblings: only descendant elements are considered when stacking is processed.

Each stacking context is self-contained. After an element's contents are stacked, the entire element is considered as a single unit in the stacking order of its parent stacking context.

Within a stacking context, child elements are stacked according to the `z-index` values of all the siblings. The stacking contexts of these nested elements only have meaning in this parent. Stacking contexts are treated atomically as a single unit in the parent stacking context. Stacking contexts can be contained in other stacking contexts, and together create a hierarchy of stacking contexts.

The hierarchy of stacking contexts is a subset of the hierarchy of HTML elements because only certain elements create stacking contexts. Elements that don't create their own stacking contexts are *assimilated* by the parent stacking context.

Features creating stacking contexts

A stacking context is formed, anywhere in the document, by any element in the following scenarios:

- Root element of the document (`<html>`).
- Element with a `position` value `absolute` or `relative` and `z-index` value other than `auto`.
- Element with a `position` value `fixed` or `sticky`.
- Element with a `container-type` value `size` or `inline-size` set (See container queries).

- Element that is a flex item with a `z-index` value other than `auto`.
- Element that is a grid item with `z-index` value other than `auto`.
- Element with an `opacity` value less than `1`.
- Element with a `mix-blend-mode` value other than `normal`.
- Element with any of the following properties with a value other than `none`:
  - `transform`
  - `scale`
  - `rotate`
  - `translate`
  - `filter`
  - `backdrop-filter`
  - `perspective`
  - `clip-path`
  - `mask` / `mask-image` / `mask-border`
- Element with the `isolation` value `isolate`.
- Element with a `will-change` value specifying any property that would create a stacking context on non-initial value.
- Element with a `contain` value of `layout` or `paint`, or a composite value that includes either of these values (i.e., `contain: strict`, `contain: content`).
- Element placed into the top layer and its corresponding `::backdrop`. Examples include fullscreen and popover elements.
- Element that has had stacking context-creating properties (such as `opacity`) animated using `@keyframes`, with `animation-fill-mode` set to `forwards`.

Nested stacking contexts

Stacking contexts can be contained in other stacking contexts, and they can together create a hierarchy of stacking contexts.

The root element of a document is a stacking context which, in most cases, contains nested stacking contexts, many of which will contain additional stacking contexts. Within each stacking context, child elements are stacked according to the same rules explained in Using `z-index`. Importantly, the `z-index` values of its child stacking contexts only have meaning within its parent's stacking context. Stacking contexts are treated atomically as a single unit in the parent stacking context.

To figure out the *rendering order* of stacked elements along the z-axis, think of each index value as a "version number" of sorts, where child elements represent minor version numbers underneath their parent's major version number.

To demonstrate how the stacking order of each element participates in the stacking order of their ancestor stacking contexts, let's look at an example page with six container elements. There are three sibling `<article>` elements. The last `<article>` contains three sibling `<section>` elements, with the `<h1>` and `<code>` of that third article appearing between the first and second sibling `<section>` elements.

```
<article id="container1">
  <h1>Article element #1</h1>
  <code>
    position: relative;<br />
    z-index: 5;
  </code>
</article>

<article id="container2">
  <h1>Article Element #2</h1>
  <code>
    position: relative;<br />
    z-index: 2;
  </code>
</article>

<article id="container3">
  <section id="container4">
    <h1>Section Element #4</h1>
    <code>
      position: relative;<br />
      z-index: 6;
    </code>
  </section>

  <h1>Article Element #3</h1>
  <code>
    position: absolute;<br />
    z-index: 4;
  </code>

  <section id="container5">
    <h1>Section Element #5</h1>
    <code>
      position: relative;<br />
      z-index: 1;
    </code>
  </section>

  <section id="container6">
    <h1>Section Element #6</h1>
    <code>
      position: absolute;<br />
      z-index: 3;
    </code>
  </section>
</article>
```

Every container element has an `opacity` of less than `1` (which creates a stacking context), and a `position` of either `relative` or `absolute` (which creates a stacking context when the element also has a `z-index` value other than `auto`).

```
* {
  margin: 0;
}
html {
  padding: 20px;
```

```
  font:
    12px/20px "Arial",
    sans-serif;
}
h1 {
  font-size: 1.25em;
}
#container1,
#container2 {
  border: 1px dashed #669966;
  padding: 10px;
  background-color: #ccffcc;
}
#container1 {
  margin-bottom: 190px;
}
#container3 {
  border: 1px dashed #990000;
  background-color: #ffdddd;
  padding: 40px 20px 20px;
  width: 330px;
}
#container4 {
  border: 1px dashed #999966;
  background-color: #ffffcc;
  padding: 25px 10px 5px;
  margin-bottom: 15px;
}
#container5 {
  border: 1px dashed #999966;
  background-color: #ffffcc;
  margin-top: 15px;
  padding: 5px 10px;
}
#container6 {
  background-color: #ddddff;
  border: 1px dashed #000099;
  padding-left: 20px;
  padding-top: 125px;
  width: 150px;
  height: 125px;
}
```

```
section,
article {
  opacity: 0.85;
  position: relative;
}
#container1 {
  z-index: 5;
}
#container2 {
  z-index: 2;
}
#container3 {
  z-index: 4;
  position: absolute;
  top: 40px;
  left: 180px;
}
#container4 {
  z-index: 6;
}
#container5 {
  z-index: 1;
}
#container6 {
  z-index: 3;
  position: absolute;
  top: 20px;
  left: 180px;
}
```

The CSS properties for colors, fonts, alignment, and box-model have been hidden for brevity.

The hierarchy of stacking contexts in the above example is as follows:

```
Root
|
├── ARTICLE #1
├── ARTICLE #2
└── ARTICLE #3
  |
  ├── SECTION #4
  ├── SECTION #5
  └── SECTION #6
```

The three `<section>` elements are children of ARTICLE #3. Therefore, the stacking of the section elements is completely resolved within ARTICLE #3. Once stacking and rendering within ARTICLE #3 is completed, the whole ARTICLE #3 element is passed for stacking in the root element with respect to its sibling `<article>` elements.

By comparing the `z-index` as "version numbers", we can see how an element with a `z-index` of `1` (SECTION #5) is stacked above an element with a `z-index` of `2` (ARTICLE #2), and how an element with a `z-index` of `6` (SECTION #4) is stacked below an element with a `z-index` of `5` (ARTICLE #1). SECTION #4 is rendered under ARTICLE #1 because ARTICLE #1's z-index (`5`) is valid within the stacking context of the root element, while SECTION #4's z-index (`6`) is valid within the stacking context of ARTICLE #3 (`z-index: 4`). So SECTION #4 is under ARTICLE #1 because SECTION #4 belongs to ARTICLE #3, which has a lower z-index value (`4-6` is less than `5-0`).

For the same reason, ARTICLE #2 (`z-index: 2`) is rendered under SECTION #5 (`z-index`: 1) because SECTION #5 belongs to ARTICLE #3 (`z-index: 4`), which has a higher z-index value (`2-0` is less than `4-1`).

ARTICLE #3's z-index is `4`, but this value is independent of the `z-index` of three sections nested inside it because they belong to a different stacking context.

In our example (sorted according to the final rendering order):

- Root
  - ARTICLE #2: (`z-index`: 2), which results in a rendering order of `2-0`
  - ARTICLE #3: (`z-index`: 4), which results in a rendering order of `4-0`
    - SECTION #5: (`z-index`: 1), stacked under an element (`z-index`: 4), which results in a rendering order of `4-1`
    - SECTION #6: (`z-index`: 3), stacked under an element (`z-index`: 4), which results in a rendering order of `4-3`
    - SECTION #4: (`z-index`: 6), stacked under an element (`z-index`: 4), which results in a rendering order of `4-6`
  - ARTICLE #1: (`z-index`: 5), which results in a rendering order of `5-0`

Additional examples

Additional examples include a 2-level hierarchy with `z-index` on the last level, a 2-level HTML hierarchy, `z-index` on all levels, and a 3-level HTML hierarchy, `z-index` on the second level.

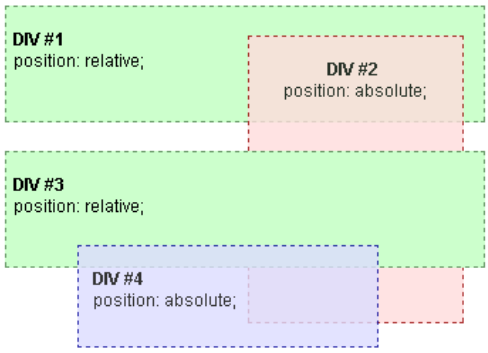
Stacking context example 1

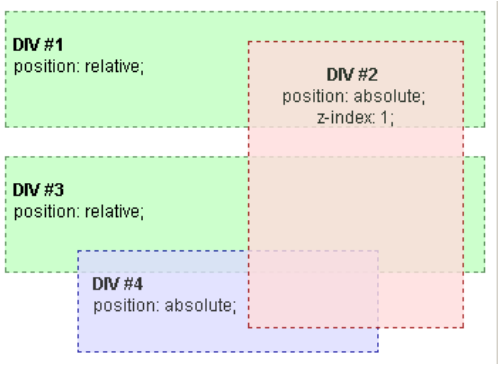
Description

Let's start with a basic example. In the root stacking context, there are two relatively positioned `<div>` elements (DIV #1 and DIV #3) without `z-index` properties. Inside DIV #1, there is an absolutely positioned DIV #2, while in DIV #3, there is an absolutely positioned DIV #4, both without `z-index` properties.

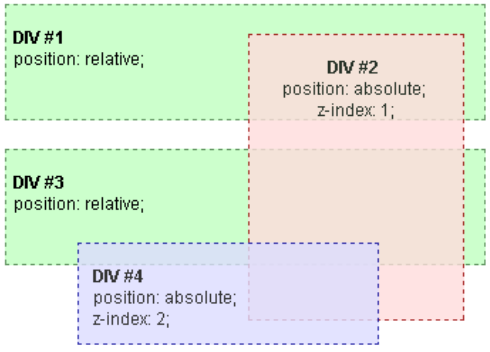
The only stacking context is the root context. Without `z-index` values, elements are stacked in order of occurrence.



If DIV #2 is assigned a positive (non-zero and non-auto) z-index value, it is rendered above all the other DIVs.



Then if DIV #4 is also assigned a positive z-index greater than DIV #2's z-index, it is rendered above all the other DIVs including DIV #2.



In this last example you can see that DIV #2 and DIV #4 are not siblings, because they belong to different parents in the HTML elements' hierarchy. Even so, stacking of DIV #4 with respect of DIV #2 can be controlled through `z-index`. It happens that, since DIV #1 and DIV #3 are not assigned any `z-index` value, or any other features that create a stacking context, they do not create a stacking context. This means that all their content, including DIV #2 and DIV #4, belongs to the same root stacking context.

In terms of stacking contexts, DIV #1 and DIV #3 are assimilated into the root element, and the resulting hierarchy is the following:

- Root stacking context
  - DIV #2 (`z-index`: 1)
  - DIV #4 (`z-index`: 2)

> **Note:** DIV #1 and DIV #3 are not translucent. It is important to remember that assigning an opacity value of less than `1` to an element implicitly creates a stacking context, as does adding a `z-index` value to a positioned element. This example also shows what happens when a parent element doesn't create a stacking context.

Example

HTML

```
<div id="div1">
  <br /><span class="bold">DIV #1</span> <br />position: relative;
  <div id="div2">
    <br /><span class="bold">DIV #2</span> <br />position: absolute;
    <br />z-index: 1;
  </div>
</div>

<br />

<div id="div3">
  <br /><span class="bold">DIV #3</span> <br />position: relative;
  <div id="div4">
    <br /><span class="bold">DIV #4</span> <br />position: absolute;
    <br />z-index: 2;
  </div>
</div>
```

CSS

```
.bold {
  font-family: "Arial";
  font-size: 12px;
  font-weight: bold;
}

#div1,
#div3 {
  height: 80px;
  position: relative;
  border: 1px dashed #669966;
  background-color: #ccffcc;
  padding-left: 5px;
}

#div2 {
  opacity: 0.8;
  z-index: 1;
  position: absolute;
  width: 150px;
  height: 200px;
  top: 20px;
  left: 170px;
  border: 1px dashed #990000;
  background-color: #ffdddd;
  text-align: center;
}

#div4 {
  opacity: 0.8;
  z-index: 2;
  position: absolute;
  width: 200px;
  height: 80px;
  top: 65px;
  left: 50px;
  border: 1px dashed #000099;
  background-color: #ddddff;
  text-align: left;
  padding-left: 10px;
}
```

Stacking context example 2

Description

This is a basic example, but it is the key for understanding the concept of *stacking context*. There are the same four DIVs of the previous example, but now `z-index` properties are assigned on both levels of the hierarchy.

You can see that DIV #2 (`z-index`: 2) is above DIV #3 (`z-index`: 1), because they both belong to the same stacking context (the root one), so z-index values rule how elements are stacked.

What can be considered strange is that DIV #2 (`z-index`: 2) is above DIV #4 (`z-index`: 10), despite their z-index values. The reason is that they do not belong to the same stacking context. DIV #4 belongs to the stacking context created by DIV #3, and as explained previously DIV #3 (and all its content) is under DIV #2.

To better understand the situation, this is the stacking context hierarchy:

- Root stacking context
  - DIV #2 (`z-index`: 2)
  - DIV #3 (`z-index`: 1)
    - DIV #4 (`z-index`: 10)

> **Note:** It is worth remembering that the HTML hierarchy is different from the stacking context hierarchy. In the stacking context hierarchy, elements that do not create a stacking context are collapsed on their parent.

Example

HTML

```
<div id="div1">
  <br />
  <span class="bold">DIV #1</span><br />
  position: relative;
  <div id="div2">
    <br />
    <span class="bold">DIV #2</span><br />
    position: absolute;<br />
    z-index: 2;
  </div>
</div>

<br />

<div id="div3">
  <br />
  <span class="bold">DIV #3</span><br />
  position: relative;<br />
  z-index: 1;
  <div id="div4">
    <br />
    <span class="bold">DIV #4</span><br />
    position: absolute;<br />
    z-index: 10;
  </div>
</div>
```

CSS

```
div {
  font: 12px "Arial";
}

span.bold {
  font-weight: bold;
}

#div2 {
  z-index: 2;
}
#div3 {
  z-index: 1;
}
#div4 {
  z-index: 10;
}

#div1,
#div3 {
  height: 80px;
  position: relative;
  border: 1px dashed #669966;
  background-color: #ccffcc;
  padding-left: 5px;
}

#div2 {
  opacity: 0.8;
  position: absolute;
  width: 150px;
  height: 200px;
  top: 20px;
  left: 170px;
  border: 1px dashed #990000;
  background-color: #ffdddd;
  text-align: center;
}

#div4 {
  opacity: 0.8;
  position: absolute;
  width: 200px;
  height: 70px;
  top: 65px;
  left: 50px;
  border: 1px dashed #000099;
  background-color: #ddddff;
  text-align: left;
  padding-left: 10px;
}
```

Stacking context example 3

Description

This example shows problems that arise when mixing several positioned elements in a multi-level HTML hierarchy and when `z-index` values are assigned using class selectors.

The example has a three-level hierarchical menu made from several positioned `div` elements. Second-level and third-level `div` elements appear when a user hovers or clicks on their parents. Usually this kind of menu is script-generated either client-side or server-side, so style rules are assigned with a class selector instead of the id selector.

If the three menu levels partially overlap, then managing stacking could become a problem.

The first-level menu is relatively positioned, creating a stacking context.

The second-level menu is absolutely positioned inside the parent element. In order to put it above all first-level menus, the `z-index` property is used. The problem is that for each second-level menu, a stacking context is created and each third-level menu belongs to the context of its parent.

So a third-level menu will be stacked under the following second-level menus, because all second-level menus share the same z-index value and the default stacking rules apply.

To better understand the situation, here is the stacking context hierarchy (the three dots "..." represent multiple repetition of the previous line):

- Root stacking context
    - LEVEL #1
        - LEVEL #2 (`z-index`: 1)
            - LEVEL #3
            - ...
            - LEVEL #3
        - LEVEL #2 (`z-index`: 1)
        - ...
        - LEVEL #2 (`z-index`: 1)
    - LEVEL #1
    - ...
    - LEVEL #1

This problem can be avoided by removing overlapping between different level menus, or by using individual (and different) `z`-index values assigned through the id selector instead of class selector, or by flattening the HTML hierarchy.

> **Note:** In the source code you will see that second-level and third level menus are made of several `div` elements contained in an absolutely positioned container. This is useful to group and position all of them at once.

Example

HTML

```
<div class="lev1">
  LEVEL #1

  <div id="container1">
    <div class="lev2">
      LEVEL #2 <br />z-index: 1;

      <div id="container2">
        <div class="lev3">LEVEL #3</div>
        <div class="lev3">LEVEL #3</div>
        <div class="lev3">LEVEL #3</div>

- Stacking context example 2: 2-level HTML hierarchy, `z-index` on all levels

Stacking floating elements

For floating elements, the stacking order is a bit different. Floating elements are placed between non-positioned elements and positioned elements:

1. The background and borders of the root element.
2. Descendant non-positioned elements, in order of appearance in the HTML.
3. *Floating elements*.
4. Descendant positioned elements, in order of appearance in the HTML.

See types of positioning for an explanation of positioned and non-positioned elements.

> **Note:** If an `opacity` value is applied to a non-positioned element (i.e., DIV #4 in the example below), something strange happens: the background and border of that block pop up above the floating blocks and the positioned blocks. This is due to a peculiar part of the specification: applying an `opacity` value creates a new stacking context (see What No One Told You About Z-Index).

Example

You can see in this example that the background and border of the non-positioned element (DIV #4) is completely unaffected by floating elements, but the content is affected. This happens according to standard float behavior which can be shown with a rule added to the above list:

1. The background and borders of the root element.
2. Descendant non-positioned elements, in order of appearance in the HTML.
3. Floating elements.
4. *Descendant non-positioned inline elements*.
5. Descendant positioned elements, in order of appearance in the HTML.

HTML

```
<div id="abs1"><strong>DIV #1</strong><br />position: absolute;</div>

<div id="flo1"><strong>DIV #2</strong><br />float: left;</div>

<div id="flo2"><strong>DIV #3</strong><br />float: right;</div>

<br />

<div id="sta1"><strong>DIV #4</strong><br />no positioning</div>

<div id="abs2"><strong>DIV #5</strong><br />position: absolute;</div>

<div id="rel1"><strong>DIV #6</strong><br />position: relative;</div>
```

CSS

```
div {
  padding: 10px;
  text-align: center;
}

strong {
  font-family: sans-serif;
}

#abs1 {
  position: absolute;
  width: 150px;
  height: 200px;
  top: 10px;
  right: 140px;
  border: 1px dashed #990000;
  background-color: #ffdddd;
}

#sta1 {
  height: 100px;
  border: 1px dashed #999966;
  background-color: #ffffcc;
  margin: 0px 10px;
  text-align: left;
}

#flo1 {
  margin: 0px 10px 0px 20px;
  float: left;
  width: 150px;
  height: 200px;
  border: 1px dashed #009900;
  background-color: #ccffcc;
}

#flo2 {
  margin: 0px 20px 0px 10px;
  float: right;
  width: 150px;
  height: 200px;
  border: 1px dashed #009900;
  background-color: #ccffcc;
}

#abs2 {
  position: absolute;
  width: 150px;
  height: 100px;
  top: 80px;
  left: 100px;
  border: 1px dashed #999900;
  background-color: #ffdddd;
}

#rel1 {
  position: relative;
  border: 1px dashed #999966;
  background-color: #ccffff;
  margin: 0px 10px;

Stacking without the z-index property

When the `z-index` property is not specified on any element, elements are stacked in the following order (from bottom to top):

1. The background and borders of the root element.
2. Descendant non-positioned elements, in order of appearance in the HTML.
3. Descendant positioned elements, in order of appearance in the HTML.

See types of positioning for an explanation of positioned and non-positioned elements.

Keep in mind, when the `order` property alters rendering from the *order of appearance in the HTML* within `flex` containers, it similarly affects the order for stacking context.

Example

In this example, DIV #1 through DIV #4 are positioned elements. DIV #5 is static, and so is drawn below the other four elements, even though it comes later in the HTML markup.

HTML

```
<div id="abs1" class="absolute">
  <strong>DIV #1</strong><br />position: absolute;
</div>
<div id="rel1" class="relative">
  <strong>DIV #2</strong><br />position: relative;
</div>
<div id="rel2" class="relative">
  <strong>DIV #3</strong><br />position: relative;
```

```
</div>
<div id="abs2" class="absolute">
  <strong>DIV #4</strong><br />position: absolute;
</div>
<div id="sta1" class="static">
  <strong>DIV #5</strong><br />position: static;
</div>
```

CSS

```
strong {
  font-family: sans-serif;
}

div {
  padding: 10px;
  border: 1px dashed;
  text-align: center;
}

.static {
  position: static;
  height: 80px;
  background-color: #ffffcc;
  border-color: #999966;
}

.absolute {
  position: absolute;
  width: 150px;
  height: 350px;
  background-color: #ffdddd;
  border-color: #990000;
  opacity: 0.7;
}

.relative {
  position: relative;
  height: 80px;
  background-color: #ccffcc;
  border-color: #669966;
  opacity: 0.7;
}

#abs1 {
  top: 10px;
  left: 10px;
}

#rel1 {
  top: 30px;
  margin: 0px 50px;
}

#rel2 {
  top: 15px;
  left: 20px;
  margin: 0px 50px;
}

#abs2 {
  top: 10px;
  right: 10px;
}

#sta1 {
  background-color: #ffffcc;
  margin: 0px 50px;
}
```

Understanding z-index

In the most basic cases, when text, images, and other elements are arranged on the page without overlapping, HTML pages can be considered two-dimensional. In such cases, there is a single rendering flow, and all elements are aware of the space taken by others. CSS isn't that simple — CSS positioning, transformation, containment, and other features can cause elements to overlap. In this guide, we introduce the `z-index` property, which lets you place elements in front or behind other elements in the same stacking context.

Layers on the z-axis

The elements rendered on a page are comprised of a series of boxes. Each box has a position in three dimensions. In addition to their inline and block positions, boxes lie along a third dimension known as the *z-axis*. Controlling an element's z-axis position becomes especially relevant when element boxes overlap visually. Several property values can cause elements to overlap. The `z-index` property provides you a way to control how they overlap!

By default, element boxes are rendered on Layer 0. The `z-index` property allows you to position elements on different layers along the z-axis, in addition to the default rendering layer. Each element's position along the imaginary z-axis (z-index value) is expressed as an integer (positive, negative, or zero) and controls the stacking order during rendering. Greater numbers mean elements are closer to the observer.

If you are not familiar with the term 'z-axis', imagine the page as a stack of layers, each with an assigned number. Layers are rendered in numerical order, with larger numbers appearing on top of smaller numbers (*X* in the table below represents an arbitrary positive integer):

Layer	Description
Bottom layer	Farthest from the observer
Layer -X	Layers with negative `z-index` values
Layer 0	Default rendering layer
Layer X	Layers with positive `z-index` values
Top layer	Closest to the observer

Elements in normal flow

By default, when no `z-index` property is specified, elements are rendered on the default rendering layer (Layer 0).

Consider the following three elements:

```
<div id="div1">#1</div>
<div id="div2">#2</div>
<div id="div3">#3</div>
```

Without any positioning properties applied, these elements flow normally in document order, one after another, without overlapping.

```
div {
  height: 100px;
  width: 100px;
  outline: 1px dotted;
  line-height: 100px;
  font-size: 40px;
  text-align: center;
  font-family: "Helvetica", "Arial", sans-serif;
}

#div1 {
  background-color: lightpink;
}

#div2 {
  background-color: lightyellow;
}

#div3 {
  background-color: lightgreen;
}
```

Default layering behavior

To stack the elements, we can position them. If we use absolute positioning to place them in (almost) the same spot, the default stacking order follows the source order: the first element in the HTML appears at the bottom layer and the last element appears at the top layer.

```
div {
  position: absolute;
}

#div1 {
  top: 0;
  left: 0;
}

#div2 {
  top: 10px;
  left: 10px;
}

#div3 {
  top: 20px;
  left: 20px;
}
```

Rearranging layers

We can use the CSS `z-index` property to position each element along the z-axis, effectively rearranging the stacking order.

By adding `z-index` values, we change the default layer order:

```
#div1 {
  z-index: 5;
}

#div2 {
  z-index: -9;
}

#div3 {
  z-index: 0;
}
```

The element with the lowest `z-index` value appears on the bottom layer. The element with the highest `z-index` value appears on the top layer. In this example, `-9` is the lowest value, so `#div2` is behind all the others. The first element in the source order, `#div1`, has the greatest value, so it appears on top of all the others.

Impact of stacking contexts

Using `z-index` may appear fairly straightforward at first: a single property assigned a single integer number with a seemingly understandable behavior. When `z-index` is applied to complex hierarchies of HTML elements, many find the resulting behavior hard to understand or predict.

If the elements are not siblings, the stacking behavior can become more complicated because each element may belong to a different stacking context. This is shown in the example below.

```
<section>
  <div id="div1">#1</div>
```

```
  <div id="div2">#2</div>
</section>
<div id="div3">#3</div>
```

```
section {
  position: absolute;
  z-index: 2;
}
```

Even though the `z-index` value of `#div3` (`0`) is greater than that of `#div2` (`-9`), `#div2` appears above `#div3` because `#div1` and `#div2` are nested in a separate stacking context created by `<section>`. The `<section>` element and `#div3` are siblings, and since the `<section>` element's z-index is greater than that of `#div3` (`2` versus `0`), `#div3` is placed behind `<section>` and all of `<section>`'s contents. For more in-depth details about the topic, see our Stacking context guide.

Conclusion

As we've seen in this guide, `z-index` provides a way to control how elements stack along z-axis. You learned how the integer values of the `z-index` property can be used to alter the stacking order. However, as demonstrated in the last example, stacking orders can be complicated. Stacking orders follow a series of complex stacking rules to ensure that all browsers stack the same content in the same manner providing consistency and predictability. It's important to understand the features that create stacking contexts and how nested stacking contexts affect layer order.

Using z-index

The first article of this guide, Stacking without the `z-index` property, explains how stacking is arranged by default. If you want to create a custom stacking order, you can use the `z-index` property on a positioned element.

The `z-index` property can be specified with an integer value (positive, zero, or negative), which represents the position of the element along an imaginary z-axis. If you are not familiar with the term 'z-axis', imagine the page as a stack of layers, each one having a number. Layers are rendered in numerical order, with larger numbers above smaller numbers (*X* represents an arbitrary positive integer):

Layer	Description
Bottom layer	Farthest from the observer
Layer -X	Layers with negative `z-index` values
Layer 0	Default rendering layer
Layer X	Layers with positive `z-index` values
Top layer	Closest to the observer

> **Note:**
>
> - When no `z-index` property is specified, elements are rendered on the default rendering layer (Layer 0).
> - If several elements share the same `z-index` value (i.e., they are placed on the same layer), stacking rules explained in the section Stacking without the `z-index` property apply.

Example

In this example, the layers' stacking order is rearranged using `z-index`. The `z-index` of DIV #5 has no effect since it is not a positioned element.

HTML

```
<div id="abs1">
  <strong>DIV #1</strong>
  <br />position: absolute; <br />z-index: 5;
</div>

<div id="rel1">
  <strong>DIV #2</strong>
  <br />position: relative; <br />z-index: 3;
</div>

<div id="rel2">
  <strong>DIV #3</strong>
  <br />position: relative; <br />z-index: 2;
</div>

<div id="abs2">
  <strong>DIV #4</strong>
  <br />position: absolute; <br />z-index: 1;
</div>

<div id="sta1">
  <strong>DIV #5</strong>
  <br />no positioning <br />z-index: 8;
</div>
```

CSS

```
div {
  padding: 10px;
  opacity: 0.7;
  text-align: center;
}

strong {
  font-family: sans-serif;
}

#abs1 {
  z-index: 5;
  position: absolute;
```

```
  width: 150px;
  height: 350px;
  top: 10px;
  left: 10px;
  border: 1px dashed #990000;
  background-color: #ffdddd;
}

#rel1 {
  z-index: 3;
  height: 100px;
  position: relative;
  top: 30px;
  border: 1px dashed #669966;
  background-color: #ccffcc;
  margin: 0px 50px;
}

#rel2 {
  z-index: 2;
  height: 100px;
  position: relative;
  top: 15px;
  left: 20px;
  border: 1px dashed #669966;
  background-color: #ccffcc;
  margin: 0px 50px;
}

#abs2 {
  z-index: 1;
  position: absolute;
  width: 150px;
  height: 350px;
  top: 10px;
  right: 10px;
  border: 1px dashed #990000;
  background-color: #ffdddd;
}

#sta1 {
  z-index: 8;
  height: 70px;
  border: 1px dashed #999966;
  background-color: #ffffcc;
  margin: 0px 50px;
}
```

CSS properties and values API

The **CSS properties and values API** module defines a method for registering new CSS properties, defining the property's data type, inheritance behavior, and, optionally, an initial value. This API expands on CSS custom properties for cascading variables module, which allows authors to define custom properties in CSS using two dash syntax (`--`). The CSS properties and values API is part of the CSS Houdini umbrella of APIs.

Custom properties let you reuse values across a project to simplify complex or repetitive stylesheets. Basic custom properties are defined in the CSS custom properties for cascading variables module. The CSS properties and values API expands on that module, enabling adding metadata to custom properties using CSS with the `@property` at-rule or, alternatively, using JavaScript's `CSS.registerProperty` method.

Whether registered with CSS or JavaScript, setting metadata on custom properties provides for an expected data type that the browser can use depending on the context, defines an initial value, and lets you control inheritance.

CSS properties and values API custom property registration is more robust than the more basic CSS cascading variable custom property declaration, especially when it comes to transitioning and animating values as browsers can interpolate between custom values of this type, whereas properties that use two dash syntax (`--`) behave more like a string substitution.

Properties and values API in action

To see how custom properties and values can be used via API, hover over the box below.

```
CSS.registerProperty({
  name: "--stop-color",
  syntax: "<color>",
  inherits: false,
  initialValue: "cornflowerblue",
});
```

```
.box {
  padding: 1rem;
  width: 90%;
  height: 4rem;
  font-family: sans-serif;
  font-size: large;
  color: white;
  border-radius: 0.5rem;
}

.box {
  background: linear-gradient(to right, var(--stop-color), lavenderblush);
  transition: --stop-color 2s;
}

.box:hover {
```

```
  --stop-color: aquamarine;
}
```

```
<div class="box"><p>Linear gradient with transition</p></div>
```

The box has a background consisting of a linear gradient from `--stop-color` (the custom property) to `lavenderblush`. The value of `--stop-color` is set to `cornflowerblue` at first, but when you hover over the box, `--stop-color` transitions to `aquamarine` over two seconds (`linear-gradient(to right, aquamarine, lavenderblush)`).

CSS Houdini

CSS Houdini is a set of APIs that expose parts of the CSS engine, enabling developers to create CSS extensions. These extensions might polyfill features that are not yet available in browsers, experiment with new layout techniques, or add creative borders and other effects.

While many Houdini examples showcase the creative possibilities of the APIs, there are many practical use cases. For example, you can use Houdini to create advanced custom properties with type checking and default values.

Basic example

A regular CSS custom property consists of a property name and a value. Therefore I might create a custom property called `--background-color` and expect it to be given a color value. The value is then used in the CSS as if it were the color value.

```
:root {
  --background-color: blue;
}

.box {
  background-color: var(--background-color);
}
```

In the above example however, there is nothing to stop someone using some other value for this property, perhaps setting it to a length. Having done so, anywhere that the property is used would have no background color as `background-color: 12px` is not valid. When browsers come across CSS they don't recognize as valid they throw that line away.

Using `@property` however, we can declare the custom property with a `syntax` of `<color>`. This shows that we need this property to have a value which is a valid color.

```
@property --background-color {
  syntax: "<color>";
  inherits: false;
  initial-value: blue;
}
```

Houdini worklets

A feature of Houdini is the `Worklet`. A worklet is a module, written in JavaScript, that extends CSS using one of the Houdini APIs. You can see an example worklet on the `PaintWorkletGlobalScope.registerPaint()` page. Once a worklet has been registered you can use it in CSS just like any other value. This means that even if you are not a JavaScript developer, you can access Houdini APIs by using worklets other people have created.

Registering custom properties in CSS

The `@property` at-rule, part of the CSS Houdini set of APIs, allows developers to explicitly define CSS custom properties. In this guide, we learn how to use `@property` for type checking and constraining, set default custom property values in CSS, and define whether a custom property can inherit values or not.

Why register custom properties?

CSS custom properties, commonly called CSS variables, can be defined by basic declaration. Generally, these are declared on the `:root`, and can be overridden with a different value in subsequent rulesets — including in rules based on UI state and within container and media queries.

In this example, `--myColor` is assigned the value `#bada55` on `:root`, then set to a different value on `main`, which is inherited by all descendants of `main`. That value is overridden when `main` is hovered or is in a viewport that is less than `750px` wide. Within elements with a class of `circles`, `--myColor` is set to `45deg`, which is a different data type.

```
:root {
  --myColor: #bada55;
}
main {
  --myColor: #cacaca;
}
main:hover {
  --myColor: #aabbbbaa;
}
@media (width < 750px) {
  main {
    --myColor: #aabbbbaa;
  }
}

.circles {
  --myColor: 45deg;
}
```

The CSS properties and values API provides methods of registering custom properties. Registering CSS custom properties sets the variable's type, inheritance, and default value, making them more predictable and performant.

Registered properties are validated when they're computed rather than when they are parsed. This means that:

- Invalid values won't appear as invalid when inspecting the element's properties.
- An invalid property included after a valid one won't fall back to the valid property. An invalid property will, however, fall back to its registered default.

By default, all CSS variables inherit. When you change a non-registered variable value, the browser re-parses the DOM to check which elements in the DOM tree are affected. With registered properties, setting the value `inherits: false;` tells the browser that, if the value changes, the children don't need to be reparsed, narrowing the scope of style recalculation.

Generally, you'll want to register your custom properties if you are animating the variable, implementing type checking, or guaranteeing predictable inheritance behavior. If you're creating a CSS framework, namespace and register your custom properties to ensure that they always have a default value, and prevent framework users from assigning invalid data types to them if they change their values.

In CSS, properties are registered using the `@property` at-rule. In this example, `--myColor` is globally registered as an inheritable color with the value `#bada55`, and used in `main` in the hovered state. The registration improves the animation performance because the value is of the correct type, and the browser doesn't need to parse the value before animating it. The `.circles` assignment is ignored because the property's data type is registered as `<color>`, not `<angle>`.

```
@property --myColor {
  syntax: "<color>";
  inherits: true;
  initial-value: #bada55;
}

main:hover {
  color: var(--myColor);
  animation: color-change 2s linear forwards;
}

@keyframes color-change {
  to {
```

```
    color: red;
  }
}

.circles {
  --myColor: 45deg;
}
```

The @property and descriptors

The `@property` rule enables custom property registration directly inside stylesheets without requiring any JavaScript. Valid `@property` rules produce registered custom properties, producing the same effect as calling `registerProperty()` with equivalent parameters.

The custom property name is a `<dashed-ident>` that starts with `--` and is followed by a valid, user-defined identifier. It is case-sensitive. The declaration includes up to three descriptors: `syntax`, `inherits`, and `initial-value`.

In this example, we create a `--rotation` custom property.

```
@property --rotation {
  syntax: "<angle>";
  inherits: false;
  initial-value: 45deg;
}
```

@property descriptors

For the `@property` rule to be valid, it must include both the `syntax` and `inherits` descriptors. The `initial-value` descriptor is optional.

`syntax`

> The `syntax` descriptor is a string that describes the allowed value types for the registered custom property. The value of the descriptor may be a data type name, such as `<color>`, `<length>`, or `<number>`, with multipliers (`+`, `#`) and combinators (`|`), or a custom ident. In our example, the `--rotation` property is set to `<angle>`, meaning it can only be assigned an `<angle>` value.

`inherits`

> The `inherits` descriptor is a boolean value that controls whether the custom property inherits by default: set it to `true` to have it inherit, `false` to not inherit. See Registering and using custom properties for an example of both values.

`initial-value`

> The `@property` at-rule also accepts the `initial-value` descriptor. The value defines the starting value for the property. This descriptor is optional only if the value of the `syntax` descriptor is the universal syntax definition (that is, `syntax: "*"`). If the syntax has any other values, it is required and has to be a *computationally independent* value, meaning the value can't be of a data-type that is dependent on another value, such as values with `%` or `em` units.

If either the `syntax` or `inherits` descriptor is missing, the entire `@property` rule is invalid and ignored. If the `initial-value` descriptor is required but omitted, the entire `@property` rule is invalid and ignored. Unknown descriptors are invalid and ignored, but do not invalidate the `@property` rule.

Registering and using custom properties

In this example, we will define two custom properties: `--item-size` and `--item-color`. We'll then use these custom properties to define the size (width and height) and background color of the three following items.

```
<div class="container">
  <div class="item one">Item one</div>
  <div class="item two">Item two</div>
  <div class="item three">Item three</div>
</div>
```

Here we use the CSS `@property` at-rule to define the `--item-size` custom property. We set its initial value to `40%` and limit valid values to `<percentage>` values only. This means that when this property is used to size an element, the element's size will always be relative to its parent's size. The property is inheritable.

```
@property --item-size {
  syntax: "<percentage>";
  inherits: true;
  initial-value: 40%;
}
```

You can also use JavaScript to register properties. JavaScript's `CSS.registerProperty()` method is equivalent to the `@property` at-rule. Here we defined our second custom property, `--item-color`, to have an initial value of `aqua`, to accept only `<color>` values, and to not be inherited.

```
window.CSS.registerProperty({
  name: "--item-color",
  syntax: "<color>",
  inherits: false,
  initialValue: "aqua",
});
```

See the JavaScript API guide to registering custom properties for more information.

Using registered custom properties

We can assign new values to registered properties. Here, we set custom property values on the parent container, then set custom property values on the items themselves. The values set on `two` are valid while the values set on `three` are invalid.

```
.container {
  --item-size: 20%;
  --item-color: orange;
}
.two {
  --item-size: initial;
  --item-color: inherit;
}
.three {
  --item-size: 1000px;
  --item-color: xyz;
}
```

We use the two custom properties as values for the items' `width`, `height`, and `background-color` properties:

```
.item {
  width: var(--item-size);
  height: var(--item-size);
  background-color: var(--item-color);
}
```

```
.container {
  display: flex;
  height: 200px;
  border: 1px dashed black;
}
```

Inheritance

The `inherits` descriptor controls whether or not the registered CSS custom property inherits by default.

In our example, the size property was set to be inheritable; the color was not. The two custom properties, `--item-size: 20%` and `--item-color: orange;` were set on the `container` parent, overriding the `40%` and `aqua` default values set when these custom properties were defined.

For item one, none of these custom properties were set. Because the `--item-size` is inheritable, the value `20%` set on its parent `container` was inherited and used. The property `--item-color` was not inheritable, so the value `orange` set on the parent was not considered. Instead, the default initial value `aqua` was used.

The `inherits` descriptor is a required descriptor; if it were missing or invalid, the entire `@property` rule would have been invalid and ignored.

Valid and invalid values

A benefit of registering your custom properties (versus using simple declarations) is that they can be set to be reassigned only to valid values. The `syntax` descriptor defines which values are valid. Any declaration with a value that doesn't meet those constraints will be ignored.

For item two, CSS global keywords were set for both custom properties. The CSS global keyword values — `initial`, `inherit`, `unset`, `revert`, and `revert-layer` — are valid values for all value types and therefore valid no matter the `syntax` descriptor value. The `--item-size` was set to `initial` and therefore used the `initial-value: 40%;` set in the `@property` declaration. The `--item-color` was set to `inherit`, explicitly inheriting the `orange` value from its parent even though the custom property was set to otherwise not be inherited. This is why item two was orange.

For item three, the `--item-size` value was set to `1000px`. While `1000px` is a `<length>` value, the `@property` declaration requires the value be a `<percentage>`, so the declaration was not valid and was ignored, meaning the inheritable `20%` set on the parent was used. The `xyz` value was also invalid. As `registerProperty()` set `--item-color` to not be inherited, the default initial value of `aqua` was used and not the parent's `orange` value.

Animating custom property values

Registered CSS custom properties offer a performance edge because they are treated as typed data rather than strings, providing the browser's rendering engine with a defined syntax and inheritance rules. The browser parses the defined syntax once; when that variable is used elsewhere, the type and internal representation are already known, so it doesn't need to be re-parsed.

Because non-registered custom properties are just strings, the browser cannot interpolate them, so it cannot smoothly animate them. Instead, non-registered custom property values are animated discretely. Registered variables can be interpolated and therefore animated; their interpolation calculations are offloaded to the GPU, which is more performant than animations done on the main thread.

See Animating a custom property value for an animation example.

CSS pseudo-elements

The **CSS pseudo-element** module defines abstract elements that are not directly present in the document tree. These abstract elements, called pseudo-elements, represent portions of the render tree that can be selected and styled. Pseudo-elements are used to create abstractions about the document tree beyond those provided by the document tree.

> **Note:** This page introduces a CSS module. To find an exhaustive list of all pseudo-elements defined by CSS specifications, see the pseudo-elements reference page.

Pseudo-elements are prefixed with a double colon (`::`). You add pseudo-elements to selectors (as in `p::first-line`) to target and style these faux elements.

Pseudo-elements enable targeting entities not included in HTML and sections of content that cannot be targeted otherwise without adding extra markup. Consider the placeholder of an `<input>` element. This is an abstract element and not a distinct node in the document tree. You can select this placeholder by using the `::placeholder` pseudo-element. As another example, the `::selection` pseudo-element matches the content currently highlighted by a user, allowing you to style what is matched as the user interacts with the content and changes the selection. Similarly, the `::first-line` pseudo-element targets the first line of an element, updating automatically if the character count of the first line changes, without having to query the element's line length.

CSS ruby layout

The **CSS ruby layout** module provides the rendering model and formatting controls related to the display of ruby annotations. Ruby annotations are a form of interlinear annotation, consisting of short runs of text alongside the base text. They are typically used in East Asian documents to indicate pronunciation or define meaning.

Reference

Properties

- `ruby-align`
- `ruby-position`

The CSS ruby layout module also introduces the `ruby-merge` and `ruby-overhang` properties. Currently, no browsers support these features.

Display values

The CSS ruby layout module adds the following values to the `display` property:

- `ruby`
- `ruby-base`
- `ruby-text`
- `ruby-base-container`
- `ruby-text-container`

Glossary terms

- Ruby

CSS scoping

The **CSS scoping** module defines the CSS scoping and encapsulation mechanisms, focusing on the Shadow DOM scoping mechanism.

CSS styles are either global in scope or scoped to a shadow tree. Globally scoped styles apply to all the elements in the node tree that match the selector, including custom elements in that tree, but not to the shadow trees composing each custom element. Selectors and their associated style definitions don't bleed between scopes.

Within the CSS of a shadow tree, selectors don't select elements outside the tree, either in the global scope or in other shadow trees. Each custom element has its own shadow tree, which contains all the components that make up the custom element (but not the custom element, or "host", itself).

Sometimes it's useful to be able to style a host from inside the shadow tree context. The CSS scoping module makes this possible by defining selectors that:

- Enable a shadow tree to style its host.
- Enable external CSS to style elements within a shadow DOM (but only if the associated custom element is set up to accept external styles).

Reference

Selectors

- `:host`
- `:host()`
- `:host-context()`
- `::slotted`

CSS scroll anchoring

The **CSS scroll anchoring** module defines a mechanism to prevent page movement due to DOM changes above the visible region of a scrolling box while the user is consuming the visible content.

Scroll anchoring attempts to keep the user's view of the document stable across layout changes. It works by selecting a DOM node (the anchor node) whose movement is used to determine adjustments to the scroll position. The anchor node is always a descendant of the scrolling box.

For scroll containers that are snapped to an element, scroll anchoring is limited to adjustments that would be allowed by re-snapping.

Overview of scroll anchoring

As a user of the web, you are probably familiar with the problem that scroll anchoring solves. You browse to a long page on a slow connection and begin to scroll to read the content; while you are busy reading, the part of the page you are looking at suddenly jumps. This has happened because large images or some other elements have just loaded further up in the content.

Scroll anchoring is a browser feature that aims to solve this problem of content jumping, which happens if content loads in after the user has already scrolled to a new part of the document.

How does it work?

Scroll anchoring adjusts the scroll position to compensate for the changes outside of the viewport. This means that the point in the document the user is looking at remains in the viewport, which may mean their scroll position actually changes in terms of how *far* they have moved through the document.

How do I turn on scroll anchoring?

You don't! The feature is enabled by default in supporting browsers. In most cases anchored scrolling is exactly what you want — content jumping is a poor experience for anyone.

What if I need to debug it?

If your page is not behaving well with scroll anchoring enabled, it is probably because some `scroll` event listener is not handling the extra scrolling to compensate for the anchor node movement.

You can check whether disabling scroll anchoring fixes the issue in Firefox by changing `layout.css.scroll-anchoring.enabled` to `false` in `about:config`. You can also check what node Firefox is using as the anchor using the `layout.css.scroll-anchoring.highlight` switch. That will show a purple overlay on top of the anchor node.

If a node doesn't seem to be an appropriate anchor, you can exclude it using `overflow-anchor`, as described below.

What if I need to disable it?

The CSS scroll anchoring module provides the `overflow-anchor` property, which can be used to disable scroll anchoring on all or part of the document. It's essentially a way to opt out of the behavior.

The only possible values are `auto` or `none`:

- `auto` is the initial value; as long as the user's browser supports scroll anchoring, the behavior will happen, and they should see fewer content jumps.
- `none` means that you have explicitly opted the document, or part of the document, out of scroll anchoring.

To opt out the entire document, you can set it on the `<body>` element:

```
body {
  overflow-anchor: none;
}
```

To opt out of scroll anchoring for a section of the document, set `overflow-anchor: none` on the section's container element:

```
.container {
  overflow-anchor: none;
}
```

If opting out of scroll anchoring on the document or a section thereof, a descendant of an opted-out area cannot be opted back in. For example, if you opt out the entire document, you can't set `overflow-anchor: auto` on a descendant node to turn scroll anchoring back on for a subsection.

Suppression triggers

There are some *suppression triggers*, which disable scroll anchoring in places where it might be problematic. If any of the triggers happen on the anchor node, or an ancestor of it, anchoring is suppressed.

These suppression triggers are changes to the computed value of any of the following properties:

- `top`, `left`, `right`, or `bottom`
- `margin` or `padding`
- Any `width` or `height`-related properties
- `transform` and the individual transform properties `translate`, `scale`, and `rotate`

Additionally, `position` changes anywhere inside the scroll container also disable scroll anchoring.

To conditionally apply styles based on whether scroll anchoring can be disabled, use `@supports` feature queries to test support for the `overflow-anchor` property.

CSS scroll snap

The **CSS scroll snap** module provides properties that let you control the panning and scrolling behavior by defining snap positions. Content can be snapped into position as the user scrolls overflowing content within a scroll container, providing paging and scroll positioning.

This module includes the scroll container scroll-padding properties to adjust the optimal viewing region of paging during scroll-into-view operations. It also includes scroll-margin and scroll-alignment, set on the scroll container's children, to adjust the children's visual area when that child is scrolled into view, as well as a property to force scrolling to stop on individual children.

Scroll snap in action

To view scroll snapping in the box below, scroll up-and-down and left-and-right through the grid of 45 numbered boxes in the scrollable viewport. Click "Play" in the example below to view or edit the source in the MDN Playground:

```
const positions = ["start", "center", "end"];
const inlineDirection = document.getElementById("inline");
const blockDirection = document.getElementById("block");
const stop = document.getElementById("stop");
const snap = document.getElementById("snap");
const all = document.querySelector("article");
const rules = document.getElementById("css-output").sheet.cssRules;

setSST();
setSSA();

inlineDirection.addEventListener("change", () => {
  setSSA();
});
blockDirection.addEventListener("change", () => {
  setSSA();
});
stop.addEventListener("change", () => {
  setSST();
});
snap.addEventListener("change", () => {
  all.classList.toggle("snapDisabled");
});

function setSSA() {
  rules[0].style.scrollSnapAlign = `${positions[blockDirection.value]} ${
    positions[inlineDirection.value]
  }`;
}

function setSST() {
  if (stop.checked) {
    rules[0].style.scrollSnapStop = "always";
  } else {
    rules[0].style.scrollSnapStop = "normal";
  }
}
```

```

```

```
    height: 12.5vw;
    width: 12.5vw;
    outline: 3px inset;
    list-style-type: none;
    background: white;
    font-family: monospace;
    font-size: 3rem;
    line-height: 12vw;
    text-align: center;
    counter-increment: items 1;
  }
  li::after {
    content: counter(items);
  }
  input {
    vertical-align: bottom;
  }
  p {
    font-family: monospace;
  }
}
```

With scroll snap, one of the numbered boxes that you scroll to will snap into place. The initial CSS makes the numbered box snap into the center of the viewport. Use the sliders to change the block and inline snap positions.

Using snap properties, you can allow or block the scrolling past an element, a numbered box in this case. Select the "Prevent scrolling past boxes" checkbox to force all scrolling actions to be limited to scrolling to an adjacent box.

To compare scroll snapping to regular scrolling, check the "disable snapping" checkbox and try scrolling again.

Basic concepts of scroll snap

The properties in the CSS scroll snap module enable you to define how scrolling snaps to specific points as a user scrolls through a document.

The scroll snap feature lets you define the snap positions where a scroll container's scrollport may end or "snap to" after a scrolling operation has completed.

Key properties for CSS scroll snap

Before you can define scroll snapping, you need to enable scrolling on a scroll container. You can do this by ensuring that the scroll container has a defined size and that it has `overflow` enabled.

You can then define scroll snapping on the scroll container by using the following two key properties:

- `scroll-snap-type`: Using this property, you can define whether or not the scrollable viewport can be snapped to, whether snapping is required or optional, and the axis on which the snapping should occur.
- `scroll-snap-align`: This property is set on every child of the scroll container and you can use it to define each child's snap position or lack thereof.
- `scroll-snap-stop`: This property ensures that a child is snapped to during scrolling and not passed over.
- `scroll-margin`: This property can be set on child elements that are snapped to during scrolling to create an outset from the defined box.
- `scroll-padding`: This property can be set on the scroll container to create a snapping offset.

The example below demonstrates scroll snapping along the vertical axis, which is defined by `scroll-snap-type`. Additionally, `scroll-snap-align` applies on all the children of the `<section>` element, dictating the point where the scrolling of each child should stop.

```
<article class="scroller">
  <section>
    <h2>Section one</h2>
  </section>
  <section>
    <h2>Section two</h2>
  </section>
  <section>
    <h2>Section three</h2>
  </section>
</article>
```

```
body {
  font: 1.2em / 1.5 sans-serif;
}

.scroller {
  border: 4px solid #333333;
  width: 300px;
}

.scroller section {
  min-height: 100%;
  padding: 10px;
}

.scroller section:nth-child(odd) {
  background-color: #cccccc;
}
```

```
.scroller {
  height: 300px;
  overflow-y: scroll;
  scroll-snap-type: y mandatory;
}

.scroller section {
  scroll-snap-align: start;
}
```

Using scroll-snap-type

The `scroll-snap-type` property needs to know the axis along which scroll snapping happens. This can be `x`, `y`, or the logical mappings `block` or `inline`. You can also use the keyword `both` to have scroll snapping work along both axes.

You can also pass in the keywords `mandatory` or `proximity`. The `mandatory` keyword tells the browser whether the content *has* to snap to a certain point, no matter where the scroll is. The `proximity` keyword means that the content may snap to the point, but does not have to.

Using `mandatory` creates a very consistent scrolling experience — you know the browser will always snap to each defined point. This means that you can be confident that something you expect to be at the top of the screen will be there when scrolling finishes. However, it can cause problems if the content is larger than you expect — users may find themselves in the frustrating position of never being able to scroll and view a certain point in the content. Therefore, the use of `mandatory` should be carefully considered and only used in situations where you know how much content is on the screen or scrollable section at any time.

> **Note:** Never use `mandatory` if the content inside one of your child elements will overflow the parent container because user will not be able to scroll the overflowing content into view.

The `proximity` value only snaps child elements to a position when it is close by, with the browsers determining the exact distance. Click "Play" to edit the example below in the MDN Playground. Alternate the `scroll-snap-type` value between `mandatory` and `proximity` to see the effect this has on the scroll experience.

```
<article class="scroller">
  <section>
```

```
    <h2>Section one</h2>
    <p>
      Turnip greens yarrow ricebean rutabaga endive cauliflower sea lettuce
      kohlrabi amaranth water spinach avocado daikon napa cabbage asparagus
      winter purslane kale. Celery potato scallion desert raisin horseradish
      spinach carrot soko.
    </p>
  </section>
  <section>
    <h2>Section two</h2>
    <p>
      Turnip greens yarrow ricebean rutabaga endive cauliflower sea lettuce
      kohlrabi amaranth water spinach avocado daikon napa cabbage asparagus
      winter purslane kale. Celery potato scallion desert raisin horseradish
      spinach carrot soko.
    </p>
  </section>
  <section>
    <h2>Section three</h2>
    <p>
      Turnip greens yarrow ricebean rutabaga endive cauliflower sea lettuce
      kohlrabi amaranth water spinach avocado daikon napa cabbage asparagus
      winter purslane kale. Celery potato scallion desert raisin horseradish
      spinach carrot soko.
    </p>
  </section>
</article>
```

```
body {
  font: 1.2em / 1.5 sans-serif;
}

.scroller {
  border: 4px solid #333333;
  width: 300px;
}

.scroller section {
  min-height: 100%;
  padding: 10px;
}

.scroller section:nth-child(odd) {
  background-color: #cccccc;
}
```

```
.scroller {
  height: 300px;
  overflow-y: scroll;
  scroll-snap-type: y mandatory;
}

.scroller section {
  scroll-snap-align: start;
}
```

In the above example, both `height: 300px;` and `overflow-y: scroll;` are set on the scroll container. If the content doesn't overflow its container, there is nothing to scroll.

Using scroll-snap-align

The valid values for the `scroll-snap-align` property include `start`, `end`, `center`, and `none`. These values are used to indicate the point in the scroll container to which the content should snap. Click "Play" in the example below and change the value of `scroll-snap-align` to see how this changes the scroll behavior.

```
<article class="scroller">
  <section>
    <h2>Section one</h2>
    <p>
      Turnip greens yarrow ricebean rutabaga endive cauliflower sea lettuce
      kohlrabi amaranth water spinach avocado daikon napa cabbage asparagus
      winter purslane kale. Celery potato scallion desert raisin horseradish
      spinach carrot soko.
    </p>
  </section>
  <section>
    <h2>Section two</h2>
    <p>
      Turnip greens yarrow ricebean rutabaga endive cauliflower sea lettuce
      kohlrabi amaranth water spinach avocado daikon napa cabbage asparagus
      winter purslane kale. Celery potato scallion desert raisin horseradish
      spinach carrot soko.
    </p>
  </section>
  <section>
    <h2>Section three</h2>
    <p>
      Turnip greens yarrow ricebean rutabaga endive cauliflower sea lettuce
      kohlrabi amaranth water spinach avocado daikon napa cabbage asparagus
      winter purslane kale. Celery potato scallion desert raisin horseradish
      spinach carrot soko.
    </p>
  </section>
</article>
```

```
body {
  font: 1.2em / 1.5 sans-serif;
}

.scroller {
  border: 4px solid #333333;
  width: 300px;
}
```

```
.scroller section {
  min-height: 100%;
  padding: 10px;
}

.scroller section:nth-child(odd) {
  background-color: #cccccc;
}
```

```
.scroller {
  height: 200px;
  overflow-y: scroll;
  scroll-snap-type: y mandatory;
}

.scroller section {
  scroll-snap-align: start;
}
```

If `scroll-snap-type` is `mandatory` and `scroll-snap-align` on a child is either set to `none` or not set (in which case, it defaults to `none`), the user will be unable to scroll that element into view.

Using scroll-padding

When using `start` or `end`, if you do not want the content to snap right to the edge of the scroll container, or if you want the snap position to be slightly offset from center when using `center`, use the `scroll-padding` property or its equivalent longhand values to add some padding.

In the example below, `scroll-padding` is set to `50px`. When the content snaps to the start of the second and third sections, scrolling stops 50 pixels away from the start of the section. Try changing the `scroll-padding` value to see how this changes the distance.

```
<article class="scroller">
  <section>
    <h2>Section one</h2>
  </section>
  <section>
    <h2>Section two</h2>
  </section>
  <section>
    <h2>Section three</h2>
  </section>
</article>
```

```
body {
  font: 1.2em / 1.5 sans-serif;
}

.scroller {
  border: 4px solid #333333;
  width: 300px;
}

.scroller section {
  min-height: 100%;
  padding: 10px;
}

.scroller section:nth-child(odd) {
  background-color: #cccccc;
}
```

```
.scroller {
  height: 300px;
  overflow-y: scroll;
  scroll-snap-type: y mandatory;
  scroll-padding: 50px;
}

.scroller section {
  scroll-snap-align: start;
}
```

This is potentially useful if you have a fixed element such as a navigation bar, which could end up overlapping scrolled content. By using `scroll-padding`, you can reserve space for the fixed element, as shown in the example below, where the `<h1>` element remains on screen as the content scrolls beneath it. Without padding, the heading would overlap some of the content when snapping happens.

```
<article class="scroller">
  <h1>Sticky Heading</h1>
  <section>
    <h2>Section one</h2>
  </section>
  <section>
    <h2>Section two</h2>
  </section>
  <section>
    <h2>Section three</h2>
  </section>
</article>
```

```
body {
  font: 1.2em / 1.5 sans-serif;
}

.scroller {
  border: 4px solid #333333;
  width: 300px;
}

.scroller section {
  min-height: 100%;
  padding: 10px;
```

```
}

.scroller section:nth-child(odd) {
  background-color: #cccccc;
}
```

```
.scroller h1 {
  position: sticky;
  top: 0;
  min-height: 40px;
  background-color: black;
  color: white;
  margin: 0;
  padding: 0;
}

.scroller h2 {
  margin: 0;
  padding: 0;
}

.scroller {
  height: 300px;
  overflow-y: scroll;
  scroll-snap-type: y mandatory;
  scroll-padding: 50px;
}

.scroller section {
  scroll-snap-align: start;
}
```

Using scroll-margin

The `scroll-margin` property or the longhand scroll margin values can be set on child elements, defining an outset from the defined box. This allows for different amounts of space for different child elements and can be used in conjunction with `scroll-padding` on the parent.

```
<article class="scroller">
  <section>
    <h2>Section one</h2>
  </section>
  <section>
    <h2>Section two</h2>
  </section>
  <section>
    <h2>Section three</h2>
  </section>
</article>
```

```
body {
  font: 1.2em / 1.5 sans-serif;
}

.scroller {
  border: 4px solid #333333;
  width: 300px;
}

.scroller section {
  min-height: 100%;
  padding: 10px;
}

.scroller section:nth-child(odd) {
  background-color: #cccccc;
}
```

```
.scroller {
  height: 300px;
  overflow-y: scroll;
  scroll-snap-type: y mandatory;
}

.scroller section {
  scroll-snap-align: start;
  scroll-margin: 40px;
}
```

Using scroll-snap-stop

Using the `scroll-snap-stop` property, you can specify whether the scrolling must snap to the defined snap points. In the above examples, this would mean that the scrolling would stop at the start of each section or be able to skip past sections.

With this property definition, you can ensure that users see each section of the scroller and don't accidentally scroll past them. However, this setting can also negatively affect user experience by preventing the user from quickly scrolling to their desired content.

Using scroll snap events

The CSS scroll snap module defines two **scroll snap events**: `scrollsnapchanging` and `scrollsnapchange`. These enable running JavaScript in response to the browser determining that new scroll snap targets are pending and selected, respectively.

This guide provides an overview of these events, along with complete examples.

Events overview

Scroll snap events are set on a scrolling container that contains potential scroll snap targets:

- The `scrollsnapchanging` event is fired when the browser determines that a new scroll snap target will be selected when the current scroll gesture ends. This is the *pending* scroll snap target. Specifically, this event fires during a scrolling gesture, each time the user moves over potential new snap targets. While the `scrollsnapchanging` event may fire multiple times for each scrolling gesture, it does not fire on all potential snap targets for a scrolling gesture that moves over multiple snap targets. Rather, it fires just for the last target that the snapping will potentially rest on.
- The `scrollsnapchange` event is fired at the end of a scrolling operation when a new scroll snap target is selected. Specifically, this event fires when a scrolling gesture is completed, but only if a new snap target is selected. This event fires just before the `scrollend` event fires.

Let's look at an example that shows the two events in action (you'll see how this is built later on in the article):

Have a go at scrolling up and down the list of boxes:

- Try slowly scrolling the container up and down without releasing the scrolling gesture. For example, drag your finger(s) over the scrolling area on a touchscreen device or trackpad, or hold down the mouse button on the scroll bar and move the mouse. The boxes you move over should turn a darker gray color as you move over them, and then return to normal as you move away from them again. This is the `scrollsnapchanging` event in action.
- Now try releasing the scrolling gesture; the nearest box to your scrolling position should animate to a purple color, with white text. The animation occurs when the `scrollsnapchange` event fires.
- Finally, try scrolling fast. For example, flick your finger hard on the screen, to scroll past several potential targets before starting to come to rest near a target further down the scroll container. You should only see one `scrollsnapchanging` event fire as the scrolling starts to slow, before the `scrollsnapchange` event fires and the selected snap target turns purple.

The <code>SnapEvent</code> event object

Both of the above events share the `SnapEvent` event object. This has two properties that are key to how scroll snap events work:

- `snapTargetBlock` returns a reference to the element snapped to in the block direction when the event fired, or `null` if scroll snapping only occurs in the inline direction so no element is snapped to in the block direction.
- `snapTargetInline` returns a reference to the element snapped to in the inline direction when the event fired, or `null` if scroll snapping only occurs in the block direction so no element is snapped to in the inline direction.

These properties enable event handler functions to report the element that has been snapped to (in the case of `scrollsnapchange`) or the element that *would be snapped to* if the scrolling gesture were to be finished now (in the case of `scrollsnapchanging`) — in one- and two-dimensions. You can then manipulate these elements in any way you want, for example by directly setting styles on them via their `style` properties, setting classes on them that have styles defined for them in a stylesheet, etc.

Relationship with CSS <code>scroll-snap-type</code>

The property values available on `SnapEvent` correspond directly to the value of the `scroll-snap-type` CSS property set on the scroll container:

- If the snap axis is specified as `block` (or a physical axis value that equates to `block` in the current writing mode), only `snapTargetBlock` returns an element reference.
- If the snap axis is specified as `inline` (or a physical axis value that equates to `inline` in the current writing mode), only `snapTargetInline` returns an element reference.
- If the snap axis is specified as `both`, `snapTargetBlock` and `snapTargetInline` return an element reference.

Handling one-dimensional scrollers

If you are dealing with a horizontal scroller, only the event object's `snapTargetInline` property will change as the snapped element changes if the content has a horizontal `writing-mode`, or the `snapTargetBlock` property if the content has a vertical `writing-mode`.

Conversely, if you are dealing with a vertical scroller, only the `snapTargetBlock` property will change as the snapped element changes if the content has a horizontal `writing-mode`, or the `snapTargetInline` property if the content has a vertical `writing-mode`.

In both cases, the non-changing property of the two returns `null`.

Let's look at an example snippet to show a typical one-dimensional scroll snap event handler function:

```
scrollingElem.addEventListener("scrollsnapchange", (event) => {
  event.snapTargetBlock.className = "select-section";
});
```

In this snippet, a `scrollsnapchange` handler function is set on a block-direction scrolling container element that snap targets appear inside. When the event fires, we set a `select-section` class on the `snapTargetBlock` element, which could be used to style a newly-selected snap target to look like it has been selected (for example, with an animation).

Handling two-dimensional scrollers

If you are dealing with a horizontal *and* vertical scroller, the code gets more complex. This is because the `snapTargetBlock` property *and* the `snapTargetInline` property values both return an element reference (neither returns `null`), and one or the other will change value depending on which direction you scroll in and the `writing-mode` of the content:

- If the scroller is scrolled horizontally, the `snapTargetInline` property will change as the snapped element changes if the content has a horizontal `writing-mode`, or the `snapTargetBlock` property if the content has a vertical `writing-mode`.
- If the scroller is scrolled vertically, the `snapTargetBlock` property will change as the snapped element changes if the content has a horizontal `writing-mode`, or the `snapTargetInline` property if the content has a vertical `writing-mode`.

To handle this, you will likely need to keep track of whether it was the `snapTargetBlock` or the `snapTargetInline` element that changed. Let's look at an example:

```
const prevState = {
  snapTargetInline: "s1",
  snapTargetBlock: "s1",
};

scrollingElem.addEventListener("scrollsnapchange", (event) => {
  if (!(prevState.snapTargetBlock === event.snapTargetBlock.id)) {
    console.log(
      `The container was scrolled in the block direction to element ${event.snapTargetBlock.id}`,
    );
  }

  if (!(prevState.snapTargetInline === event.snapTargetInline.id)) {
    console.log(
      `The container was scrolled in the block direction to element ${event.snapTargetBlock.id}`,
    );
  }

  prevState.snapTargetBlock = event.snapTargetBlock.id;
  prevState.snapTargetInline = event.snapTargetInline.id;
});
```

In this snippet, we first define an object (`prevState`) that stores the ID of the previous `snapTargetBlock` and `snapTargetInline` elements.

In the event handler function, we use `if` statements to test whether:

- The `prevState.snapTargetBlock` ID is equal to the ID of the current `event.snapTargetBlock` element.
- The `prevState.snapTargetInline` ID is equal to the ID of the current `event.snapTargetInline` element.

If the values are different, it means that the scroller has been scrolled in that direction (block or inline), and we log a message to console to indicate this. In a real example, you'd likely style the snapped element in some way to indicate that it has been snapped to.

We then update the values of `prevState.snapTargetBlock` and `prevState.snapTargetInline` ready for when the event handler next runs.

For the remainder of this article, we'll look at a couple of complete scroll snap event examples, which you can play with in the live rendered versions at the end of each section.

One-dimensional scroller example

This example features a vertically-scrolling `<main>` element containing multiple light gray `<section>` elements, which are all scroll snap targets. When a new snap target is pending, it will turn a darker shade of gray. When a new snap target is selected, it will smoothly animate to purple with white text. If a different snap target was previously selected, it will smoothly animate back to gray with black text.

HTML

The HTML for the example is a single `<main>` element. We will add the `<section>` elements dynamically with JavaScript later on, to save on page space.

```
<main></main>
```

CSS

```
* {
  box-sizing: border-box;
}

html {
  height: 100%;
}

body {
  display: flex;
  align-items: center;
  justify-content: center;
  height: inherit;
}

h2 {
  font-size: 1rem;
  letter-spacing: 1px;
}

section {
  font-family: "Helvetica", "Arial", sans-serif;
  border-radius: 5px;
  background: #eeeeee;
  box-shadow:
    inset 1px 1px 4px rgb(255 255 255 / 0.5),
    inset -1px -1px 4px rgb(0 0 0 / 0.5);
  width: 150px;
  height: 150px;

  display: flex;
  align-items: center;
  justify-content: center;
}
```

In the CSS, we start off by giving the `<main>` element a chunky black `border` and a fixed `width` and `height`. We set its `overflow` value to `scroll` so overflowing content will be hidden and can be scrolled to, and set `scroll-snap-type` to `block mandatory` so that snap targets in the block direction only will always be snapped to.

```
main {
  border: 3px solid black;
  width: 250px;
  height: 450px;
  overflow: scroll;
  scroll-snap-type: block mandatory;
}
```

Each `<section>` element is given a `margin` of `50px` to separate out the `<section>` elements and make the scroll snapping behavior more apparent. We then set `scroll-snap-align` to `center`, to specify that we want to snap to the center of each snap target. Finally, we apply a `transition` to smoothly animate to and from the style changes applied when a snap target selection has been made or is pending.

```
section {
  margin: 50px auto;
  scroll-snap-align: center;
  transition: 0.5s ease;
}
```

The style changes mentioned above will be applied through classes applied to the `<section>` elements via JavaScript. The `select-section` class will be applied to signify a selection — this set a purple background and white text color. The `pending` class will be applied to signify a pending snap target selection — this colors the target selection's background a darker gray.

```
.pending {
  background-color: #cccccc;
}

.select-section {
  background: purple;
  color: white;
}
```

JavaScript

In the JavaScript, we start by grabbing a reference to the `<main>` element and defining the number of `<section>` elements to generate (in this case, 21) and a variable to begin counting from. We then use a `while` loop to generate the `<section>` elements, giving each one a child `h2` with text that reads `Section` plus the current value of `n`.

```
const mainElem = document.querySelector("main");
const sectionCount = 21;
let n = 1;

while (n <= sectionCount) {
  mainElem.innerHTML += `
    <section>
      <h2>Section ${n}</h2>
    </section>
  `;
  n++;
}
```

Now on to the `scrollsnapchanging` event handler function. When a child of the `<main>` element (i.e., any `<section>` element) becomes a pending snap target selection, we:

1. Check to see if an element previously had the `pending` class applied and, if so, remove it. This is so that only the current pending target is given the `pending` class and colored darker gray. We don't want previously-pending targets that are no longer pending to keep the styling.
2. Give the element referenced by the `snapTargetBlock` property (which will be one of the `<section>` elements) the `pending` class so it turns a darker gray.

```
mainElem.addEventListener("scrollsnapchanging", (event) => {
  const previousPending = document.querySelector(".pending");
  if (previousPending) {
    previousPending.classList.remove("pending");
  }

  event.snapTargetBlock.classList.add("pending");
});
```

> **Note:** We don't need to worry about the `snapTargetInline` event object property for this demo — we are only scrolling vertically and the demo is using a horizontal writing mode, therefore only the `snapTargetBlock` value will change. In this case, `snapTargetInline` will always return `null`.

When a scrolling gesture ends, and a `<section>` element is actually selected as a snap target, the `scrollsnapchange` event handler function fires. This:

1. Checks to see if a snap target was previously selected — i.e., if a `select-section` class was previously applied to an element. If so, we remove it.
2. Applies the `select-section` class to the `<section>` element referenced in the `snapTargetBlock` property so that the snap target that was just selected will have the selection animation applied to it.

```
mainElem.addEventListener("scrollsnapchange", (event) => {
  const currentlySnapped = document.querySelector(".select-section");
  if (currentlySnapped) {
    currentlySnapped.classList.remove("select-section");
  }

  event.snapTargetBlock.classList.add("select-section");
});
```

Result

Try scrolling up and down the scroll container and observing the behavior described above:

Two-dimensional scroller example

This example is similar to the previous one, except that it features a horizontally- *and* vertically-scrolling `<main>` element containing multiple light gray `<section>` elements, which are all snap targets.

The HTML for the example is the same as for the previous example — a single `<main>` element.

```
<main></main>
```

CSS

```
* {
  box-sizing: border-box;
}

html {
  height: 100%;
}

body {
  display: flex;
  align-items: center;
  justify-content: center;
  height: inherit;
}

section {
  font-family: "Helvetica", "Arial", sans-serif;
  border-radius: 5px;
  background: #eeeeee;
  box-shadow:
    inset 1px 1px 4px rgb(255 255 255 / 0.5),
    inset -1px -1px 4px rgb(0 0 0 / 0.5);
  width: 150px;
  height: 150px;

  display: flex;
  align-items: center;
  justify-content: center;

  scroll-snap-align: center;
}

h2 {
  font-size: 1rem;
  letter-spacing: 1px;
}
```

The CSS for this example is similar to the CSS in the previous example. The most significant differences are as follows.

First let's look at the `<main>` element styling. We want the `<section>` elements to be laid out as a grid, so we use CSS grid layout to specify that we want them displayed in seven columns, using a `grid-template-columns` value of `repeat(7, 1fr)`. We also specify the space around the `<section>` elements by setting `padding` and `gap` on the `<main>` element rather than `margin` on the `<section>` elements.

Finally, since we are scrolling in both directions in this example, we set `scroll-snap-type` to `both mandatory` so that snap targets in the block direction *and* inline direction will always be snapped to.

```
main {
  display: grid;
  grid-template-columns: repeat(7, 1fr);
  padding: 100px;
  gap: 50px;
  overflow: scroll;
  border: 3px solid black;
  width: 350px;
  height: 350px;

  scroll-snap-type: both mandatory;
}
```

Next, we are going to use CSS animations in this example instead of transitions. This results in more complex code, but enables more fine-grained control over the animations applied.

We first define the classes that will be applied to signal that a snap target selection has been made or is pending. The `select-section` and `deselect-section` classes will apply keyframe animations to signify a selection or deselection. The `pending` class will be applied to signify a pending snap target selection (it applies a darker gray background to the selection, as in the previous example).

The `@keyframes` animate from a gray background and black (default) text color to a purple background and white text color, and back again, respectively. The latter animation is somewhat different from the first one — it also uses `opacity` to create a fade out/fade in effect.

```
.select-section {
  animation: select 0.8s ease forwards;
}

.deselect-section {
  animation: deselect 0.8s ease forwards;
}

.pending {
  background-color: #cccccc;
}

@keyframes select {
  from {
    background: #eeeeee;
    color: black;
  }

  to {
    background: purple;
    color: white;
  }
}

@keyframes deselect {
  0% {
    background: purple;
    color: white;
    opacity: 1;
  }

  80% {
    background: #eeeeee;
    color: black;
    opacity: 0.1;
  }

  100% {
    background: #eeeeee;
    color: black;
    opacity: 1;
  }
}
```

JavaScript

In the JavaScript, we start off in the same way as with the previous example, except that this time we generate 49 `<section>` elements, and we give each one an ID of `s` plus the current value of `n` to help track them later on. With the CSS grid layout we specified above, we have seven columns of seven `<section>` elements.

```
const mainElem = document.querySelector("main");
const sectionCount = 49;
let n = 1;

while (n <= sectionCount) {
  mainElem.innerHTML += `
    <section id="s${n}">
      <h2>Section ${n}</h2>
    </section>
  `;
  n++;
}
```

Next we specify an object called `prevState`, which allows us to keep track of the previously-selected snap target at any point — its properties store the previous inline and block snap targets' IDs. This is important for figuring out if we need to style the new block target or the new inline target each time an event handler fires.

```
const prevState = {
  snapTargetInline: "s1",
  snapTargetBlock: "s1",
};
```

For example, let's say the scroll container is scrolled so that the ID of the new `SnapEvent.snapTargetBlock` element has changed (it doesn't equal the ID stored in `prevState.snapTargetBlock`), but the ID of the new `SnapEvent.snapTargetInline` element is still the same as the ID stored in `prevState.snapTargetInline`. This means that we've moved to a new snap target in the block direction, so we should style `SnapEvent.snapTargetBlock`, but we've not moved to a new snap target in the inline direction, so we shouldn't style `SnapEvent.snapTargetInline`.

This time around, we'll explain the `scrollsnapchange` event handler function first. In this function, we:

1. Start by making sure that a previously-selected `<section>` element snap target (as signified by the presence of the `select-section` class) has the `deselect-section` class applied so it shows the deselection animation. If no snap target was previously selected, we apply the `select-section` class to the first `<section>` in the DOM so it shows up as selected when the page first loads.
2. Compare the previously-selected snap target ID to the newly-selected snap target ID, for both the block *and* inline selections. If they are different, it indicates that the selection has changed, so we apply the `select-section` class to the appropriate snap target to visually indicate this.
3. Update `prevState.snapTargetBlock` and `prevState.snapTargetInline` to be equal to the IDs of the scroll snap targets that were just selected, so that when the event next fires, they will be the previous selections.

```
mainElem.addEventListener("scrollsnapchange", (event) => {
  if (document.querySelector(".select-section")) {
    document.querySelector(".select-section").className = "deselect-section";
  } else {
    document.querySelector("section").className = "select-section";
  }

  if (!(prevState.snapTargetBlock === event.snapTargetBlock.id)) {
    event.snapTargetBlock.className = "select-section";
  }

  if (!(prevState.snapTargetInline === event.snapTargetInline.id)) {
    event.snapTargetInline.className = "select-section";
  }

  prevState.snapTargetBlock = event.snapTargetBlock.id;
  prevState.snapTargetInline = event.snapTargetInline.id;
});
```

When the `scrollsnapchanging` event handler function fires, we:

1. Remove the `pending` class from the element that previously had it applied so that only the current pending target is given the `pending` class and colored darker gray.
2. Give the current pending element the `pending` class so it turns a darker gray, but only if it has not already got the `select-section` class applied — we want a previously selected target to keep the purple selection styling until a new target is actually selected. We also include an extra check in the `if` statements to make sure we style only the inline or block pending snap target, depending on which one has changed. Again, we compare the previous snap target to the current snap target in each case.

```
mainElem.addEventListener("scrollsnapchanging", (event) => {
  const previousPending = document.querySelector(".pending");
  if (previousPending) {
    previousPending.className = "";
  }

  if (
    !(event.snapTargetBlock.className === "select-section") &&
    !(prevState.snapTargetBlock === event.snapTargetBlock.id)
  ) {
    event.snapTargetBlock.className = "pending";
  }

  if (
    !(event.snapTargetInline.className === "select-section") &&
    !(prevState.snapTargetInline === event.snapTargetInline.id)
  ) {
    event.snapTargetInline.className = "pending";
  }
});
```

Result

Try scrolling horizontally and vertically around the scroll container and observing the behavior described above:

Scroll snap events on <code>Document</code> and <code>Window</code>

In this article, we've covered the scroll snap events that fire on the `Element` interface, but the same events also fire on the `Document` and `Window` objects. See:

- `Document` `scrollsnapchange` and `scrollsnapchanging` event references.
- `Window` `scrollsnapchange` and `scrollsnapchanging` event references.

These work in much the same way as the `Element` versions, except that the overall HTML document has to be set as the scroll snap container (i.e., `scroll-snap-type` is set on the `<html>` element).

For example, if we took a similar example to the ones we've looked at above, where we've got a `<main>` element containing significant content:

```
<main>
  <!-- Significant content -->
</main>
```

The `<main>` element could be turned into a scroll container using a combination of CSS properties, for example:

```
main {
  width: 250px;
  height: 450px;
  overflow: scroll;
}
```

You could then implement scroll snapping behavior on the scrolling content by specifying the `scroll-snap-type` property on the `<html>` element:

```
html {
  scroll-snap-type: block mandatory;
}
```

The following JavaScript snippet would cause the `scrollsnapchange` event to fire on the HTML document when a child of the `<main>` element becomes a newly-selected snap target. In the handler function, we set a `selected` class on the child referenced by the `SnapEvent.snapTargetBlock`, which could be used to style it to look like it has been selected (for example, with an animation) when the event fires.

```
document.addEventListener("scrollsnapchange", (event) => {
  event.snapTargetBlock.classList.add("selected");
});
```

We could fire the event on `Window` instead, to achieve the same functionality:

```
window.addEventListener("scrollsnapchange", (event) => {
  event.snapTargetBlock.classList.add("selected");
});
```

CSS scroll-driven animations

The **CSS scroll-driven animations** module provides functionality that builds on the CSS animations module and Web Animations API. It allows you to animate property values along a scroll-based timeline rather than the default time-based document timeline. This means that you can animate an element by scrolling the element, its scroll container, or its root element, rather than just by the passing of time.

Scroll-driven animations in action

You can define the scroller that controls the animation either by naming the animation or with the `scroll()` or `view()` functions.

```
<main>
  <div></div>
</main>
```

```
main {
  scroll-timeline: --main-timeline;
}

div {
  animation: background-animation linear;
  animation-timeline: scroll(nearest inline);
}

div::after {
  animation: shape-animation linear;
  animation-timeline: --main-timeline;
}
```

```
@layer animations {
  @keyframes background-animation {
    0% {
      background-color: palegoldenrod;
    }
    100% {
      background-color: magenta;
    }
  }
  @keyframes shape-animation {
    0% {
      left: 0;
      top: 0;
      background-color: black;
    }
    50% {
      top: calc(100% - var(--elSize));
      left: calc(50% - var(--elSize));
      background-color: red;
    }
    100% {
      left: calc(100vw - var(--elSize));
      top: 0;
      rotate: 1800deg;
      background-color: white;
    }
  }
}

@layer page-setup {
  :root {
    --elSize: 50px;
  }
  main {
    height: 90vh;
    overflow: scroll;
    border: 1px solid;
    margin: 5vh auto;
  }
  div {
    height: 400vh;
    width: 400vw;
  }
  div::after {
    content: "";
    border: 1px solid red;
    height: var(--elSize);
    width: var(--elSize);
    position: absolute;
    border-radius: 20px;
    corner-shape: superellipse(-4);
  }
}

@layer no-support {
  @supports not (scroll-timeline: --main-timeline) {
    body::before {
      content: "Your browser doesn't support scroll-driven animations.";
      background-color: wheat;
      display: block;
      text-align: center;
```

```
      padding: 1rem 0;
    }
  }
}
```

Scroll the element in the inline direction to see its background color change. Scroll it vertically to see the generated content move, spin, and change colors.

Understanding timeline insets

By default, view progress timelines track elements across the entire animation attachment range. The `0%` progress point is at the start of the range, while the `100%` progress point is at the end. The animation attachment range can be changed by setting a timeline range name, and the location of the `0%` and `100%` progress points along the range can be adjusted by setting length or percentage-based inset values.

This guide explains how to limit the animation timeline to a specific portion of the animation timeline range using length or percentage inset values.

Animation timelines: a primer

CSS animations are created by defining named `@keyframes` animations, which specify an animation's behavior, and then attaching the keyframe animation to an element using the animation's name.

The element's animation timeline, defined by the `animation-timeline` property, determines how and when the element progresses through those keyframes. By default, the timeline is time-based, using the document's default time-based `DocumentTimeline`.

The CSS scroll-driven animation module defines scroll progress and view progress timelines, which are methods for animating property values along a scroll-based timeline rather than the default time-based document timeline. In this article, we'll only discuss view progress timelines, as scroll progress timelines are not relevant to timeline insets.

View progress timelines

With view progress timelines, the animation's timeline, or progress, is driven by element visibility instead of the passage of time, with keyframe progression tied to the subject element position and visibility within the scroll container. The animation advances and reverses as the element advances or reverses through the scrollport. The animation only occurs when at least part of the element is visible within its scrollport, pausing when scrolling pauses.

```
.animated_element {
  animation-name: nameOfAnimation;
  animation-timeline: view();
}
```

Setting an `animation-name` applies the animation to the selected element.

> **Note:** The `animation-timeline` property should always come after any `animation` shorthand declarations. While the shorthand property can't be used to set the `animation-timeline` property, it does reset the timeline to the default time-based document timeline.

> **Note:** In all the examples, the scroll container is `250px` tall and we are using the default values for `animation-iteration-count` (`1`), `animation-delay` (`0s`), and `animation-direction` (`normal`). We set the `animation-timing-function` to `step-end` and the `animation-fill-mode` is to `forward` to make the it more apparent when the animation iteration has not yet started, when it is active, and when it is complete. See the Using CSS animations guide to learn more.

As you scroll up, the animation progresses. As you scroll down, the animation reverses.

In this example, whenever any part of the subject element is visible in the scrollport, the animation occurs. By default, view progress animations begin just as the top edge of the subject element aligns with the bottom edge of the scroll container and end, reaching `100%` progress, when the end edge aligns with the start edge of the container, no matter the size of the subject element. By default, the animation is applied when any part of the subject is visible within the scrollport.

Animation attachment ranges

In a view progress timeline, when no animation range properties are defined, the `<timeline-range-name>` is `normal`, which defaults to `cover`. The animation is applied whenever any portion of the subject element is visible, meaning the default **animation attachment range** is the sum of the height of the scroll container and the height of the subject element, with that extra height being at the scroll end edge. In our example, as the scroll container is `250px` tall, and the subject is `50px`, `250px`, or `500px` tall, with the vertical animation attachment range being `300px`, `500px`, or `750px` respectively.

The `0%` progression occurs when the subject element's start edge intersects the scrollport at the end edge, reaching `100%` progress when the subject's end edge exits via the scrollport's start edge. These are the subject and scrollport's top and bottom edges when scrolling vertically, and the left and right or right and left edges when scrolling horizontally, depending on the writing mode.

The following diagram illustrates the position of the subject at the `0%` and `100%` progress points for the three subject sizes:

```
<div>
  <svg viewBox="-1 -1 462 1252" xmlns="http://www.w3.org/2000/svg">
    <title>Default view progress timeline</title>
    <rect class="container" width="350" height="250" x="0" y="500" />
    <rect class="small end" width="100" height="50" x="10" y="450" />
    <rect class="medium end" width="100" height="250" x="125" y="250" />
    <rect class="large end" width="100" height="500" x="240" y="0" />
    <rect class="small start" width="100" height="50" x="10" y="750" />
    <rect class="medium start" width="100" height="250" x="125" y="750" />
    <rect class="large start" width="100" height="500" x="240" y="750" />
    <text y="520" x="360">100%</text>
    <line x1="0" x2="350" y1="500" y2="500" />
    <line x1="0" x2="350" y1="750" y2="750" />
    <text y="760" x="360">0%</text>
  </svg>
</div>
```

The yellow subject elements represents the position of the element when the `from` keyframe is applied, which is the animation range's `0%` progress mark. The red represents the location of the animated element relative to the scrollport when the `to` keyframe is applied, which is the end of the animation, or the `100%` progress mark. The gray represents the scrollport.

By default, the element animates while it is "in view", but this default definition of "in view" may not fit your needs. Fortunately, we can control which edges define the edges of the animation attachment range and then offset the start and end of that range with the animation range properties.

Animation range properties

The `animation-range` properties enable specifying a named timeline range, such as `contain` or `exit-crossing`, which changes the range used from the default `cover` range. You can also include a `<length-percentage>` value, which insets the attachment range from the start of the range. Percentages are relative to the named or default timeline range.

Named timeline ranges define the portions of a `ViewTimeline` that define an animation's range, specifying the start and end of the animations's attachment range.

The `animation-range` property is a shorthand property, defining the `animation-range-start` and `animation-range-end` properties. The `animation-range-start` defines the position of the subject element when the animation starts. The `animation-range-end` defines the position of the subject element when the animation ends.

See the timeline range names guide to learn about the different named timeline ranges. This guide focuses on how the `<length-percentage>` inset values work.

Setting insets using lengths

The `animation-range-start` and `animation-range-end` properties each accept a named animation range, a `<length-percentage>` offset value, or both. Any length or percentage offset is measured from the *start* of the animation attachment range.

When a `<length>` is set, the offset is fairly intuitive. Here we use the `animation-range-start` and `animation-range-end` properties to inset the animation timeline. This defines a subsection of the element's full animation attachment range as the active interval, with the `<length>` values specifying distances from the start of the default `normal` animation attachment range.

```
.animated_element {
  animation-range-start: 1em;
  animation-range-end: 125px;
}
```

The start and end of the animation range are `1em` and `125px` from the start of the animation attachment range, respectively. Because the timeline range default is `normal`, which resolves to `cover`, the start of the animation attachment range is the block end edge of the container.

```
:root {
  --start: 1em;
  --end: 125px;
}

article {
  background-image: linear-gradient(
    to top,
    transparent calc(var(--start) - 1px),
    #cccccc calc(var(--start) - 1px) calc(var(--start) + 1px),
    transparent calc(var(--start) + 1px) calc(var(--end) - 1px),
    #cccccc calc(var(--end) - 1px) calc(var(--end) + 1px),
    transparent calc(var(--end) + 1px)
  );
}
```

We've added lines `1em` and `125px` from the block end edge of the scroll container. The animation starts when the block start edge of the subject element reaches the `1em` line and ends when it reaches the `125px` line.

In this case, as the animation attachment range resolves to `cover` for both the start and end inset values, the location of the insets is fairly straightforward.

Effect of named ranges on length offsets

The offset distance is always from the start of the associated animation range. In this example, we set the `animation-range-start` to be `50px` from the start of the default `normal` range and set the `animation-range-end` to be `100px` from the start of the explicitly set `entry` range:

```
.animated_element {
  animation-range-start: 50px;
  animation-range-end: entry 100px;
}
```

```
<main>
  <article>
    <p> </p>
    <p> </p>
    <p>Scroll down ⇩</p>
    <p> </p>
    <p> </p>
    <section class="triple">
      <div>
        <i id="A" class="animated_element">50px</i>
        <i id="B" class="animated_element">250px</i>
        <i id="C" class="animated_element">500px</i>
      </div>
    </section>
    <p> </p>
    <p> </p>
    <p> </p>
    <p> </p>
    <p>Scroll up ⇧</p>
  </article>
</main>
```

As the start edge of both the `normal` and `entry` ranges is the container's end edge, the animation begins when the subject start edge is `50px` from the bottom of the scrollport and ends, reaching `100%` progress, when the subject start edge is `100px` from the bottom of the scrollport, irrespective of the subject size. While the size of the `entry` range is different for the three different subject sizes, in this case, the size of the underlying range didn't matter.

Length offsets with varying ranges

The size of range matters when the range doesn't start at the element's end edge, as is the case with `exit` and `exit-crossing`, or if the offset is a percentage value. This fact, and the fact that you can mix and match animation range names, make view progress timeline offsets a bit more complicated to understand than non-offsetted timeline range names.

For example, when setting `exit` as the timeline range name, the subject size matters as it determines the location of the range's end edge.

```
.animated_element {
  animation-range-start: entry 60px;
  animation-range-end: exit 75px;
}
```

With both `entry` and `exit`, the range is the size of the subject, with the size clamped to the size of the scrollport. This means that the height of the `entry` and `exit` ranges are the height of the box in both the `50px` and `250px` examples, while in the `500px` example, the range is clamped to the height of the scrollport, which is `250px` tall.

We added a few lines to facilitate the explanations that follow: the bottom blue line is `60px` from the end edge of the scrollport, and the top red line is `75px` from that same edge. These are where the animation range start and end respectively.

This example demonstrates several important features, which we'll explain in greater detail, including:

- Offsets are measured from their respective named ranges
- Offsets can occur beyond the edges of the scrollport
- Ranges may be clamped if the subject is larger than the scrollport

Measured from the start edge of the range

As the offset position is always relative to the start of the declaration's animation range, the start of the animation for all three elements occurs when the elements start edge crosses the point that is `60px` from the start of the `entry` range.

The `animation-range-end` value defines the position where the animation. The `exit 75px` value basically means "when `75px` of the subject has exited the start edge of the scrollport." This varies for each subject. For the `50px` subject, this only occurs `25px` after it has left the scrollport; when the element is not visible. The animation range end for both the `250px` and `500px` subjects occurs when their bottom end edge intersects the top blue line; 75 pixels from the end edge of the scrollport. Why are their end offsets the same? Because of clamping! The maximum size of the named animation range is clamped to the size of the scrollport. The `exit` range for both subjects is the same, so the range end offsets are the same.

Beyond the scrollport edges

For our `50px` tall subject, the `exit` range is 50px tall abutting the start edge of the scroll port. Setting `animation-range-end: exit 75px` for any element less than `75px` tall means the end of the range is outside the scrollport, as the point `75px` from the start of the `exit` range is past the start edge of the scrollport. In our example, the end of the animation range for the `50px` subject occurs when the subject's start edge is `75px`

past the scrollport's start edge. The animation ends, reaching the `to` keyframe and the `animationend` event, only when (and if) the element is scrolled `25px` out of view.

The animation ends even if the animation range end is outside of the scrollport, as long as there is room to scroll to that point. Had we set `animation-range-end: exit 250px`, the animation would have ended when the end edge of the medium and tall subjects exited the scrollport at the container's start edge.

With the end set to `exit 250px`, the small subject's animation might not end, as there might not be `450px` of content after the subject for the user to scroll to before the end point is reached.

Effects of clamping

With our `250px` tall container, when the subject is `250px` or `500px` tall, the `exit` range is the size of the container, with the start being the scroll container's end edge. With a `75px` offset, the end of the animation occurs when the end edge of the subject is `75px` from the end edge of the scroll container (denoted by the top red line).

As the offset position is always relative to the start of the named or default animation range, in our example, clamping impacts the large subject's `animation-range-end`. We set the end of the range to `exit 75px` which is `75px` from the start edge of the `exit` range. When the subject is the same size as the scrollport (our `250px` subject) or larger (our `500px` subject), the animation range end is `75px` from the end edge of the scrollport, which is `75px` from the start of the scrollport-clamped `exit` range.

```
article {

  .animated_element {
    --clr: yellow;
    background-color: hsl(from var(--clr) h s calc(l * 1.4));
    display: block;
    animation: showAnim step-end 1 forwards;
    animation-timeline: view();
    flex: 1 0 auto;
  }

  i {
    font-family: sans-serif;
    font-size: 1.5rem;
  }

  @keyframes showAnim {
    from {
      --clr: green;
    }
    to {
      --clr: red;
    }
  }
  @layer no-support {
    @supports not (animation-timeline: view()) {
      body::before {
        content: "Your browser doesn't support view progress scrolling.";
        background-color: wheat;
        display: block;
```

```
        text-align: center;
      }
    }
  }
}
```

Negative lengths

Up to this point, all the offsets have been greater than zero. It's important to note that negative lengths are valid. A negative offset on the `animation-range-start` makes the range longer while a negative offset on the `animation-range-end` makes the range shorter.

Let's compare the negative insets compared to the `0` values:

```
#A {
  animation-range-start: contain -25px;
  animation-range-end: exit -25px;
}
#B {
  animation-range-start: contain 0;
  animation-range-end: exit 0;
}
```

The first animation range is offset by `25px` toward the container end edge.

```
fieldset.double {
  display: none;
}
#A::after {
  content: " (-25px)";
}
#B::after {
  content: " (0)";
}
```

Setting insets using percentages

Like length values, percentage values define offsets from the *start* of the animation attachment range. The percentage offsets are relative to the timeline range dimension, not relative to the scrollport. For this reason, percentage values are not as intuitive as length values for most people (realizing length values weren't that intuitive either).

Here, we use `animation-range-start` and `animation-range-end` to inset the animation timeline. While we are using the same properties, we set `<percentage>` values instead of `<length>` values:

```
.animated_element {
  animation-range-start: 20%;
  animation-range-end: 60%;
}
```

```
i {
  background-image: linear-gradient(
    to bottom,
    transparent calc(20% - 1px),
    #33333333 calc(20% - 1px) calc(20% + 1px),
    transparent calc(20% + 1px) calc(60% - 1px),
    #33333333 calc(60% - 1px) calc(60% + 1px),
    transparent calc(60% + 1px)
  );
}
article {
  --total: calc(var(--animElHeight) + 250px);
  background-image:
    linear-gradient(
      to top,
      transparent 0 calc(var(--total) * 0.2 - 1px),
      green calc(var(--total) * 0.2 - 1px) calc((var(--total) * 0.2) + 1px),
      transparent calc(var(--total) * 0.2 + 1px)
    ),
    linear-gradient(
      to top,
      transparent 0 calc(var(--total) * 0.6 - 1px),
      red calc(var(--total) * 0.6 - 1px) calc((var(--total) * 0.6) + 1px),
      transparent calc(var(--total) * 0.6 + 1px)
    ),
    linear-gradient(
      to top,
      transparent 0 calc(var(--containerHeight) * 0.2 - 0.5px),
      #33333333 calc(var(--containerHeight) * 0.2 - 0.5px)
        calc(var(--containerHeight) * 0.2 + 0.5px),
      transparent calc(var(--containerHeight) * 0.2 + 0.5px)
        calc(var(--containerHeight) * 0.6 - 0.5px),
      #33333333 calc(var(--containerHeight) * 0.6 - 0.5px)
        calc(var(--containerHeight) * 0.6 + 0.5px),
      transparent 0 calc(var(--containerHeight) * 0.6 + 0.5px)
    );
  background-attachment: local, local, fixed;
}
```

This defines the active interval to begin `20%` into the default attachment range and end `60%` through that same range. The default `normal` animation attachment range, which behaves as `cover`, is the height of the scroll container plus the height of the subject element, meaning the range will differ based on which radio button is selected.

For illustrative purposes, there are two dark lines crossing the container at the `20%` and `60%` points of the full animation range. The animation starts when the block-start edge reaches the `20%` point, which is the bottom green line. The animation ends when the start block edge is 60% of the way through the normal range, which is the top red line.

Only when the element is `50px` tall is the top of the subject still in the scrollport when the end of the animation is reached; there are no top red lines when `250px` or `500px` are selected, as the end of the animation range is outside of the scrollport.

Based on the height of our subjects, the `20%` mark is either `60px`, `100px`, or `150px` from the end edge of the scrollport (marked by the green line, which is always in the scrollport), and the `60%` mark is `180px`, `300px`, or `450px` from the same point (marked with a red line, but only visible for the `50px` subject).

For illustrative purposes, there are two light gray lines crossing the container `20%` and `60%` of the way through the scrollport, which are `50px` and `150px` from the bottom of the scrollport, respectively. As the `animation-range-*` percentages are relative to the timeline range, not the scrollport, these lines only show how the percentages **don't** align. We've also included two horizontal light gray lines going across each

subject at their own `20%` and `60%` marks. These lines align with the scrollport's light gray lines when each subjects animation starts and ends.

The following image demonstrates where the subject elements are located when the animation starts (the `0%` keyframe) and ends (the `100%` `keyframe`). This image includes the insets from the animation timeline in the previous demonstration and the timeline without insets for comparison.

```
<div>
  <svg viewBox="-1 -1 482 1252" xmlns="http://www.w3.org/2000/svg">
    <title>Default view progress timeline with insets</title>

    <text y="760" x="390">0%</text>
  </svg>
</div>
```

As before, the yellow represents the position of the element when the `from` keyframe is applied, the red represents the location when the `to` keyframe is applied, and the gray represents the scrollport. The striped areas are where the red and yellow element representations overlap. For illustrative purposes, we've added dashed black horizontal lines `20%` and `60%` way through the scrollport, starting from the bottom.

The animation only begins when the element reaches the `20%` mark along the animation attachment range. This point is `60px`, `100px`, or `150px` from the bottom edge of the scroll port, depending on the size of the element. The location of the subject element at this point, representing the position of the element when the `from` or `0%` keyframe is applied, is shown in yellow.

The red represents the location of the animated element relative to the scrollport when the `to` or `100%` keyframe is applied, which is the end of the animation. This point is either `180px`, `300px`, or `450px` from the bottom edge of the scrollport, depending on the subject size. The animation occurs when the element is between the `to` and the `from` positions.

You may have noticed something interesting about the dashed horizontal lines: when the animation starts, the line that is `20%` from the end edge of the viewport is `20%` from the *top* of the subject element and the line that is `60%` from the end edge of the viewport is `60%` from the *top* of the subject element when the animation ends. This is what was illustrated by the very light gray lines in the live demo for this example.

Subject size matters

As we saw when we set insets with lengths, the size of the subject can make a difference. When setting animation ranges, percentage values are relative to the size of animation attachment range, not the scrollport. For most named ranges, the size of the attachment range depends partially on the subject size. As percentages are based on the size of the range, the named range impacts the resolved size of the insets. Depending on the name, the start position may also change, impacting the location of the range and therefore the location of progress points.

In this example, we define an active range that is `40%` of the size of the subject:

```
.animated_element {
  animation-range-start: exit-crossing -20%;
  animation-range-end: exit-crossing 20%;
}
```

```
article {
  background-image: none;
}
body .animated_element {
  align-self: start;
}
```

The animation lasts `40%` of the animation-attachment range. As you scroll, note how the larger the subject, the longer the range. With exit-crossing, the animation range is not cropped; it is the size of the subject even if the subject is larger than the viewport, with the range abutting the start edge of the scrollport, and extending off the end edge if the subject is larger than the scrollport.

With the `-20%` and `20%` insets, the `50px` subject's will animation over `20px`: the animation starts when the subject's end is `-10px` from range start, or `60px` from exiting the screen, and ends when the subject's end is `40px` from exiting the screen. The middle subject will animate over `100px`: the animation starts when the subject end is `-50px` from range start, which is `50px` off of the scrollport's end edge, and ends when the subject's end is `50px` into the scrollport. The large subject animates over `200px`, starting when the bottom is `600px` from the container's start edge, with only `150px` in view, and ends when the bottom is 400px from that start edge, when `100px` have scrolled off the start edge.

Percentages equal to the scrollport

When it comes to offsetting with percentages, the least complicated named timeline range is `contain`. With `contain`, the animation range is the size of the scrollport, meaning the start and end percentages are relative to the scrollport. For this reason, when using offsets, you may want to use `contain` instead of letting the range default and resolve to `cover`.

The `contain` range fully *contains* the animation within the scrollport. It represents the range during which the principal box is either fully contained by, or fully covers, its view progress visibility range within the scrollport. With `contain`, if the subject is the same size or smaller than the scrollport, it can be fully visible. If the element is the same size as the container, however, the animation occurs over `0px`. This means that it runs, but it is not visible to the user.

In other words, without needing to know the size of the container or the subjects, we are able to limit our animation to the middle of scrollport, though the animation will happen over `0px` if the subject is the same size as the scrollport.

```
.animated_element {
  animation-range-start: contain 25%;
  animation-range-end: contain 75%;
}
```

```
article {
  background-image: linear-gradient(
    transparent 25%,
```

```
    #ededed 25% 75%,
    transparent 75%
  );
}
body .animated_element {
  align-self: center;
}

.animated_element {
  background-image:
    linear-gradient(black, black), linear-gradient(black, black);
  background-size: 1px 1px;
  background-position:
    center 25%,
    center 75%;
  background-repeat: repeat-x;
```

The horizontal lines denote the middle half of the scrollport and the middle half of each subject.

```
<svg class="gradient">
  <title>Striped repeating gradient</title>

Understanding timeline range names

By default, view progress timelines track elements across the entire scrollport. The animation timeline begins when the first pixel of the element's start edge crosses the scrollport's end edge, and ends when the element's end edge crosses the scrollport's start edge. You can change this default animation attachment range. For example, you can restrict the view progress timeline to begin only when the subject element has fully entered the scrollport.

This guide explains how to modify timeline range names, specifically examining the various timeline range names, their meanings, and how they are used.

Limiting the animation timeline to a specific portion of a named animation timeline range is discussed in the insetting scroll animations guide.

View progress timeline primer

CSS animations are created by attaching `@keyframes` animations to an element using the `animation-name` property (or `animation` shorthand). The keyframes define the animation's behavior, while the `animation-timeline` determines when and how the element progresses through those keyframes.

By default, the animation's timeline is the document's default time-based `DocumentTimeline`. With CSS scroll-driven animations, the animation's timeline, or progress, is driven either by user scroll (scroll progress timelines) or element visibility (view progress timelines), instead of the passage of time.

With view progress timelines, keyframe progression is tied to how much of the subject element is visible within the scroller, and its position within the scroller. As the element enters the viewport, the timeline advances. If the user reverses the scrolling, the timeline reverses. In other words, as the element comes into or moves out of view, the timeline progresses or reverses, respectively. The animation only occurs when the subject is visible within its scrollport. If scrolling stops while the element is in view, the animation pauses.

Default view progress timeline

By default, the view progress timeline's progression starts when the tracked subject's start edge intersects the scrollport at the end edge and ends when the subject's end edge exits the scrollport at the start edge. These are the subject and scrollport's top and bottom edges when scrolling vertically, and the left and right or right and left edges when scrolling horizontally, depending on the writing mode.

In the following example, try scrolling down. Note how the animation begins just as the top edge of the animated element aligns with the bottom edge of the scroll container and ends, reaching `100%` progress, when the bottom edge aligns with the top edge of the container, no matter how tall the animated element is.

The scroll container's writing mode and scroll direction determine the scroll container's start and end edges.

The animation attachment range

By default, the element is animated the entire time any portion of the subject element is visible. This means the default **animation attachment range** is the sum of the height of the scroll container and the height of the subject element, with that extra height being at the scroll end edge.

In the previous example, the scroll container is `250px` tall, and the animated element is `50px` tall by default, which means the vertical animation attachment range is `300px` tall. When the subject is set to `250px`, the range becomes `500px`; when the element is set to `500px`, the animation attachment range size grows to `750px`.

The CSS scroll driven animations module provides mechanisms for defining different animation attachment ranges. The `animation-range-start` and `animation-range-end` properties, which can both be set using the `animation-range` shorthand, define the attachment range for the animation range's start edge and the end edge, along with any insets from either edge, respectively.

The animation-range properties accept the keyword `normal`, a `<timeline-range-name>`, a `<length-percentage>`, or both a `<timeline-range-name>` and the `<length-percentage>`. In this guide, we are covering the values for the `<timeline-range-name>` component of the value only.

The length-percentage values, such as `20%` or `100px`, inset the animation timeline from the named animation attachment ranges, by the set amount, with the value defaulting to `0`. This is covered in Understanding timeline insets.

Timeline range names

The `<timeline-range-name>` value type accepts six keywords: `cover`, `contain`, `entry`, `exit`, `entry-crossing`, and `exit-crossing`. Each of these represents a predefined *named timeline range*. A named timeline range is a named segment of an animation timeline. These keywords allow the developer to set the animation attachment range base that offsets are relative to. The start of the segment is represented as `0%` progress through the range; the end of the segment is represented as `100%` progress through the range. Where these points are depends on the named range used.

Cover

The animation attachment range in the previous examples all "cover" the entire range. This range represents the full range of the view progress timeline. `0%` progress represents the point at which the start border edge of the subject aligns with the end edge of the scrollport, and `100%` progress represents the point where the subject's end border edge reaches the start edge of the scrollport. As we've seen, the size of the `cover` range is the sum of subject and scrollport dimensions in the scroll direction. In all the examples thus far, the height of the animation attachment range is the height of the container plus the height of the animated element.

The `cover` named timeline range is the default range. We could have explicitly set the `<timeline-range-name>` to achieve the same results:

```
.animated_element {
  animation-range-start: cover;
  animation-range-end: cover;
}
```

```
<div>
  <svg viewBox="-1 -1 462 1252" xmlns="http://www.w3.org/2000/svg">
    <rect class="small end" width="100" height="50" x="10" y="450" />
    <rect class="medium end" width="100" height="250" x="125" y="250" />
    <rect class="large end" width="100" height="500" x="240" y="0" />
    <rect class="container" width="350" height="250" x="0" y="500" />
    <rect class="small start" width="100" height="50" x="10" y="750" />
    <rect class="medium start" width="100" height="250" x="125" y="750" />
    <rect class="large start" width="100" height="500" x="240" y="750" />
    <text y="625" x="5">cover</text>
    <text y="520" x="360">100%</text>
    <line x1="0" x2="350" y1="500" y2="500" />
    <line x1="0" x2="350" y1="750" y2="750" />
    <text y="760" x="360">0%</text>
  </svg>
</div>
```

The image demonstrates the animation timeline. The location of the element when it reaches the start of the animation attachment range's `0%` mark is shown as a yellow block. This represents the element position when the `from` keyframe is applied. The red block represents the location of the subject element relative to the scrollport when the `to` keyframe is applied. This is the position of the animated element when it reaches the end of the animation.

Depending on the size of the subject element and the chosen timeline range, the start and end positions may overlap. Areas of overlap (as seen in subsequent diagrams) will be represented by striped red and yellow areas.

Contain

The `contain` named timeline range fully *contains* the animation within the scrollport — the range starts when the animated element is 100% visible and ends when it ceases to be fully visible, if it can be fully visible.

The `contain` value represents the range during which the principal box is either fully contained by or fully covers its view progress visibility range within the scrollport, depending on whether the subject element is smaller (can be fully contained by) or larger than the scrollport.

- If the element is smaller than the scrollport in the scroll direction, `0%` occurs when the animated element's end border edge aligns with the end edge of the scrollport, and `100%` occurs when the animated element's start border edge aligns with the start edge of the scrollport. In other words, the `contain` value ranges from the point where the subject element is first completely contained by the scroll port (`0%`), to the point where it is no longer completely contained by the scroll port (`100%`).
- If the element is larger than the scrollport, the `0%` progress is when the animated element's start border edge reaches the start edge of the scrollport, and `100%` is when the end border edge aligns with the end edge. In other words, if the animation is larger than its container, the animated element is never fully visible as it is not "contained" within the scrollport. The animation starts when the start edge reaches the start edge of the scrollport, and ends when the animated element's end edge reaches the end edge of the container.
- If the animated element is the same size as its container, the animation still happens, but over `0px`, which is not visible to the user.

```
.animated_element {
  animation-range: contain;
}
```

```
body::before {
  content: "Contain";
}
```

In this example, the original height of the animated element is 20% of the height of the scrollport, and therefore can be completely contained within it. As a result, as explained earlier, the animation should start as soon as the element starts to enter the scrollport, and finish as soon as it begins to leave the scrollport.

If you check the `500px` radio button, the subject becomes twice as tall as the scrollport. The animation range begins when the subject element first completely covers the scroll port, with the `0%` occurring when the start edge reaches the start edge of the container. It ends when the element no longer completely covers the scrollport, with the `100%` occurring when the end edge crosses the container's end edge.

When the subject is the same size as the scroll container, as occurs when `250px` is selected, the animation still occurs, but over `0px`. As the `0%` and `100%` occur at the same time, the animation is instantaneous. The difference in styling is only perceivable because the properties defined in the `100%` keyframe state are applied after the animation ends. This is because the `animation-fill-mode` property is set to `forwards`. Otherwise, the middle-sized `250px` subject, being the same height as the scroll container, would appear not to animate at all.

```
<div>
  <svg viewBox="-1 -1 462 1000" xmlns="http://www.w3.org/2000/svg">
    <rect class="small end" width="100" height="50" x="10" y="500" />
    <rect class="medium end" width="100" height="250" x="120" y="500" />
    <rect class="large end" width="100" height="500" x="230" y="500" />
    <rect class="container" width="350" height="250" x="0" y="500" />
    <rect class="small start" width="100" height="50" x="10" y="700" />
    <rect class="medium start" width="100" height="250" x="120" y="500" />
    <rect class="large start" width="100" height="500" x="230" y="250" />
    <rect width="100" height="250" x="120" y="500" fill="url(#g)" />
    <rect width="100" height="250" x="230" y="500" fill="url(#g)" />
    <text y="460" x="10">contain</text>
    <text y="520" x="360">100%</text>
    <line x1="0" x2="350" y1="500" y2="500" />
    <line x1="0" x2="350" y1="750" y2="750" />
    <text y="760" x="360">0%</text>
  </svg>
</div>
```

```
body div,
body svg {
  margin: -60px 0 -300px;
}
```

The animation occurs when the element is within the areas represented by the white of the container in the `50px` example and by the red/yellow areas in the `250px` and `500px` examples.

It may be helpful for some to compare and contrast the `cover` and `contain` values. We can use the shorthand `animation-range` property to set the `animation-range-start` and `animation-range-end` properties to the same `<animation-name-range>` value:

```
#A {
  animation-range: contain;
}
#B {
  animation-range: cover;
}
```

```
body::before {
  content: "contain vs cover";
}
#A,
#B {
  width: 140px;
}
#A::after {
  content: " ( contain )";
}
#B::after {
  content: " ( cover ) ";
}
```

Select different radio buttons and scroll the scrollport to compare the effects of the `cover` and `contain` values on animation timelines.

Let's look at the other `<timeline-range-name>` keyword values!

Entry and exit

To make the entire animation happen only when the subject is in the process of entering or exiting the scrollport, use the `entry` or `exit` values, respectively. With these two values, the animation attachment range is based on the size of the animated element, not the size of the scrollport.

Entry

With `entry`, `0%` progress occurs the moment the animated element starts to enter the scrollport, when the subject's start edge crosses the scrollport's end edge.

The entire animation occurs as the subject comes into view, ending when it becomes completely visible or when it reaches the start edge; whichever occurs first. If the animated element is smaller than the scrollport, the animation attachment range is the size of the subject.

The position at `0%` progress is shown in yellow. The position at `100%` progress is displayed in red. When the animated element is larger than the scrollport, these two positions overlap, which is denoted by a striped background.

With `entry`, the animation attachment range is either the size of the animated element or the size of the container, whichever is smaller. If the subject is larger than the scrollport, the animation attachment range is the entire scrollport. With `entry`, the `100%` occurs when the subject's end edge crosses the end edge of the scrollport or, if the animated element is larger than the scrollport in the scroll direction, when the animated element's start edge reaches the start edge of the scrollport.

Setting `animation-range-start: entry` is the same as setting `animation-range-start: cover`. Setting `animation-range-end: entry` is equivalent to setting `animation-range-end: contain`.

```
<div>
  <svg viewBox="-60 400 530 980" xmlns="http://www.w3.org/2000/svg">
    <rect class="small end" width="100" height="50" x="10" y="700" />
    <rect class="medium end" width="100" height="250" x="120" y="500" />
    <rect class="large end" width="100" height="500" x="230" y="500" />
    <rect class="container" width="350" height="250" x="0" y="500" />
    <rect class="small start" width="100" height="50" x="10" y="750" />
    <rect class="medium start" width="100" height="250" x="120" y="750" />
    <rect class="large start" width="100" height="500" x="230" y="750" />
    <rect width="100" height="250" x="230" y="750" fill="url(#g)" />
    <text y="460" x="10">entry</text>
    <text y="520" x="360">100%</text>
    <text y="690" x="-50">100%</text>
    <line x1="130" x2="350" y1="500" y2="500" />
    <line x1="-10" x2="120" y1="700" y2="700" />
    <line x1="0" x2="350" y1="750" y2="750" />
    <text y="760" x="360">0%</text>
  </svg>
</div>
```

Exit

The `exit` value is the inverse of `entry`. With `exit`, the attachment range starts when the animated element's start edge crosses the scrollport's start edge.

```
<div>
  <svg viewBox="-60 -1 530 800" xmlns="http://www.w3.org/2000/svg">
    <rect class="small end" width="100" height="50" x="10" y="450" />
    <rect class="medium end" width="100" height="250" x="120" y="250" />
    <rect class="large end" width="100" height="500" x="230" y="0" />
    <rect class="container" width="350" height="250" x="0" y="500" />
    <rect class="small start" width="100" height="50" x="10" y="501" />
    <rect class="medium start" width="100" height="250" x="120" y="500" />
    <rect class="large start" width="100" height="500" x="230" y="250" />
    <rect width="100" height="250" x="230" y="250" fill="url(#g)" />
    <text y="600" x="10">exit</text>
    <text y="520" x="370">100%</text>
    <line x1="-5" x2="365" y1="500" y2="500" />
    <line x1="-10" x2="140" y1="550" y2="550" />
    <line x1="110" x2="360" y1="750" y2="750" />
    <text y="760" x="370">0%</text>
    <text y="560" x="-60">0%</text>
  </svg>
</div>
```

```
:root body div {
  margin: 0 0 -140px 0;
}
```

The `0%` progress occurs when the subject's start edge reaches the scrollport's start edge. The `100%` progress occurs when the subject's end edge crosses the start edge. Setting `animation-range-start: exit 0%` is equivalent to setting `animation-range-start: contain 100%`. Setting `animation-range-end: exit 100%` is equivalent to `animation-range-end: cover 100%`.

Comparing entry and exit

It may help to take a look at `entry` and `exit` side-by-side to understand the effect the size of the subject has on the animation attachment range: with these two values, the animation attachment range is never larger than the container.

```
#A {
  animation-range: entry;
}
#B {
  animation-range: exit;
}
```

```
body::before {
  content: "Entry and exit";
}
#A,
#B {
  width: 140px;
}
#A::after {
  content: " ( entry )";
}
#B::after {
  content: " ( exit ) ";
}
```

Scroll the viewbox to see the range of the `entry` and `exit` values, then change the size of the subjects using the radio buttons and scroll again.

When the subjects are small enough to be fully contained within the scrollport, the animation attachment timeline is at the start (`entry`) or end (`exit`) of the scrollport and the size of the attachment range is limited to the size of the animated element in the scroll direction.

With `entry` and `exit`, the animation range is contained to the size of the scrollport, while the element is not.

If the subject element is the size of the scrollport or larger:

- In the case of `entry`, the animation ends when the element fully covers the scrollport in the scroll direction.
- In the case of `exit`, the animation doesn't begin until, the element fully covers the scrollport in the scroll direction.

This may not be the effect you want. If you want an entry animation to keep running until the entire element has finished entering the start edge of the scrollport, or if you want an exit animation to start as soon as the element starts to exit the end edge of the scrollport, you need to use `entry-crossing` and `exit-crossing`.

Entry- and exit-crossing

If the subject element is smaller than the scrollport, and you want the full animation to occur as it enters or exits the scrollport, you can happily use `entry` or `exit`, respectively.

When the subject is larger than the scrollport, the animation doesn't run the full course of the element entering or exiting the scrollport. The `entry` value sets the `100%` progress to be when the element's start edge reaches the start-edge of the scrollport, before the element has fully entered the scrollport. With `exit`, the `0%` progress occurs when the element's end-edge reaches the scroll container's end edge, when part of the subject has already exited the scrollport. With both these values, the animation attachment range is smaller than the subject. If this isn't the effect you want, the `*-crossing` values may be the solution you seek.

Entry-crossing

The `entry-crossing` value represents the range during which the animated element crosses the end edge of the scrollport, with `0%` progress occurring when the element's start edge aligns with the end edge the scrollport and `100%` progress occurring when the element's end edge reaches the end edge of the scrollport, meaning it has finished fully scrolling into the scrollport.

It may be helpful to compare the two values in a live example.

```
#A {
  animation-range: entry;
}
#B {
  animation-range: entry-crossing;
}
```

```
body::before {
  content: "entry vs. entry-crossing";
}
#A::after {
  content: " ( entry )";
}
#B::after {
  content: " ( entry-crossing ) ";
}
```

Select the different height values, then scroll to compare `entry` with `entry-crossing` for each size.

Note how the effects are similar, except for when the `500px` is selected and the animated element is taller than the container. The `entry-crossing` range produces the same results as `entry` when the element is equal to or smaller than the scrollport, but when the element is larger than the scrollport, the `100%` occurs later, occurring only when the end edge has entered the view port. The animation attachment range is the size of the subject, and not clamped to the size of the scrollport.

```
<div>
  <svg viewBox="-60 -1 530 1252" xmlns="http://www.w3.org/2000/svg">
    <rect class="small end" width="100" height="50" x="10" y="700" />
    <rect class="medium end" width="100" height="250" x="120" y="500" />
    <rect class="large end" width="100" height="500" x="230" y="500" />
    <rect class="container" width="350" height="250" x="0" y="500" />
    <rect class="small start" width="100" height="50" x="10" y="750" />
    <rect class="medium start" width="100" height="250" x="120" y="750" />
    <rect class="large start" width="100" height="500" x="230" y="750" />
    <rect
      class="orange"
      width="100"
      height="250"
      x="230"
      y="750"
      fill="url(#g)" />
    <text y="460" x="10">entry</text>
    <text y="520" x="360">100%</text>
    <text y="690" x="-50">100%</text>
    <line x1="130" x2="350" y1="500" y2="500" />
    <line x1="-10" x2="120" y1="700" y2="700" />
    <line x1="0" x2="350" y1="750" y2="750" />
    <text y="760" x="360">0%</text>
  </svg>

  <svg viewBox="-60 -1 530 1252" xmlns="http://www.w3.org/2000/svg">
    <rect class="small end" width="100" height="50" x="10" y="700" />
    <rect class="medium end" width="100" height="250" x="120" y="500" />
    <rect class="large end" width="100" height="500" x="230" y="250" />
    <rect class="container" width="350" height="250" x="0" y="500" />
    <rect class="small start" width="100" height="50" x="10" y="750" />
    <rect class="medium start" width="100" height="250" x="120" y="750" />
    <rect class="large start" width="100" height="500" x="230" y="750" />
    <text y="200" x="0">entry-crossing</text>
    <text y="260" x="330">100%</text>
    <text y="490" x="80">100%</text>
    <text y="690" x="-50">100%</text>
    <line x1="225" x2="345" y1="250" y2="250" />
    <line x1="0" x2="230" y1="500" y2="500" />
    <line x1="-10" x2="120" y1="700" y2="700" />
    <line x1="0" x2="350" y1="750" y2="750" />
    <text y="760" x="360">0%</text>
  </svg>
</div>
```

```
:root body div {
  margin: -70px 0 -100px;
}
```

Exit-crossing

The `exit-crossing` value represents the range during which the animated element crosses the start edge of the scrollport, with `0%` progress occurring when the element's start edge aligns with the start edge the scrollport and `100%` progress occurring when the element's end edge reaches the start edge of the scrollport.

With `exit-crossing`, the animation starts as soon as the subject covers the scrollport (with `exit`, the animation doesn't start until the end edge of the subject enters into view). In both cases, the animation continues until the subject fully exits the scrollport's start edge.

```
#A {
  animation-range: exit;
}
#B {
  animation-range: exit-crossing;
}
```

```
body::before {
  content: "exit vs. exit-crossing";
}
#A::after {
  content: " ( exit )";
}
#B::after {
  content: " ( exit-crossing ) ";
}
```

The `exit-crossing` produces the same results as `exit` when the element is equal to or smaller than the scrollport, but when the element is larger than the scrollport, the `0%` occurs earlier, occurring as soon as the element's start edge reaches the scrollport's start edge, rather than waiting until the element's end edge enters the scrollport.

Like with `entry-crossing`, the animation attachment range is the size of the subject, and not clamped to the size of the scrollport.

```
<div>
  <svg viewBox="-60 -1 530 1052" xmlns="http://www.w3.org/2000/svg">
    <rect class="small end" width="100" height="50" x="10" y="450" />
    <rect class="medium end" width="100" height="250" x="120" y="250" />
    <rect class="large end" width="100" height="500" x="230" y="0" />
    <rect class="container" width="350" height="250" x="0" y="500" />

Other progress values

In this guide, we have mentioned `0%` and `100%` progress points. The animation-range values aren't limited to these to progress points. You can inset any of the named animation ranges by a set amount or a percentage of the full animation attachment range. This is discussed in the insets guide.

Scroll-driven animation timelines

A common UI pattern involves elements that animate as the user scrolls vertically or horizontally across a page. These *scroll-driven animations* occur in direct response to page scrolling or an overflowing scroll container within a page.

The properties defined in the CSS scroll-driven animations module expand upon CSS animations by enabling animating property values defined in `@keyframes` animations in response to user interaction.

This guide provides an overview of using CSS to create scroll-driven animation timelines and animations.

What is scroll-driven animation?

The CSS scroll-driven animations module defines properties that enable CSS keyframe animations to be linked to scrolling.

Timeline progression

Animations can be set to progress along a *scroll-based timeline* instead of the default time-based document timeline, without needing JavaScript. CSS enables us to define which animation timeline to use, including animating elements by scrolling a scrollable element rather than by the passing of time.

Performance benefits

CSS scroll-driven animations are performant. JavaScript scroll-driven animations require `scroll` event listeners and `IntersectionObserver` objects on the main thread to track elements across the scrollport. Any time you rely on the main thread to render effects with JavaScript, you run the risk of blocking the main thread, which can lead to an unresponsive page and a bad user experience, or jank.

Foundations

Scroll-driven animations build upon CSS animations and the Web Animations API. Before creating scroll-driven animations, you must have an understanding of CSS `@keyframes` animations. See the using CSS animations guide to learn more.

In CSS, animations are created by attaching keyframe animations to an element using the `animation-name` property (or `animation` shorthand). By default, animations run on the default document timeline, moving from the `from` keyframe to the `to` keyframe as time passes by, with the animation lasting as long as the time defined by the `animation-duration` property value. When set to run on the default document timeline, animations play through to completion unless prevented from doing so, for example, by having the `animation-play-state` set to `paused` or by removing the `animation-name` from the element.

Scroll-driven animations are CSS animations that are not run on the default DocumentTimeline. Instead, they run on a scroll-progress or view-progress timeline, which is driven by the scrolling of an element's contents. There's a direct link between the user's scrolling action and the animation's progress along the `@keyframe` keyframes. As the user scrolls up, down, left, or right, the animation moves forward or backward through the keyframe progression. When scrolling is paused, the animation pauses, as if `animation-play-state` were set to `pause`.

Animation timelines

The `animation-timeline` property, defined in the CSS animations module, is used to set the timeline used for the animation.

The CSS scroll-driven animations module defines features for setting the `animation-timeline` as a scroll-progress or view-progress timeline. You can explicitly name an element as a timeline controller using the `scroll-timeline-*` and `view-timeline-*` properties, then set that name as the `animation-timeline` of a descendant element. You can also define *anonymous scroll progress timelines* and *anonymous view progress timelines* using the `scroll()` and `view()` functions.

Alternatively, the `animation-timeline` property can be used to explicitly state that the default document timeline be used or to specify that the animation doesn't have a timeline, and therefore shouldn't occur at all.

Regular CSS animations: default document timeline

Setting `animation-timeline` explicitly to `auto`, or omitting the property and allowing it to default to `auto`, sets the timeline to be the default document timeline. When set to this default value, the animation's progress is determined by the `animation-duration`, the `animation-delay`, and how much time has passed since the animation was associated with the element via the `animation-name` property. The time-based document timeline is the timeline traditionally associated with CSS animations.

```
:checked ~ .container > .item {
  animation-name: action;
  animation-duration: 3s;
  animation-delay: 500ms;
```

```
  animation-timeline: auto;
}
```

We create a rotation keyframe animation called `action`:

```
@keyframes action {
  from {
    rotate: 45deg;
  }
  to {
    rotate: 765deg;
  }
}
```

```
<input type="checkbox" id="i" />
<label for="i">
  Check to apply the animation. Uncheck to remove the animation
</label>
<div class="container">
  <span class="item"></span>
</div>
```

```
div {
  width: 400px;
  height: 100px;
  border: 1px solid;
  background-color: palegoldenrod;
  position: relative;
}
span {
  --size: 50px;
  height: var(--size);
  width: var(--size);
  background-color: magenta;
  border: 1px solid;
  position: absolute;
  left: calc(50% - (var(--size) / 2));
  top: calc(50% - (var(--size) / 2));
}
```

When the checkbox is checked, the `action` animation is applied to the element. When unchecked, the animation is not applied to the `<div>`.

Try checking the checkbox. Nothing will happen during the half-second animation delay. Then, once the animation starts, the box will jump to a 45-degree rotation, and then it will take 3 seconds to rotate an additional 720 degrees, or two additional full rotations. After a total of three and a half seconds, the animation concludes, and the `<div>` will return to its default non-rotated state.

> **Note:** The `animation-timeline` is reset to the default `auto` value by the `animation` shorthand property, but cannot be set using the shorthand. Therefore, when creating scroll-driven animations, always declare the `animation-timeline` after any `animation` shorthand declarations to achieve the desired effect.

Scroll progress timelines

With *scroll progress timeline*, the timeline progresses based on the scrolling of the scrollable element (*scroller*) from top to bottom (or left to right) and back again. By default, the position in the scroll range is converted into a percentage of progress — `0%` at the start and `100%` at the end.

To create a scroll progress timeline, the `animation-timeline` value must reference the scroller, which can be named or anonymous.

Named scroll progress timelines

A *named scroll progress timeline* is one where the scroller is explicitly named using the `scroll-timeline-name` property (or the `scroll-timeline` shorthand). The name is a `<dashed-ident>`. The scroller is linked to the element to be animated by specifying its `scroll-timeline-name` as the value of that element's `animation-timeline` property.

Our HTML includes three elements: the `item`, which we will animate; its `container`, which we will scroll; and the scroller. The `container` needs to be large enough to overflow its `scroller` parent: If there is no scrolling, there will be no scroll timeline.

```
<main class="scroller">
  <div class="container">
    <span class="item"></span>
  </div>
</main>
```

We provide some basic styles. The important ones include setting a height on the container that is taller than the scroller, and then setting the overflow to allow scrolling:

```
.scroller {
  width: 400px;
  height: 100px;
  overflow: scroll;
}
.container {
  height: 200px;
}
```

Setting an `animation-timeline` on the animated element that matches the `scroll-timeline-name` of an ancestor element is what creates the named scroll progress timeline. We also have to include an animation, which we do by setting the value of the `animation-name` component of the `animation` shorthand to the `<custom-ident>` name of our keyframe animation:

```
.scroller {
  scroll-timeline-name: --rotate;
}
.item {
  animation: action 1ms linear;
  animation-timeline: --rotate;
}
```

```
main {
  border: 1px solid;
  background-color: palegoldenrod;
}
div {
```

```
  position: relative;
}
span {
  --size: 50px;
  height: var(--size);
  width: var(--size);
  background-color: magenta;
  border: 1px solid;
  position: absolute;
  left: calc(50% - (var(--size) / 2));
  top: calc(50% - (var(--size) / 2));
}
```

In this case, we don't have a checkbox, as the `action` animation progression is controlled by the scrolling of the overflowing scroller, which, unlike time, does not expire.

Before any scrolling occurs, the container's position is at the top of the scroller, and the animation is at the 0% keyframe. Try scrolling down. As you scroll, the animation progresses through the timeline, rotating an additional 720 degrees. When you can no longer scroll, the animation's progression is at the 100%, or `to`, keyframe. The animated item doesn't return to its default rotation unless the scroller is scrolled back up to the top.

Animation duration

You may have noticed that the `animation-duration` component of the `animation` shorthand was set to `1ms`. When creating CSS scroll-driven animations, specifying an `animation-duration` value does not affect the duration of the animation, and shouldn't be necessary. However, durations can affect non-linear view progress animation timelines, and Firefox requires a non-zero `animation-duration` to apply an animation to an element. For these reasons, it is common practice to set `animation-duration` to `1ms`.

Setting `animation-duration: 1ms` ensures that the animation works in Firefox, the animation effect is consistent across all browsers, and the animation is hidden if a browser doesn't support view progress animation timelines. If the browser supports keyframe animations, the animation will not be visible to the user. However, the animation still happens, and animation events are fired.

Anonymous scroll progress timelines

You don't have to name your scroll progress timeline. Instead, you can associate an *anonymous scroll progress timeline* with the animation. In this case, the `animation-timeline` of the element to animate is set to a `scroll()` function. The function selects the scroller that provides the scroll progress timeline and the scroll axis to use based on the optional arguments you pass to it. One parameter is a `<scroller>` keyword defining the relationship of the scroller element to the current element (`nearest`, `root`, or `self`). The other is the scrollbar `<axis>` value (`block`, `inline`, `y`, or `x`).

This example uses all the same CSS as the previous example, except for the `animation-timeline`, which we set to a `scroll()` function. We are also overriding the size of the container to change the direction of the scroll:

```
.item {
  animation: action 1ms linear;
  animation-timeline: scroll(nearest inline);
}
.container {
  inline-size: 800px;
  block-size: 100%;
}
```

We set an `inline-size` on the container so that it overflows in the inline direction, and set the `block-size` to `100%` so it no longer overflows in the block direction. Try scrolling in the inline direction.

View progress timelines

You can also progress an animation based on the change in visibility of an element inside a scroller — this is done via *view progress timelines*. Instead of tracking the scroll offset of a scroll container, view progress timelines track the relative position of an element, called the *subject*, within a scrollport. The progression of an animation's keyframes is based on the *visibility* of the subject inside the scroller. Unlike scroll progress timelines, with view progress timelines, you can't specify the scroller — the subject's visibility is always tracked within its nearest ancestor scroller.

A view progress timeline animation only occurs when the element is visible within its scrollport. Timeline progress starts at `0%` when the tracked subject starts intersecting the scrollport at the block or inline end edge. The `100%` occurs when the subject exits the scrollport at the block or inline start edge.

Because the `100%` is generally reached when the element leaves the viewport, you likely want to set the final effect of your animation in a keyframe block that occurs well before the end of the animation. You can set your completed effect within the `20%`, `50%`, or `80%` keyframe block rather than using the `to` or `100%` keyframe to ensure the element finishes animating while still in view.

With view progress timelines, you can adjust the view progress visibility range. Use `view-timeline-inset`, part of the `view-timeline` shorthand, to adjust when the subject is considered to be in view. The default value is `auto`. The effect of any non-`auto` inset value is as if you moved the edges of the scroll port: a positive inset value creates an inward adjustment, and a negative value creates an outward adjustment.

Similar to scroll progress timelines, the view progress timeline can be named or anonymous.

Named view progress timeline

A *named view progress timeline* is one where the subject is explicitly named using the `view-timeline-name` property, a component of the `view-timeline` shorthand. The `<dashed-ident>` name is then linked to the element to animate by specifying it as the value of that element's `animation-timeline` property.

With named view progress timelines, the element to animate does not have to be the same as the subject. In other words, the element controlling the timeline doesn't have to be the same as the element being animated. This means you can animate one element based on another element's movement within its scrollable container.

Here we use the `view-timeline-name` property to name an element, identifying the element itself as the source of a view progress timeline. We then set that name as the value of the `animation-timeline` property.

```
.item {
  animation: action 1ms linear;

  view-timeline-name: --a-name;
  animation-timeline: --a-name;
}
```

We applied the animation **before** the animation timeline, as the `animation` resets the `animation-timeline` to `auto`.

The animation is slightly different from the previous examples in that the spinning effect starts at `20%` and ends at `80%` of the way through the animation; this means the element will not be actively spinning when it first comes into view and will stop spinning before it is completely out of view.

```
@keyframes action {
  0%,
  20% {
    rotate: 45deg;
  }
  80%,
  100% {
    rotate: 720deg;
  }
}
```

```
.scroller {
  width: 400px;
  height: 200px;
  line-height: 2;
  overflow: scroll;
  border: 1px solid;
  background-color: palegoldenrod;
}
.item {
  --size: 50px;
  height: var(--size);
  width: var(--size);
  background-color: magenta;
  border: 1px solid;
  left: calc(50% - (var(--size) / 2));
  top: calc(50% - (var(--size) / 2));
}
```

```
<main class="scroller">
  <p>Scroll down to view the animation</p>
  <p> </p>
  <p> </p>
  <p> </p>
  <div class="item"></div>
  <p> </p>
  <p> </p>
  <p> </p>
  <p> </p>
  <p>Scroll up to view the animation</p>
</main>
```

Scroll the element into view. Note that the element animates through the `@keyframes` animation as it moves through the visible area of its ancestor scroller.

Anonymous view progress timeline: the <code>view()</code> function

Alternatively, a `view()` function can be set as the value of the `animation-timeline` property to specify that an element's animation timeline is an *anonymous view progress timeline*. This causes the element to be animated based on its position inside its nearest parent scroller.

The `view()` function creates a view timeline. You attach the timeline to the element you want to animate using the `animation-timeline` property. The function creates a view timeline for each element matched by the selector.

In this example, we again define the `animation` before the `animation-timeline`, so the timeline is not reset. We then include an argument-less `view()` function. We don't specify a scroller, as, by definition, the subject's visibility is tracked by its nearest ancestor scroller.

```
.item {
  animation: action 1ms linear;
  animation-timeline: view();
}
```

Parameters of the <code>view()</code> function

The `view()` function takes up to three optional values as arguments:

- Zero or one `<axis>` parameters. If set, this specifies the scroll axis along which the animation progresses.
- Either the keyword `auto` or zero, one, or two `<length-percentage>` inset values. If set, these values specify offsets for the scrollport start and/or end.

Declaring `view()` is equivalent to `view(block auto)`, which defines `block` as the axis of the parent element that supplies the timeline and the `scroll-padding`, which generally defaults to `0`, as the insets within the visible area at which the animation starts and ends.

The function sets the values of the `view-timeline-axis` and `view-timeline-inset` properties.

The `view-timeline-inset` arguments specify insets (if positive) or outsets (if negative) that adjust the start and end of the scrollport. They are used to determine the scroll positions at which the element is considered "in view", which determines the length of the animation timeline. In other words, instead of starting at the start edge and ending at the end edge of the scrollport, the animation occurs at the start and end of the inset-adjusted view.

Unlike the scroll timeline's `scroll()` function, there is no `<scroller>` argument in the `view()` function, as the view timeline always tracks the subject within its nearest ancestor scroll container.

In this example, as we are using inset values, we can use the `from` and `to` keyframe selectors.

```
@keyframes action {
  from {
    rotate: 45deg;
  }
  to {
    rotate: 720deg;
  }
}

.item {
  animation: action 1ms linear;
  animation-timeline: view(block 20% 20%);
}
```

Accessibility concerns

As with all animations and transitions, always take any user's `prefers-reduced-motion` preference into account.

Removing an animation's timeline

Setting `animation-timeline: none` disassociates the element from all animation timelines, including the default time-based document timeline, meaning the element will not animate. While some animations may be necessary, you can remove animations based on the user's `prefers-reduced-motion` setting with:

```
@media (prefers-reduced-motion: reduce) {
  .optionalAnimations {
    animation-timeline: none;
  }
}
```

Because the `animation` shorthand sets the `animation-timeline` to `auto`, use a selector with enough specificity to ensure your `animation-timeline` isn't overridden by your `animation` shorthand declarations.

CSS scrollbars styling

The **CSS scrollbars styling** module defines properties that you can use for visual styling of scrollbars. You can customize the scrollbar width as needed. You can also customize the scrollbar *track* color (the background) and the scrollbar *thumb* color (the draggable handle).

Scrollbar styling in action

This example defines a thin scrollbar with a teal thumb and lighter teal track. To see the thumb, scroll the text. After the scrollbar is visible, hover over it to see the track.

```
.poem {
  width: 300px;
  height: 100px;
  border: 1px solid;
}
```

```
.poem {
  overflow: scroll;
  scrollbar-color: #0b4f4a #5f9e98;
  scrollbar-width: thin;
}
```

```
<blockquote class="poem">
  <h3>A Small Needful Fact</h3>
  <pre>
Is that Eric Garner worked
for some time for the Parks and Rec.
Horticultural Department, which means,
perhaps, that with his very large hands,
perhaps, in all likelihood,
he put gently into the earth
some plants which, most likely,
some of them, in all likelihood,
continue to grow, continue
to do what such plants do, like house
and feed small and necessary creatures,
like being pleasant to touch and smell,
like converting sunlight
into food, like making it easier
for us to breathe.
</pre>
  <p>
    - <a href="https://onbeing.org/poetry/a-small-needful-fact/">Ross Gay</a>
  </p>
</blockquote>
```

> **Note:** When customizing scrollbars, ensure that the thumb and track have enough contrast with the surrounding background. Also ensure that the scrollbar hit area is large enough for people who use touch input.

CSS selectors

The **CSS selectors** module defines the patterns to select elements to which a set of CSS rules are then applied along with their specificity. The CSS selectors module provides us with more than 60 selectors and five combinators. Other modules provide additional pseudo-class selectors and pseudo-elements.

> **Note:** This page introduces a CSS module. To find an exhaustive list of all selectors defined by CSS specifications, see the selectors reference page.

In CSS, selectors are patterns used to match, or select, the elements you want to style. Selectors are also used in JavaScript to enable selecting the DOM nodes to return as a `NodeList`.

Selectors, whether used in CSS or JavaScript, enable targeting HTML elements based on their type, attributes, current states, and even position in the DOM. Combinators allow you to be more precise when selecting elements by enabling selecting elements based on their relationship to other elements.

Reference

Combinators and separators

- `+` (Next-sibling combinator)
- `>` (Child combinator)
- `~` (Subsequent sibling combinator)
- `" "` (Descendant combinator)
- `|` (Namespace separator)
- `,` (Selector list)

The CSS selectors module also introduces the column combinator (`||`). Currently, no browsers support this feature.

Privacy and the :visited selector

Originally, the CSS `:visited` selector was a privacy and security risk. With a little bit of JavaScript, websites could uncover a user's browsing history and figure out what sites the user had visited. This was done using methods like `window.getComputedStyle` and other techniques. This process was quick, enabling websites to not only determine where the user had been on the web, but also to guess a lot of information about the user's identity.

To mitigate this privacy concern, browsers limit the amount of information that can be obtained from visited links.

Little white lies

To preserve users' privacy, browsers lie to web applications under certain circumstances:

- The `window.getComputedStyle` method and similar functions, such as `element.querySelector`, always return values indicating that a user has never visited any of the links on a page.
- When using a sibling selector, such as `:visited + span`, the adjacent element (`span` in this example) is styled as though the link were unvisited.
- In rare scenarios, if you're using nested link elements and the element being matched is different from the link whose presence in history is being tested, the element will be rendered as though the link were unvisited.

Limits to visited link styles

You can style visited links, but there are limits to which styles you can use. Only the following styles can be applied to visited links:

- `color`
- `background-color`
- `border-color` (and its sub-properties)
- `column-rule-color`
- `outline-color`
- `text-decoration-color`
- `text-emphasis-color`
- Color parts of the `fill` and `stroke` attributes

In addition, even for the styles mentioned above, transparency differences between unvisited and visited links are not applied. This restriction prevents the use of the `alpha` parameter in various `<color>` functions or the `transparent` keyword to distinguish between the two states.

Here is an example of how to use styles with the aforementioned restrictions:

```
:link {
  outline: 1px dotted blue;
  background-color: white;
  /* The default value of `background-color` is `transparent`. You need to
     specify a different value, otherwise changes on `:visited` won't apply. */
}

:visited {
  outline-color: orange; /* Visited links have an orange outline */
  background-color: green; /* Visited links have a green background */
  color: yellow; /* Visited links have yellow colored text */
}
```

Impact on web developers

You may want to consider the following when developing sites:

- Changing `background-image` values based on a link's visited state will not work since only colors can be used to style visited links.
- Colors that are otherwise transparent will not apply when styled via a `:visited` selector.

CSS selector structure

The CSS selector represents a particular pattern of element or elements in a tree structure. The term "selector" can refer to a simple selector, a compound selector, or a complex selector. When included in the `:has()` pseudo-class as a parameter, these selectors are referred to as relative selectors, representing elements relative to one or more anchor elements.

These selectors can be combined into a comma-separated selector list. If any selector in a non-forgiving selector list is invalid, the entire selector list is invalidated.

Simple selector

A **simple selector** is a selector with a single component, such as a single type selector, attribute selector, or pseudo-class, that's not used in combination with or contains any other selector component or combinator. A given element is said to match a simple selector when that simple selector accurately describes the element. Any selector that contains a single basic selector, attribute selector, pseudo-class, or pseudo-element selector is a simple selector.

```
#myId {
}

[pattern*="\d"] {
}
```

Compound selector

A **compound selector** is a sequence of simple selectors that are not separated by a combinator. A compound selector represents a set of simultaneous conditions on a single element. A given element is said to match a compound selector when the element matches all the simple selectors in the compound selector.

```
a#selected {
}

[type="checkbox"]:checked:focus {
}
```

In a compound selector, the type selector or universal selector must come first in the sequence of selectors. Only one type selector or universal selector is allowed in the sequence. As whitespace represents the descendant combinator, no whitespace is allowed between the simple selectors that make up a compound selector.

Complex selector

A **complex selector** is a sequence of one or more simple and/or compound selectors that are separated by combinators, including the white space descendant combinator.

A complex selector represents a set of simultaneous conditions on a set of elements.

```
a#selected > .icon {
}

.box h2 + p {
}
```

Selectors can be read from right to left. For example, `a#selected > .icon` matches all elements with a class of `icon` that are the direct children of the `<a>` element with the id `selected`. The selector `.box h2 + p` matches the first `<p>`s to come immediately after any `<h2>` elements that are descendants of any element with the class of `box`.

Selector list

A **selector list** is a comma-separated list of simple, compound, and/or complex selectors. A given element is said to match a selector list when the element matches any (at least one) of the selectors in that selector list.

```
#main,
article.heading {
}
```

If any selector in a non-forgiving selector list is invalid, the entire selector list is invalidated.

```
#main,
:bad-pseudoclass,
.validClass {
  /* `:bad-pseudoclass` is invalid, invalidating this style block */
}
```

The `:is()` and `:where()` pseudo-classes can be used to construct forgiving selector lists.

Relative selector

A **relative selector** is a selector representing an element relative to one or more anchor elements preceded by a combinator. Relative selectors that don't begin with an explicit combinator have an implied descendant combinator.

Relative selectors cannot be used in a selector list. Rather, it is accepted within certain contexts, such as the `:has()` pseudo-class.

```
:has(+ div#topic > #reference) {
}

:has(> .icon) {
}

dt:has(+ img) ~ dd {
}
```

CSS selectors and combinators

CSS selectors are used to define a pattern of the elements that you want to select for applying a set of CSS rules on the selected elements. Combinators define the relationship between the selectors. Using various selectors and combinators, you can precisely select and style the desired elements based on their type, attributes, state, or relationship to other elements.

Types of selectors

There are over 80 selectors and combinators. CSS selectors can be grouped into the following categories based on the type of elements they can select.

Basic selectors

The type selector selects all elements that have the given node name. For example, `div` will select all `<div>` elements and `input` will match any `<input>` element. The universal selector, denoted with an asterisk (`*`), is a special type selector that selects all elements.

The class selector selects all elements that have the given `class` attribute denoted by the class name prefixed with a period (`.`). For example, `.index` will match any element that has `class="index"`. The ID selector selects an element based on the value of its `id` attribute. The selector is the `id` prefixed with a "number sign" (U+0023, `#`). For example, `#toc` will match the element that has `id="toc"`. Both `class` and `id` are global attributes. There should be only one element with a given `id` in a document; but if there is more than one, the ID selector will match all the elements with that `id`.

When combining a type or universal selector with a class or id selector to create a compound selector, the type or universal selector must precede the class or id.

CSS

In this example, we declare four simple selectors and one compound selector using the four basic selector types, as described above.

```
* {
  font-style: italic;
}
p {
  color: red;
}
.myClass {
  text-decoration: underline;
}
#myId {
  font-family: monospace;
}
p.myClass#myId {
  font-size: 1.5rem;
}
```

HTML

```
<p class="myClass" id="myId">I match everything.</p>
<p>I match the universal and type selectors only.</p>
```

Result

Combinators

Using CSS combinators, we can combine selectors to select DOM nodes based on their relationship to other elements within the document node tree. This combining of selectors with combinators creates complex selectors.

Descendant combinator

The descendant combinator, denoted with one or more spaces, selects nodes that are descendants of the first element. For example, `div span` will match all `<span>` elements that are inside a `<div>` element.

Child combinator

The child combinator is more specific than the descendant combinator. Denoted with the greater than character (`>`), the child combinator selects nodes that are direct children of the first element. Comparing with our previous example, `div > span` will match only the `<span>` elements that are direct children of a `<div>` element.

Subsequent-sibling combinator

In addition to descendant selectors, CSS also enables selecting elements based on their siblings. The subsequent-sibling combinator, denoted with a tilde (`~`), selects siblings. Given `A ~ B`, all elements matching `B` will be selected if they are preceded by `A`, provided both `A` and `B` share the same parent. For example, `h2 ~ p` will match all `<p>` elements that follow an h2, immediately or not.

Next-sibling combinator

The next-sibling combinator, denoted by the plus symbol (`+`), is similar to the subsequent-sibling. However, given `A + B`, it only matches `B` if `B` is immediately preceded by `A`, with both sharing the same parent. Amending our previous example, `h2 + p` will match only the single `<p>` element that *immediately* follows an `<h2>` element.

Column combinator

There is also a column combinator, denoted by two pipe characters (`||`), which, when supported, selects nodes that belong to a column. For example, `col || td` will match all `<td>` elements that belong to the scope of the `<col>`.

Namespace separator

The namespace separator is another combinator that is generally used in conjunction with the `@namespace` at-rule. This combinator is denoted by a single pipe character (`|`). It enables limiting type selectors and the universal selector to a specific namespace. For example, by defining a namespace such as `@namespace SVG url('http://www.w3.org/2000/svg');`, you can include selectors that target elements nested in an SVG namespace only. Declaring `SVG|a` would match links within SVGs and not those in the rest of the document. Namespacing can be useful to target MathML, SVG, or other XML-based content within your HTML.

CSS

In this example, we declare five relative selectors using simple selectors combined with combinators.

```
h2 + p ~ p {
  font-style: italic;
}
h2 + p + p {
  color: red;
}
.myClass + p {
  text-decoration: underline;
}
#myId > .myClass {
  outline: 3px dashed red;
}
* > p {
  font-size: 1.1rem;
}
```

HTML

```
<h2 class="myClass" id="myId">
  No selectors match. <span class="myClass">This span has an outline</span> as
  it is both myClass and a child of #myId.
</h2>
<p>The first paragraph is underlined. All the paragraphs are 1.1rem.</p>
<p>
  The second paragraph is red. This and the following paragraphs are italic.
</p>
<p>The third paragraph is NOT red. It is italic and 1.1rem.</p>
<p class="myClass">
  Does not have an outline; this is a sibling of H2, not a child. It is italic
  and 1.1rem.
</p>
```

Result

Creating complex selectors with CSS nesting

The above complex selectors can also be defined using simple selectors, combinators, and CSS nesting, with or without the `&` nesting selector.

CSS

In this example, we replicate the same five relative selectors using simple selectors combined with combinators, but this time with CSS nesting.

```
h2 {
  & + p {
    & ~ p {
      font-style: italic;
    }
    & + p {
      color: red;
    }
  }
}
.myClass {
  & + p {
    text-decoration: underline;
  }
}
#myId {
  & > .myClass {
    outline: 3px dashed red;
  }
}
* {
  & > p {
    font-size: 1.1rem;
  }
}
```

HTML

```
<h2 class="myClass" id="myId">
  No selectors match. <span class="myClass">This span has an outline</span> as
  it is both myClass and a child of #myId.
</h2>
<p>The first paragraph is underlined. All the paragraphs are 1.1rem.</p>
<p>
  The second paragraph is red. This and the following paragraphs are italic.
</p>
<p>The third paragraph is NOT red. It is italic and 1.1rem.</p>
<p class="myClass">
  Does not have an outline; this is a sibling of H2, not a child. It is italic
  and 1.1rem.
</p>
```

Result

Attribute selectors

Attribute selectors select all elements that, depending on how the selector is written, either have the given attribute or have the given attribute with a substring value match. For example, `[type]` will match all elements that have the `type` attribute set (to any value), and `[type="submit"]` will match `<input type="submit">` and `<button type="submit">`, or any element with `type="submit"` set, even though this attribute-value pair is only supported on `<input>` and `<button>` elements. The match is case-insensitive.

The case sensitivity of the attribute depends on the language. Generally, in HTML, if an attribute is enumerated, the value in the selector is case-insensitive, even if the value is not one of the enumerated values or if the attribute is not a valid value for the element on which it is set. For non-enumerated attributes, like `class`, `id`, or any `data-*` attribute, or for non-HTML attributes, like `role` or `aria-*` attributes, the value match is case-sensitive; the match can be made case-insensitive with a case-insensitive modifier (`i`).

Pseudo-class selectors

The CSS selectors module defines over 60 pseudo-classes. Pseudo-classes are simple selectors, prefixed with a colon (`:`), that allow the selection of elements based on state information that is not contained in the document tree. `pseudo-classes` can be used to style an element based on its *state*. For example, the `:target` simple selector targets element of a URL containing a fragment identifier, and the `a:visited` compound selector matches all `<a>` elements that have been visited by a user.

The pseudo-classes can be categorized as element display state, input, linguistic, location, resource state, time-dimensional, tree-structural, user action, and functional.

Multiple pseudo-classes can be combined to create compound selectors. When combining a pseudo-class into a compound selector with a type or universal selector, the pseudo-class must follow the type selector or universal selector, if present.

Pseudo-element selectors

Not all CSS selectors are defined in the CSS selectors module. CSS pseudo-element selectors are defined in the CSS pseudo-elements module.

CSS pseudo-elements, prefixed with two colons (`::`), represent entities that are not included in HTML. For example, the simple `::marker` selector selects list item bullets, and the compound selector `p::first-line` matches the first line of all `<p>` elements.

See the pseudo-classes and pseudo-elements specification tables for details on those.

Using the :target pseudo-class in selectors

When a URL points at a specific piece of a document using a URL fragment identifier, it can be difficult for the user to notice. This guide discusses using CSS to draw attention to the target of a URL to improve user experience.

Picking a Target

The pseudo-class `:target` is used to style the target element of the document identified using the URL fragment identifier. For example, the URL `https://developer.mozilla.org/en-US/docs/Web/CSS#reference` contains the fragment identifier `#reference`. In HTML, identifiers are found as the values of either `id` or `name` attributes, since the two share the same namespace. Thus, the example URL would point to the element that has the id `reference` in that document.

To style any `h2` element that is the target of a URL, while not affecting any other kind of element to get a target style, use the `:target` pseudo-class with the type selector:

```
h2:target {
  outline: 2px solid;
}
```

It's also possible to create styles that are specific to a particular fragment of the document. This is done using the same identifying value that is found in the URI. Thus, to add a background color to the `#reference` fragment, we would write:

```
#reference:target {
  background-color: yellow;
}
```

Targeting all elements

If the intent is to create a "blanket" style that will apply to all targeted elements, then the universal selector comes in handy:

```
:target {
  color: red;
}
```

Example

In the following example, there are five links that point to elements in the same document. Selecting the "First" link, for example, will cause `<h1 id="one">` to become the target element. Note that the document may jump to a new scroll position, since target elements are placed on the top of the browser window if possible.

```
<h4 id="one">…</h4>
<p id="two">…</p>
<div id="three">…</div>
<a id="four">…</a> <em id="five">…</em>

<a href="#one">First</a>
<a href="#two">Second</a>
<a href="#three">Third</a>
<a href="#four">Fourth</a>
<a href="#five">Fifth</a>
```

Conclusion

In cases where a fragment identifier points to a portion of the document, readers may become confused about which part of the document they're supposed to be reading. By styling the target of a URI, reader confusion can be reduced or eliminated.

CSS shadow parts

The **CSS shadow parts** module defines the `::part()` pseudo-element that can be set on a shadow host. Using this pseudo-element, you can enable shadow hosts to expose the selected element in the shadow tree to the outside page for styling purposes.

By default, elements in a shadow tree can be styled only within their respective shadow roots. The CSS shadow parts module enables including a `part` attribute on `<template>` descendants that make up the custom element, exposing the shadow tree node to external styling via the `::part()` pseudo-element.

CSS shapes

The **CSS shapes** module describes geometric shapes. It also defines CSS properties that can use the shapes to control the geometry of an element's float area; this area can then be applied to exclusions, or specify an element's content area.

The specification defines several ways to create shapes. Content can be wrapped around or within a shape rather than following the default rectangle shape of the element's box.

Shapes define geometries that can be used as CSS values. This module provides functions for creating ellipses, polygons, and arbitrary geometries. Other CSS modules can make use of shapes defined in this specification, including CSS motion path and CSS masking.

CSS shapes in action

The example below shows an image that has been floated left, and the `shape-outside` property applied with a value of `circle(50%)`. This creates a circle shape, and the content wrapping the float now wraps around that shape. This changes the length of the wrapping text's line boxes. You can click "Play" to edit the code in the MDN Playground.

```
<div class="box">
  <img
    alt="A hot air balloon"
    src="https://mdn.github.io/shared-assets/images/examples/round-balloon.png" />
  <p>
    One November night in the year 1782, so the story runs, two brothers sat
    over their winter fire in the little French town of Annonay, watching the
    grey smoke-wreaths from the hearth curl up the wide chimney. Their names
    were Stephen and Joseph Montgolfier, they were papermakers by trade, and
    were noted as possessing thoughtful minds and a deep interest in all
    scientific knowledge and new discovery. Before that night—a memorable night,
    as it was to prove—hundreds of millions of people had watched the rising
    smoke-wreaths of their fires without drawing any special inspiration from
    the fact.
  </p>
</div>
```

```
body {
  font: 1.2em / 1.5 sans-serif;
}
img {
  float: left;
  shape-outside: circle(50%);
}
```

Shapes from box values

A straightforward way to create a shape is to use a value from the CSS box model module. This article explains how to do this.

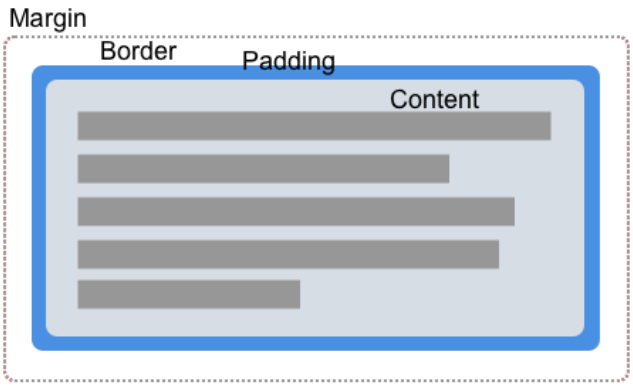
The `<box-edge>` box values allowable as a shape value are:

- `content-box`
- `padding-box`
- `border-box`
- `margin-box`

The `border-radius` values are also supported. This means you can give an element a curved border, and flow your content around the created shape.

CSS box model

The values listed above correspond to the various parts of the CSS Box Model. A box in CSS has content, padding, border, and margin.



By using box values for shapes, we can wrap our content around the edges defined by these values. In each of the examples below, I am using an element that has padding, a border, and a margin defined so that you can see the different ways in which content will flow.

margin-box

The `margin-box` is the shape defined by the outside margin edge and includes the corner radius of the shape, should `border-radius` have been used in defining the element.

In the example below, we have a circular purple item which is a `<div>` with a height, width, and background color. The `border-radius` property has been used to create a circle by setting `border-radius: 50%`. As the element has a margin, you can see that the content is flowing around the circular shape and the margin applied to it.

```
<div class="box">
  <div class="shape"></div>
  <p>
    One November night in the year 1782, so the story runs, two brothers sat
    over their winter fire in the little French town of Annonay, watching the
    grey smoke-wreaths from the hearth curl up the wide chimney. Their names
    were Stephen and Joseph Montgolfier, they were papermakers by trade, and
    were noted as possessing thoughtful minds and a deep interest in all
    scientific knowledge and new discovery.
  </p>
</div>
```

```
body {
  font: 1.2em sans-serif;
}

.shape {
  background-color: rebeccapurple;
  height: 80px;
  width: 80px;
  padding: 20px;
  margin: 20px;
  border: 10px solid black;
  border-radius: 50%;
  float: left;
  shape-outside: margin-box;
}
```

border-box

The `border-box` value is the shape defined by the outside border edge. This shape follows all of the normal border radius shaping rules for the outside of the border. You still have a border, even if you have not used the CSS `border` property. In this case, it will be the same as `padding-box`, the shape defined by the outside padding edge.

In the example below, you can see how the text now follows the line created by the border. Change the border size, and the content will follow it.

```
<div class="box">
  <div class="shape"></div>
  <p>
    One November night in the year 1782, so the story runs, two brothers sat
    over their winter fire in the little French town of Annonay, watching the
    grey smoke-wreaths from the hearth curl up the wide chimney. Their names
    were Stephen and Joseph Montgolfier, they were papermakers by trade, and
    were noted as possessing thoughtful minds and a deep interest in all
    scientific knowledge and new discovery.
  </p>
</div>
```

```
body {
  font: 1.2em sans-serif;
}
.box {
  width: 70%;
}

.shape {
  background-color: rebeccapurple;
  height: 80px;
  width: 80px;
  padding: 20px;
  margin: 20px;
  border: 10px solid black;
  border-radius: 50%;
  float: left;
  shape-outside: border-box;
}
```

padding-box

The `padding-box` value defines the shape enclosed by the outside padding edge. This shape follows all of the normal border radius shaping rules for the inside of the border. If you have no padding then `padding-box` is the same as `content-box`.

```
<div class="box">
  <div class="shape"></div>
  <p>
    One November night in the year 1782, so the story runs, two brothers sat
    over their winter fire in the little French town of Annonay, watching the
    grey smoke-wreaths from the hearth curl up the wide chimney. Their names
    were Stephen and Joseph Montgolfier, they were papermakers by trade, and
    were noted as possessing thoughtful minds and a deep interest in all
    scientific knowledge and new discovery.
  </p>
</div>
```

```
body {
  font: 1.2em / 1.2 sans-serif;
}
.box {
  width: 70%;
}

.shape {
  background-color: rebeccapurple;
  height: 80px;
  width: 80px;
  padding: 20px;
  margin: 20px;
  border: 10px solid black;
  border-radius: 50%;
  float: left;
```

```
  shape-outside: padding-box;
}
```

content-box

The `content-box` value defines the shape enclosed by the outside content edge. Each corner radius of this box is the `border-radius` less the `border-width` and `padding`, or `0`, whichever is larger. This means that it is impossible to have a negative value here.

```
<div class="box">
  <div class="shape"></div>
  <p>
    One November night in the year 1782, so the story runs, two brothers sat
    over their winter fire in the little French town of Annonay, watching the
    grey smoke-wreaths from the hearth curl up the wide chimney. Their names
    were Stephen and Joseph Montgolfier, they were papermakers by trade, and
    were noted as possessing thoughtful minds and a deep interest in all
    scientific knowledge and new discovery.
  </p>
</div>
```

```
body {
  font: 1.2em / 1.2 sans-serif;
}
.box {
  width: 70%;
}

.shape {
  background-color: rebeccapurple;
  height: 80px;
  width: 80px;
  padding: 20px;
  margin: 20px;
  border: 10px solid black;
  border-radius: 50%;
  float: left;
  shape-outside: content-box;
}
```

When to use box values

Using box values is a way to create shapes; however, this naturally works only with very basic shapes that can be defined using the `border-radius` property. The examples shown above show one such use case. You can create a circular shape using `border-radius` and then curve text around it.

With just this basic technique, you can create some interesting effects. In my final example of this section, I have floated two elements left and right, giving each a border radius of 100% in the direction closest to the text.

```
<div class="box">
  <div class="shape-left"></div>
  <div class="shape-right"></div>
  <p>
    One November night in the year 1782, so the story runs, two brothers sat
    over their winter fire in the little French town of Annonay, watching the
    grey smoke-wreaths from the hearth curl up the wide chimney. Their names
    were Stephen and Joseph Montgolfier, they were papermakers by trade, and
    were noted as possessing thoughtful minds and a deep interest in all
    scientific knowledge and new discovery.
  </p>
</div>
```

```
body {
  font: 1.2em / 1.5 sans-serif;
}

.box {
  text-align: justify;
}

.shape-left,
.shape-right {
  height: 100px;
  width: 100px;
}

.shape-left {
  margin: 0 20px 20px 0;
  border-bottom-right-radius: 100%;
  float: left;
  shape-outside: margin-box;
}
.shape-right {
  margin: 0 20px 20px;
  border-bottom-left-radius: 100%;
  float: right;
  shape-outside: margin-box;
}
```

For more complex shapes, you will need to use one of the basic shapes as a value, or define your shape from an image as covered in other guides in this section.

Shapes from images

In this guide, we will take a look at how we can create a shape from an image file with an alpha channel or even from a CSS Gradient. This is a very flexible way to create shapes. Rather than drawing a path with a complex polygon in CSS, you can create the shape in a graphics program and then use the path created by the pixels less opaque than a threshold value.

Creating shapes from images

To use an image for creating a shape, the image needs to have an Alpha Channel, an area that is not fully opaque. The `shape-image-threshold` property is used to set a threshold for this opacity. Pixels that are more opaque than this value will be used to calculate the area of the shape.

In the example below, there is an image of a star with a solid red area and an area that is fully transparent. The path to the image file is used as the value for the `shape-outside` property. The content now wraps around the star shape.

```
<div class="box">
  <img
    alt="A red star"
    src="https://mdn.github.io/shared-assets/images/examples/star-shape.png" />
  <p>
    One November night in the year 1782, so the story runs, two brothers sat
    over their winter fire in the little French town of Annonay, watching the
    grey smoke-wreaths from the hearth curl up the wide chimney. Their names
    were Stephen and Joseph Montgolfier, they were papermakers by trade, and
    were noted as possessing thoughtful minds and a deep interest in all
    scientific knowledge and new discovery. Before that night—a memorable night,
    as it was to prove—hundreds of millions of people had watched the rising
    smoke-wreaths of their fires without drawing any special inspiration from
    the fact.
  </p>
</div>
```

```
body {
  font: 1.2em / 1.5 sans-serif;
}
img {
  float: left;
  shape-outside: url("https://mdn.github.io/shared-assets/images/examples/star-shape.png");
}
```

You can use `shape-margin` to move the text away from the shape, giving a margin around the created shape and the text.

```
<div class="box">
  <img
    alt="A red star"
    src="https://mdn.github.io/shared-assets/images/examples/star-shape.png" />
  <p>
    One November night in the year 1782, so the story runs, two brothers sat
    over their winter fire in the little French town of Annonay, watching the
    grey smoke-wreaths from the hearth curl up the wide chimney. Their names
    were Stephen and Joseph Montgolfier, they were papermakers by trade, and
    were noted as possessing thoughtful minds and a deep interest in all
    scientific knowledge and new discovery. Before that night—a memorable night,
    as it was to prove—hundreds of millions of people had watched the rising
    smoke-wreaths of their fires without drawing any special inspiration from
    the fact.
  </p>
</div>
```

```
body {
  font: 1.2em / 1.5 sans-serif;
}

img {
  float: left;
  shape-outside: url("https://mdn.github.io/shared-assets/images/examples/star-shape.png");
  shape-margin: 20px;
}
```

CORS compatibility

Something that you will run into when creating shapes from an image is that the image you use must be CORS compatible. An image hosted on the same domain as your site should work, however, if your images are hosted on a different domain such as on a CDN you should ensure that they are sending the correct headers to enable them to be used for Shapes. Due to this requirement for CORS-compatible images, if you are previewing your file locally without using a local web server, your shape will not work.

Is it a CORS issue?

DevTools can help you to identify CORS errors. In Chrome the Console will alert you to CORS problems. In Firefox if you inspect the property you will be alerted to the fact that the image could not be loaded. This should alert you to the fact that your image cannot be used as the source of a shape due to CORS.

Setting a threshold

The `shape-image-threshold` property enables the creation of shapes from areas which are not fully transparent. If the value of `shape-image-threshold` is `0.0` (which is the initial value) then the area must be fully transparent. If the value is `1.0` then it is fully opaque. Values in between mean that you can set a semi-transparent area as the defining area.

In the example below, the background of the star is not fully transparent, it has a 20% opacity as created in my graphics program. If I set `shape-image-threshold` to `0.2` or greater, then I see the shape, if I set it to something smaller than `0.2` I do not get the shape.

```
<div class="box">
  <img
    alt="A red star"
    src="https://mdn.github.io/shared-assets/images/examples/star-red-20.png" />
  <p>
    One November night in the year 1782, so the story runs, two brothers sat
    over their winter fire in the little French town of Annonay, watching the
    grey smoke-wreaths from the hearth curl up the wide chimney. Their names
    were Stephen and Joseph Montgolfier, they were papermakers by trade, and
    were noted as possessing thoughtful minds and a deep interest in all
    scientific knowledge and new discovery. Before that night—a memorable night,
    as it was to prove—hundreds of millions of people had watched the rising
    smoke-wreaths of their fires without drawing any special inspiration from
    the fact.
  </p>
</div>
```

```
body {
  font: 1.2em / 1.5 sans-serif;
}

img {
  float: left;
```

```
  shape-outside: url("https://mdn.github.io/shared-assets/images/examples/star-red-20.png");
  shape-image-threshold: 0.2;
}
```

Using images with generated content

In the above example, I have both used the image as the value of `shape-outside` and also added it to the page. Many demos do this as it helps to show the shape we are following, however, the `shape-outside` property is not related to the image that is displayed on the page and so you do not need to display an image to use an image to create a shape.

You do need something to float, but that could be some generated content as in the below example. I am floating generated content and using a larger star image to shape my content without displaying any image on the page.

```
<div class="box">
  <p>
    One November night in the year 1782, so the story runs, two brothers sat
    over their winter fire in the little French town of Annonay, watching the
    grey smoke-wreaths from the hearth curl up the wide chimney. Their names
    were Stephen and Joseph Montgolfier, they were papermakers by trade, and
    were noted as possessing thoughtful minds and a deep interest in all
    scientific knowledge and new discovery. Before that night—a memorable night,
    as it was to prove—hundreds of millions of people had watched the rising
    smoke-wreaths of their fires without drawing any special inspiration from
    the fact.
  </p>
</div>
```

```
body {
  font: 1.2em / 1.5 sans-serif;
}

.box::before {
  content: "";
  float: left;
  width: 400px;
  height: 300px;
  shape-outside: url("https://mdn.github.io/shared-assets/images/examples/star-shape.png");
  shape-image-threshold: 0.3;
}
```

Creating shapes using a gradient

Because a CSS gradient is treated as an image, you can use a gradient to generate a shape by having transparent or semi-transparent areas as part of the gradient.

The next example uses generated content. The content has been floated, giving it a background image of a linear gradient. I am using that same value as the value of `shape-outside`. The linear gradient goes from purple to transparent. By changing the value of `shape-image-threshold`, you can decide how transparent the pixels need to be that create the shape. You can play with that value in the example below to see how the diagonal line will move across the shape depending on that value.

You could also try removing the background image completely, thus using the gradient purely to create the shape and not displaying it on the page at all.

```
<div class="box">
  <p>
    One November night in the year 1782, so the story runs, two brothers sat
    over their winter fire in the little French town of Annonay, watching the
    grey smoke-wreaths from the hearth curl up the wide chimney. Their names
    were Stephen and Joseph Montgolfier, they were papermakers by trade, and
    were noted as possessing thoughtful minds and a deep interest in all
    scientific knowledge and new discovery. Before that night—a memorable night,
    as it was to prove—hundreds of millions of people had watched the rising
    smoke-wreaths of their fires without drawing any special inspiration from
    the fact.
  </p>
</div>
```

```
body {
  font: 1.2em / 1.5 sans-serif;
}

.box::before {
  content: "";
  float: left;
  height: 250px;
  width: 400px;
  background-image: linear-gradient(
    to bottom right,
    rebeccapurple,
    transparent
  );
  shape-outside: linear-gradient(to bottom right, rebeccapurple, transparent);
  shape-image-threshold: 0.3;
}
```

The next example uses a radial gradient with an ellipse, once again using a transparent part of the gradient to create the shape.

```
<div class="box">
  <p>
    One November night in the year 1782, so the story runs, two brothers sat
    over their winter fire in the little French town of Annonay, watching the
    grey smoke-wreaths from the hearth curl up the wide chimney. Their names
    were Stephen and Joseph Montgolfier, they were papermakers by trade, and
    were noted as possessing thoughtful minds and a deep interest in all
    scientific knowledge and new discovery. Before that night—a memorable night,
    as it was to prove—hundreds of millions of people had watched the rising
    smoke-wreaths of their fires without drawing any special inspiration from
    the fact.
  </p>
</div>
```

```
body {
  font: 1.2em / 1.5 sans-serif;
```

```
}

.box::before {
  content: "";
  float: left;
  height: 250px;
  width: 400px;
  background-image: radial-gradient(
    ellipse closest-side,
    rebeccapurple,
    blue 50%,
    transparent
  );
  shape-outside: radial-gradient(
    ellipse closest-side,
    rebeccapurple,
    blue 50%,
    transparent
  );
  shape-image-threshold: 0.3;
}
```

You can experiment directly in these live examples to see how changing the gradient will change the path of your shape.

Overview of shapes

The CSS Shapes module describes geometric shapes in CSS. This article provides an overview of how you can use shapes to wrap text around floated elements that are not necessarily rectangular.

When you float an item left, text will wrap around the right and bottom of the item in a rectangular fashion. With CSS shapes you can, for example, apply a circle shape, and the text will wrap around the line of the circle.

There are several ways to create this circle. In this guide, we will look at how CSS Shapes work and how to use them.

What does the specification define?

The specification defines a few properties, including:

- `shape-outside` — Allows definition of basic shapes.
- `shape-image-threshold` — Sets an opacity threshold value. If an image is being used to define a shape, only the parts of the image that are the same opacity or greater than the threshold value are used in the shape. Any other parts are ignored.
- `shape-margin` — Sets a margin around the defined shape.

Defining basic shapes

The `shape-outside` property allows us to define a shape. It takes a variety of values that define different shapes specified in the `<basic-shape>` data type.

In the following example, an image is floated to the left. We apply the `shape-outside` property with a `circle(50%)` value. The result is that the content now curves around the circular shape rather than following the rectangle created by the box of the image.

```
<div class="box">
  <img
    alt="An orange hot air balloon as seen from below"
    src="https://mdn.github.io/shared-assets/images/examples/round-balloon.png" />
  <p>
    One November night in the year 1782, so the story runs, two brothers sat
    over their winter fire in the little French town of Annonay, watching the
    grey smoke-wreaths from the hearth curl up the wide chimney. Their names
    were Stephen and Joseph Montgolfier, they were papermakers by trade, and
    were noted as possessing thoughtful minds and a deep interest in all
    scientific knowledge and new discovery. Before that night—a memorable night,
    as it was to prove—hundreds of millions of people had watched the rising
    smoke-wreaths of their fires without drawing any special inspiration from
    the fact.
  </p>
</div>
```

```
body {
  font: 1.2em / 1.4 sans-serif;
}

img {
  float: left;
  shape-outside: circle(50%);
}
```

Here we used the `circle()` function, which is supported across all modern browsers. If we used a newer shape type that doesn't have full support, users of non-supporting browsers would see the content flowing around the sides of a rectangular, due to the image being floated. Shapes are a visual progressive enhancement.

Basic shapes

The value `circle(50%)` is an example of a basic shape. The specification defines several `<basic-shape>` values, including:

- `circle()`
- `ellipse()`
- `inset()`
- `path()`
- `polygon()`
- `rect()`
- `shape()`
- `xywh()`

Three of these functions only define rectangles. With the `inset()` function, you define four offset values, thus pulling the line boxes of any wrapping content closer to the object than they otherwise would. The `rect()` function defines a rectangle by specifying the distance from the top and left edges of the containing block. The `xywh()` function works by specifying distances from the top and left edges of the reference box and setting the width and height of the rectangle from that starting point.

We have already seen how `circle()` creates a circular shape. An `ellipse()` is essentially a squashed circle. If none of these basic shapes do the trick you can create more complex shapes using the `polygon()` function, which allows the definition of a series of lines. The `path()` and `shape()` functions can be used to create ANY shape via a series of line, curve, and move commands.

In our Guide to Basic Shapes we explore each of the possible Basic Shapes and how to create them.

Shapes from the box value

Shapes can also be created around the box value. Therefore, you could create your shape on:

- `border-box`
- `padding-box`
- `content-box`
- `margin-box`

In the example below, you can change the value `border-box` to any of the other allowed values to see how the shape moves closer or further away from the box.

```
<div class="box">
  <div class="shape"></div>
  <p>
    One November night in the year 1782, so the story runs, two brothers sat
    over their winter fire in the little French town of Annonay, watching the
    grey smoke-wreaths from the hearth curl up the wide chimney. Their names
    were Stephen and Joseph Montgolfier, they were papermakers by trade, and
    were noted as possessing thoughtful minds and a deep interest in all
    scientific knowledge and new discovery. Before that night—a memorable night,
    as it was to prove—hundreds of millions of people had watched the rising
    smoke-wreaths of their fires without drawing any special inspiration from
    the fact.
  </p>
</div>
```

```
body {
  font: 1.2em / 1.4 sans-serif;
}

.shape {
  background-color: rebeccapurple;
  height: 150px;
  width: 150px;
  padding: 20px;
  margin: 20px;
  border-radius: 50%;
  float: left;
  shape-outside: border-box;
}
```

To explore the box values in more detail, see our guide covering Shapes from box values.

Shapes from images

An interesting way to generate your path is to use an image with an alpha channel—the text will then wrap around the non-transparent parts of the image. This allows the overlay of wrapped content around an image or the use of an image that is never displayed on the page purely as a method of creating a complex shape without needing to carefully map a polygon.

Note that images used in this way must be CORS compatible, otherwise `shape-outside` will act as if `none` had been given as the value, and you will get no shape.

In this next example, we have an image with a fully transparent area, and we are using an image as the URL value for `shape-outside`. The shape is created around the opaque area — the image of the balloon.

```
<div class="box">
  <img
    alt="An orange hot air balloon as seen from below"
    src="https://mdn.github.io/shared-assets/images/examples/round-balloon.png" />
  <p>
    One November night in the year 1782, so the story runs, two brothers sat
    over their winter fire in the little French town of Annonay, watching the
    grey smoke-wreaths from the hearth curl up the wide chimney. Their names
    were Stephen and Joseph Montgolfier, they were papermakers by trade, and
    were noted as possessing thoughtful minds and a deep interest in all
    scientific knowledge and new discovery. Before that night—a memorable night,
    as it was to prove—hundreds of millions of people had watched the rising
    smoke-wreaths of their fires without drawing any special inspiration from
    the fact.
  </p>
</div>
```

```
body {
  font: 1.2em / 1.4 sans-serif;
}

img {
  float: left;
  shape-outside: url("https://mdn.github.io/shared-assets/images/examples/round-balloon.png");
}
```

`shape-image-threshold`

The `shape-image-threshold` property is used to set the threshold of image transparency used to define the area of the image used for the shape. If the value of `shape-image-threshold` is `0.0` (which is the initial value) then the area must be fully transparent. If the value is `1.0` then it is fully opaque. Values in between mean that you can set a semi-transparent area as the defining area of the shape.

You can see the threshold in action if we use a gradient as the image on which to define our shape. In the example below, if you change the threshold the path that the shape takes changes based on the level of opacity you have selected.

```
<div class="box">
  <div class="shape"></div>
  <p>
    One November night in the year 1782, so the story runs, two brothers sat
    over their winter fire in the little French town of Annonay, watching the
    grey smoke-wreaths from the hearth curl up the wide chimney. Their names
    were Stephen and Joseph Montgolfier, they were papermakers by trade, and
    were noted as possessing thoughtful minds and a deep interest in all
    scientific knowledge and new discovery. Before that night—a memorable night,
    as it was to prove—hundreds of millions of people had watched the rising
    smoke-wreaths of their fires without drawing any special inspiration from
    the fact.
```

```
  </p>
</div>
```

```
body {
  font: 1.2em / 1.4 sans-serif;
}

.shape {
  float: left;
  width: 200px;
  height: 200px;
  background-image: linear-gradient(
    45deg,
    rebeccapurple,
    transparent 80%,
    transparent
  );
  shape-outside: linear-gradient(
    45deg,
    rebeccapurple,
    transparent 80%,
    transparent
  );
  shape-image-threshold: 0.4;
}
```

To learn more about creating shapes from images, see the Shapes from images guide.

The <code>shape-margin</code> property

The `shape-margin` property adds a margin to `shape-outside`. This will further shorten the line boxes of any content wrapping the shape, pushing it away from the shape itself.

In the example below we have added a `shape-margin` to a basic shape. Change the margin to push the text further away from the path the shape would take by default.

```
<div class="box">
  <img
    alt="An orange hot air balloon as seen from below"
    src="https://mdn.github.io/shared-assets/images/examples/round-balloon.png" />
  <p>
    One November night in the year 1782, so the story runs, two brothers sat
    over their winter fire in the little French town of Annonay, watching the
    grey smoke-wreaths from the hearth curl up the wide chimney. Their names
    were Stephen and Joseph Montgolfier, they were papermakers by trade, and
    were noted as possessing thoughtful minds and a deep interest in all
    scientific knowledge and new discovery. Before that night—a memorable night,
    as it was to prove—hundreds of millions of people had watched the rising
    smoke-wreaths of their fires without drawing any special inspiration from
    the fact.
  </p>
</div>
```

```
body {
  font: 1.2em / 1.4 sans-serif;
}
img {
  float: left;
  shape-outside: circle(50%);
  shape-margin: 5px;
}
```

Using Generated Content as the floated item

In the examples above, we have used images or a visible element to define the shape, meaning that you can see the shape on the page. Instead, you might want to flow some text along a non-rectangular invisible line. We could, for example, add an empty floated `<div>` or `<span>` element to our DOM and make it invisible. However, we can create a shape with only CSS using generated content and keep all our styling functionality inside the CSS.

In this example, we use generated content to insert an element with a height and width of 150px. We can then use basic shapes, box values, or even the alpha channel of an image to create a shape for the text to wrap around.

```
<div class="box">
  <p>
    One November night in the year 1782, so the story runs, two brothers sat
    over their winter fire in the little French town of Annonay, watching the
    grey smoke-wreaths from the hearth curl up the wide chimney. Their names
    were Stephen and Joseph Montgolfier, they were papermakers by trade, and
    were noted as possessing thoughtful minds and a deep interest in all
    scientific knowledge and new discovery. Before that night—a memorable night,
    as it was to prove—hundreds of millions of people had watched the rising
    smoke-wreaths of their fires without drawing any special inspiration from
    the fact.
  </p>
</div>
```

```
body {
  font: 1.2em sans-serif;
}

.box::before {
  content: "";
  display: block;
  height: 150px;
  width: 150px;
  padding: 20px;
  margin: 20px;
  border-radius: 50%;
  float: left;
  shape-outside: border-box;
}
```

Relationship to <code>clip-path</code>

The basic shapes and box values used to create shapes are the same as those used as values for `clip-path`. Therefore, if you want to create a shape using an image, and also clip away part of that image, you can use the same values.

The image below is a square image with a blue background. We have defined a shape using `shape-outside: ellipse(40% 50%);` and also used `clip-path: ellipse(40% 50%);` to clip away the same area that we used to define the shape.

```
<div class="box">
  <img
    alt="An orange hot air balloon as seen from below"
    src="https://mdn.github.io/shared-assets/images/examples/balloon-small.jpg" />
  <p>
    One November night in the year 1782, so the story runs, two brothers sat
    over their winter fire in the little French town of Annonay, watching the
    grey smoke-wreaths from the hearth curl up the wide chimney. Their names
    were Stephen and Joseph Montgolfier, they were papermakers by trade, and
    were noted as possessing thoughtful minds and a deep interest in all
    scientific knowledge and new discovery. Before that night—a memorable night,
    as it was to prove—hundreds of millions of people had watched the rising
    smoke-wreaths of their fires without drawing any special inspiration from
    the fact.
  </p>
</div>
```

```
body {
  font: 1.2em / 1.4 sans-serif;
}

img {
  float: left;
  shape-outside: ellipse(40% 50%);
  clip-path: ellipse(40% 50%);
}
```

Developer Tools for Shapes

There is a Shape Path Editor in the Firefox DevTools. This tool can be used to inspect the `circle()`, `inset()`, `ellipse()`, and `polygon()` values. If your polygon isn't quite right you can use the Shapes Editor to tweak it, then copy the new value back into your CSS.

More CSS Shapes Features

In this guide, we discussed wrapping text around floated shapes. See the CSS shapes module for links to all the module features plus additional related features. This includes all the shape functions and relevant guides.

Shape generator

This shape generator tool can be used to define the coordinates and syntax for features that use `<basic-shape>`

- The `coords` attribute of the `<area>` element
- The CSS `inset()`, `xywh()`, `rect()`, `circle()`, `polygon()` functions
- The SVG `<rect>`, `<circle>`, `<polygon>` elements

The shape generator helps you visualize basic shapes, outputting the coordinates of each point, superimposed over your image. Upload an image by either dragging or clicking to select a file. Then select the type of shape you want to create from the dropdown menu. Optionally, you can also adjust the scale of the canvas using the range input. Then click on points on the image to add reference points for the shape you want to create. The tool will then output the markup for the HTML `coords` attribute value, CSS basic shape function with coordinates, and SVG shape.

```
<fieldset>
  <legend>Controls</legend>
  <p>
    <label for="scale">
      Scale:
      <input type="range" id="scale" min="0.1" max="3" value="1" step="any" />
    </label>
  </p>
  <p>
    <label for="shape">
      Shape:
      <select id="shape">
        <option value="rect">Rectangle</option>
        <option value="circle">Circle</option>
        <option value="poly">Polygon</option>
        <option value="points">Discrete points</option>
      </select>
    </label>
  </p>
  <p>
    <button id="reset">Reset</button>
  </p>
</fieldset>
<canvas id="canvas">Drop and image here, or click to upload.</canvas>
<p>
  <output id="coords">Click on the canvas to add points.</output>
</p>
```

```
#canvas {
  display: block;
  border: 1px solid black;
  transform-origin: top left;
  margin: 0.5em 0;
}

#coords {
  display: block;
  position: relative;
  word-break: break-all;
}

```

Basic shapes with shape-outside

CSS shapes can be defined using the `<basic-shape>` type. In this guide, we discuss creating rectangles, circles, ellipses, and polygons with the `shape-outside` property. These are features defined in the CSS shapes module.

Before looking at shapes, it is worth understanding two pieces of information that go together to make these shapes possible:

- The `<basic-shape>` type
- The reference box

The <basic-shape> type

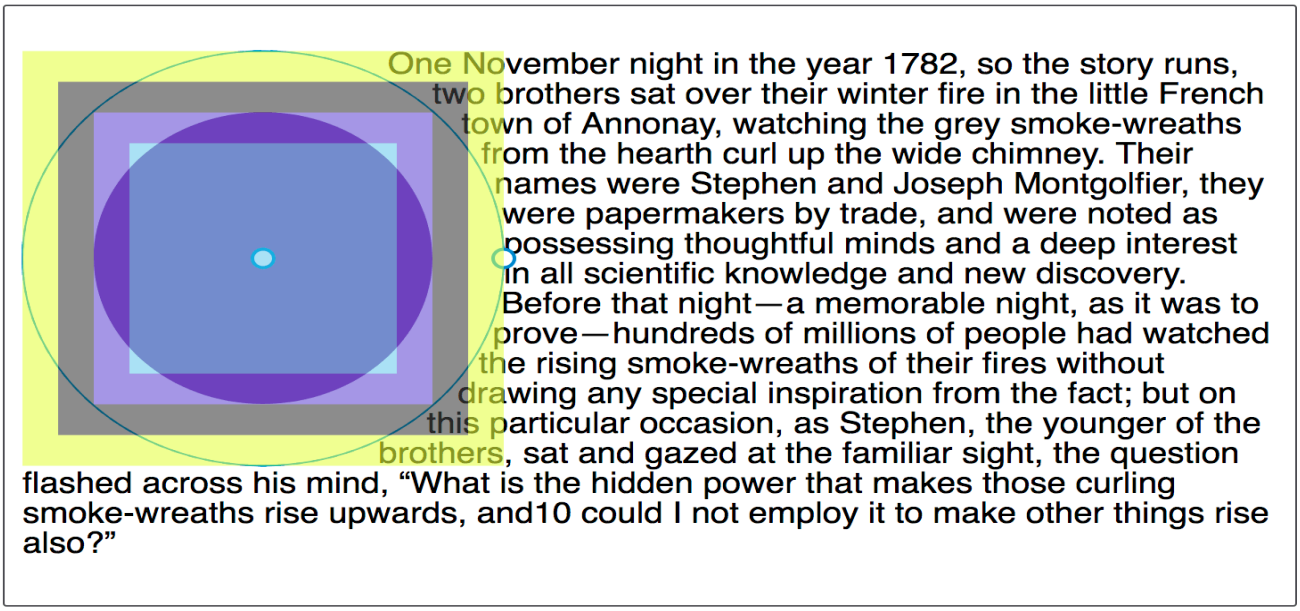
The `<basic-shape>` type is used as the value for all of our basic shapes. This type is a functional notation: the function parentheses contain arguments used to describe the shape.

The accepted arguments vary depending on the shape you are creating. We will cover these in the examples below.

The reference box

Understanding the reference box used by CSS shapes is important when using basic shapes, as it defines each shape's coordinate system. You have already met the reference box in the guide on creating shapes from box values, which directly uses the reference box to create the shape.

The screenshot below shows the Firefox Shapes Inspector displaying the reference box of a circle created using `shape-outside: circle(50%)`. The element has 20 pixels of padding, border, and margin applied. The Shapes Inspector highlights these reference boxes.



The default reference box for a basic shape is the `margin-box`. You can see in the screenshot that the shape is defined relative to that part of the Box Model.

While the default reference box is `margin-box`, this can be modified. To set a different box as the reference box, include the desired box value after your basic shape definition.

These two declarations are the same:

```
shape-outside: circle(50%);
shape-outside: circle(50%) margin-box;
```

For your shape to use a different reference box, include a different `<box-edge>` value, for example, to use the border as a reference box for our circle, set:

```
.shape {
  shape-outside: circle(50%) border-box;
}
```

Shapes created that extend past the margin box will have the shape clipped to the margin box. The following basic shapes demonstrate this.

inset()

The `inset()` function defines a rectangle. This may not seem very useful as floating an item, without shapes, will give you a rectangular shape around it. However, the `inset()` type enables the definition of offsets, thus pulling the wrapping text around the reduced-size rectangle, over parts of the floated element.

The `inset()` function takes up to four side offset values, plus an optional `round` keyword, followed by a `border-radius` value. The below CSS creates a rectangular shape inset from the reference box of the floated element 20 pixels from the top and bottom and 10 pixels from the left and right, with a `border-radius` value of 10 pixels.

```
.shape {
  float: left;
  shape-outside: inset(20px 10px 20px 10px round 10px);
}
```

The offset values use the same rules as the `margin` shorthand. Four space-separated values define the top, right, bottom, and left offsets — in that order. You can also set more than one offset at once:

- If there is only one value, it applies to all sides.
- If there are two values, the top and bottom offsets are set to the first value and the right and left offsets are set to the second.
- If there are three values, the top is set to the first value, the left and right are set to the second, and the bottom is set to the third.

The above rules can therefore also be written as:

```
.shape {
  float: left;
  shape-outside: inset(20px 10px round 10px);
}
```

In the example below we have an `inset()` shape used to pull content over the floated element. Change the offset values to see how the shape changes.

```
<div class="box">
  <div class="shape"></div>
  <p>
    One November night in the year 1782, so the story runs, two brothers sat
    over their winter fire in the little French town of Annonay, watching the
    grey smoke-wreaths from the hearth curl up the wide chimney. Their names
    were Stephen and Joseph Montgolfier, they were papermakers by trade, and
    were noted as possessing thoughtful minds and a deep interest in all
    scientific knowledge and new discovery. Before that night—a memorable night,
    as it was to prove—hundreds of millions of people had watched the rising
    smoke-wreaths of their fires without drawing any special inspiration from
    the fact.
  </p>
</div>
```

```
body {
  font: 1.2em sans-serif;
}

.shape {
```

```
  float: left;
  width: 150px;
  height: 100px;
  shape-outside: inset(20px 50px 10px 0 round 50px);
  background-color: rebeccapurple;
  border: 2px solid black;
  border-radius: 10px;
  margin: 20px;
  padding: 20px;
}
```

You can also add a box value as an alternative reference box. In the example below, try changing the reference box from `margin-box` to `border-box`, `padding-box`, or `content-box` to see how the reference box used as the starting point changes before offsets are calculated.

```
<div class="box">
  <div class="shape"></div>
  <p>
    One November night in the year 1782, so the story runs, two brothers sat
    over their winter fire in the little French town of Annonay, watching the
    grey smoke-wreaths from the hearth curl up the wide chimney. Their names
    were Stephen and Joseph Montgolfier, they were papermakers by trade, and
    were noted as possessing thoughtful minds and a deep interest in all
    scientific knowledge and new discovery. Before that night—a memorable night,
    as it was to prove—hundreds of millions of people had watched the rising
    smoke-wreaths of their fires without drawing any special inspiration from
    the fact.
  </p>
</div>
```

```
body {
  font: 1.2em sans-serif;
}

.shape {
  float: left;
  width: 150px;
  height: 100px;
  shape-outside: inset(20px 50px 10px 0 round 50px) margin-box;
  background-color: rebeccapurple;
  border: 2px solid black;
  border-radius: 10px;
  margin: 20px;
  padding: 20px;
}
```

You can also create rectangles based on distances from the top and left edges of the reference box with the `rect()` function, or by width and height with the `xywh()` function; both of these also support optional rounded corners.

circle()

The `circle()` value for `shape-outside` can accept two possible arguments: a `<shape-radius>` defining the size and the `<position>` defining its location.

The `circle()` and `ellipse()` `shape-outside` values both accept `<shape-radius>` as an argument. This can be a `<length>`, a `<percentage>`, or one of the keywords `closest-side` or `farthest-side`.

The `closest-side` keyword value uses the length from the center of the shape to the closest side of the reference box to create the radius length. The `farthest-side` keyword value uses the length from the center of the shape to the farthest side of the reference box.

The second argument is a `position`, which accepts a one- or two-keyword `<position>` value, to indicate the position of the center of the circle. This is specified the same way as `background-position`; if one or both values are omitted, the values default to `center`.

To create a circle, we include a single radius value, optionally followed by the keyword **at** followed by a position value. This example has a circle applied to an `<img>` with a `width` and `height` of `210px` and a `margin` of `20px`. This gives a total width for the reference box of `250px`. The `50%` value for the `<shape-radius>` means the radius is `125px`. The position value is set to `30%`, which is `30%` from the left and at the default vertical `center`.

```
<div class="box">
  <img
    alt="An orange hot air balloon as seen from below"
    src="https://mdn.github.io/shared-assets/images/examples/round-balloon.png" />
  <p>
    One November night in the year 1782, so the story runs, two brothers sat
    over their winter fire in the little French town of Annonay, watching the
    grey smoke-wreaths from the hearth curl up the wide chimney. Their names
    were Stephen and Joseph Montgolfier, they were papermakers by trade, and
    were noted as possessing thoughtful minds and a deep interest in all
    scientific knowledge and new discovery. Before that night—a memorable night,
    as it was to prove—hundreds of millions of people had watched the rising
    smoke-wreaths of their fires without drawing any special inspiration from
    the fact.
  </p>
</div>
```

```
body {
  font: 1.2em sans-serif;
}

img {
  float: left;
  shape-outside: circle(50% at 30%);
  margin: 20px;
}
```

Play with increasing or decreasing the size of the circle by changing the size of the radius, moving the circle around with the position value, or setting a reference box as we did for `inset()`.

The below example combines generated content with a `circle()` function that uses the keywords `top left` for position. This creates a quarter circle shape in the top left corner of the page for text to flow around.

```
<div class="box">
  <p>
    One November night in the year 1782, so the story runs, two brothers sat
    over their winter fire in the little French town of Annonay, watching the
```

```
    grey smoke-wreaths from the hearth curl up the wide chimney. Their names
    were Stephen and Joseph Montgolfier, they were papermakers by trade, and
    were noted as possessing thoughtful minds and a deep interest in all
    scientific knowledge and new discovery. Before that night—a memorable night,
    as it was to prove—hundreds of millions of people had watched the rising
    smoke-wreaths of their fires without drawing any special inspiration from
    the fact.
  </p>
</div>
```

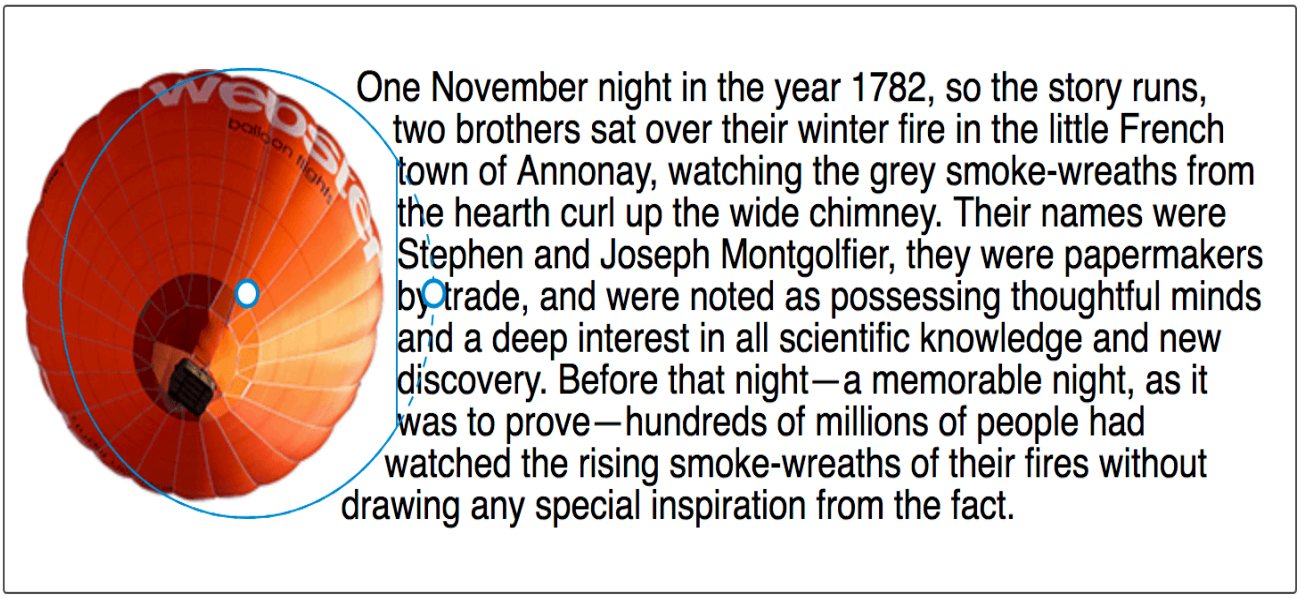
```
body {
  font: 1.2em sans-serif;
}

.box::before {
  content: "";
  float: left;
  width: 250px;
  height: 250px;
  shape-outside: circle(50% at top left);
}
```

The shape will be clipped by the margin box

As noted in reference boxes above, the `margin-box` will clip the shape. You can see this by moving the center of our circle towards the content by setting the position to `60%`. The center of the circle will be nearer to the content and the circle will extend past the margin-box. This means that the extension becomes clipped and squared off.

```
img {
  float: left;
  shape-outside: circle(50% at 60%);
}
```



ellipse()

An ellipse is a squashed circle. As such, the `ellipse()` function acts in a very similar way to `circle()` except that we have to specify two radii, `x` and `y`, in that order.

These may then be followed by one or two `<position>` values, as with `circle()`, to define the location of the center of the ellipse. In the example below, we have an ellipse with an `x` radius of `40%`, a `y` radius of `50%` and the `<position>` set to `left`. This means that the center of the ellipse is at the center of the left edge of the reference box. This creates a half ellipse shape around which the text will wrap. You can change these values to see how the ellipse changes.

```
<div class="box">
  <div class="shape"></div>
  <p>
    One November night in the year 1782, so the story runs, two brothers sat
    over their winter fire in the little French town of Annonay, watching the
    grey smoke-wreaths from the hearth curl up the wide chimney. Their names
    were Stephen and Joseph Montgolfier, they were papermakers by trade, and
    were noted as possessing thoughtful minds and a deep interest in all
    scientific knowledge and new discovery. Before that night—a memorable night,
    as it was to prove—hundreds of millions of people had watched the rising
    smoke-wreaths of their fires without drawing any special inspiration from
    the fact.
  </p>
</div>
```

```
body {
  font: 1.2em sans-serif;
}
.shape {
  float: left;
  shape-outside: ellipse(40% 50% at left);
  margin: 20px;
  width: 100px;
  height: 200px;
}
```

The keyword values of `closest-side` and `farthest-side` are useful in creating a quick ellipse based on the size of the floated element reference box.

```
<div class="box">
  <div class="shape"></div>
  <p>
    One November night in the year 1782, so the story runs, two brothers sat
    over their winter fire in the little French town of Annonay, watching the
    grey smoke-wreaths from the hearth curl up the wide chimney. Their names
    were Stephen and Joseph Montgolfier, they were papermakers by trade, and
    were noted as possessing thoughtful minds and a deep interest in all
    scientific knowledge and new discovery. Before that night—a memorable night,
    as it was to prove—hundreds of millions of people had watched the rising
    smoke-wreaths of their fires without drawing any special inspiration from
    the fact.
  </p>
</div>
```

```
body {
  font: 1.2em sans-serif;
}

.shape {
  float: left;
  shape-outside: ellipse(closest-side farthest-side at 30%);
  margin: 20px;
  width: 100px;
  height: 140px;
}
```

polygon()

The `polygon()` function is more complex, enabling the creation of multiple-sided polygon shapes. This shape accepts three or more pairs of values (a polygon must at least draw a triangle). Each space-separated pair of values is separated with a comma and represents the coordinates of a single vertex drawn relative to the reference box. Each pair of coordinates defines an edge of the polygon, with the final edge defined by the first and last set of coordinates.

The example below creates a shape for text to follow using the `polygon()` function. Try changing the coordinate values to see how the shape changes.

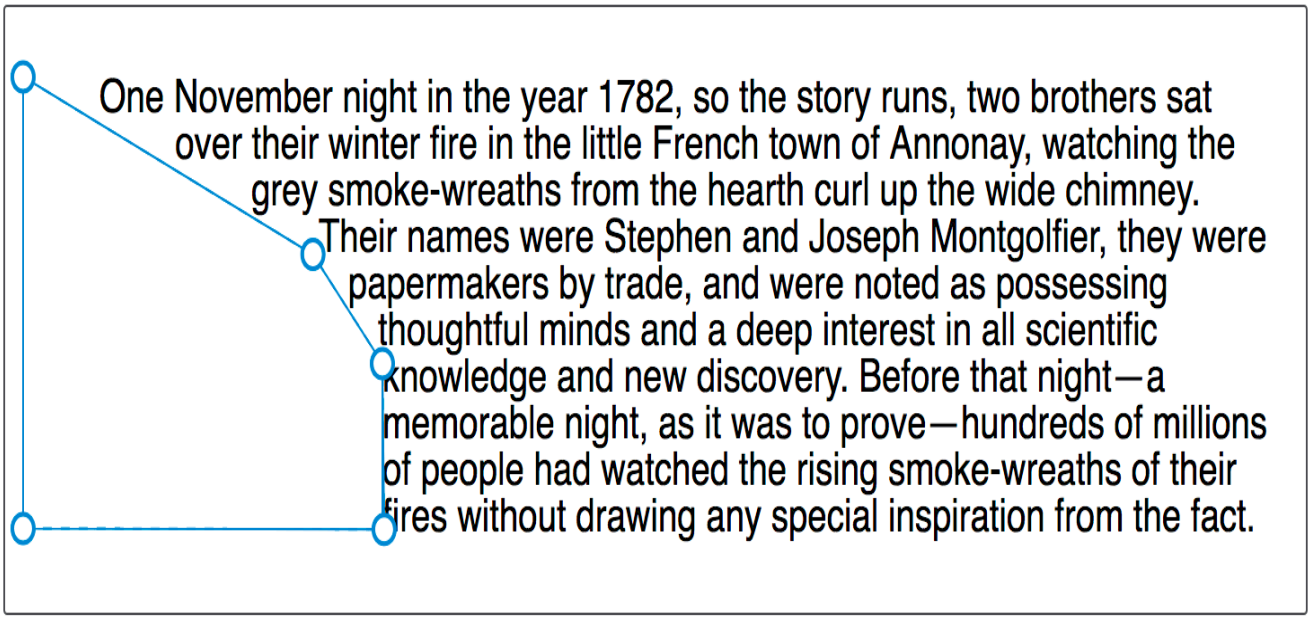
```
<div class="box">
  <div class="shape"></div>
  <p>
    One November night in the year 1782, so the story runs, two brothers sat
    over their winter fire in the little French town of Annonay, watching the
    grey smoke-wreaths from the hearth curl up the wide chimney. Their names
    were Stephen and Joseph Montgolfier, they were papermakers by trade, and
    were noted as possessing thoughtful minds and a deep interest in all
    scientific knowledge and new discovery. Before that night—a memorable night,
    as it was to prove—hundreds of millions of people had watched the rising
    smoke-wreaths of their fires without drawing any special inspiration from
    the fact.
  </p>
</div>
```

```
body {
  font: 1.2em sans-serif;
}

.shape {
  float: left;
  shape-outside: polygon(
    0px 0px,
    0px 189px,
    100.48% 94.71%,
    200px 120px,
    80.67% 37.17%
  );
  width: 200px;
  height: 200px;
}
```

To create even more complex shapes, you can define the outline of any shape with the `path()` or `shape()` functions.

The `inset()`, `circle()`, `ellipse()`, and `polygon()` are inspectable and editable using the Firefox Developer Tools Shape Inspector. The screenshot below shows the shape highlighted in the tool.



Another resource is Clippy, a tool for creating shapes with examples using the CSS `clip-path` property, which uses the same basic shape functions and values as the `shape-outside` property.

CSS syntax

The **CSS syntax** module describes, in general terms, the structure and syntax of cascading stylesheets, or CSS. It defines CSS as the language for describing the rendering of structured documents (such as HTML and XML), on the web and elsewhere.

This module doesn't define any properties, data types, functions, or at-rules. Rather, it elaborates on how all of these features should be defined and how user agents should parse CSS.

Reference

At-rules and descriptors

- none

> **Note:** The module explicitly states that `@charset` is not an actual at-rule, but rather an unrecognized legacy rule that should be omitted when a stylesheet is grammar-checked. The only valid `@charset` usage is at the very beginning of a stylesheet, where it is interpreted as a special byte sequence stripped before processing the content.

Key concepts

- At-rules
- character escaping
- CSS comments
- CSS declaration
- CSS declaration block
- CSS function
- Invalid
- Style rule

Glossary terms

- CSS descriptor
- Parse
- Style sheet
- Whitespace

At-rules

At-rules are CSS statements that instruct CSS how to behave. They begin with an at-sign, `@` (U+0040 COMMERCIAL AT), followed by an identifier. They include everything from the at-keyword up to the next semicolon, `;` (U+003B SEMICOLON), or the next CSS block, whichever comes first.

At-rules are used to group and structure style rules and other at-rules, declare style information not directly associated with selected content, and manage syntactic constructs such as imports and namespaces keyword mappings.

Syntax

The at-rule is defined in the CSS syntax module, with different at-rules being defined in their respective modules. They generally take one of two forms depending on the specific rule and its purpose: statement at-rules and block at-rules, which can contain nested qualified rules, at-rules, or declarations.

Statement at-rules

```
/* General structure */
@identifier (RULE);

/* Example: tells browser to use UTF-8 character set */
@charset "utf-8";
```

Statement at-rules end in a semicolon. There are several statement at-rules, designated by their identifiers, each with a different syntax:

`@charset`

: An algorithm (has the syntactic form of an at-rule, but isn't a definition) that determines the fallback character set used by the style sheet (CSS Syntax).

`@import`

: Tells the CSS engine to include an external style sheet (CSS cascading and inheritance).

`@layer`

: Defines the order of precedence in case of multiple cascade layers (CSS cascading and inheritance). Also used as a block at-rule to define a layer's styles.

`@namespace`

: Defines a default namespace for a style sheet or a namespace prefix that a selector only matches if the namespace and other selector components match (CSS namespaces).

Block at-rules

```
@identifier (RULE) {
}
```

Block at-rules end in a `{}`-block that contain nested rules, other at-rules, or property or descriptor declarations.

`@counter-style`

: Define custom counter styles and extend predefined list styles (CSS counter styles).

`@container`

: A conditional group rule that applies its content if the container meets the `<container-condition>`s (CSS containment).

`@font-face`

: Defines font resource locations, both local and external, along with the style characteristics for when those resources are used with a declared `font-family` (CSS fonts).

`@font-feature-values` (plus `@swash`, `@ornaments`, `@annotation`, `@stylistic`, `@styleset` and `@character-variant`)

: Controls font display per font-family by defining font-specific alternates, or custom names, to feature indexes in `font-variant-alternates` in OpenType (CSS fonts).

`@keyframes` (and the `@-webkit-keyframes` alias)

: Define a named animation by describing defining CSS styles for intermediate steps (or keyframes) in the animation sequence (CSS animations).

`@layer`

Creates a named cascade layer with the CSS rules for that layer inside (CSS cascading and inheritance). Also used as a statement at-rule to define the order of precedence in case of multiple cascade layers

`@media`

A conditional group rule that applies its content if the device meets the criteria of the condition defined using a *media query* (CSS conditional rules).

`@page`

Specifies aspects of a page to be printed, such as its dimensions, orientation, and margins (CSS paged media).

`@position-try`

Defines custom position options which can be used to define fallback positioning and alignment options for anchor-positioned elements (CSS anchor positioning).

`@property`

Defines a CSS custom property, allowing for property type checking and constraining, setting default values, and defining whether a custom property can inherit values or not (CSS custom properties for cascading variables).

`@scope`

Defines a scope in which to apply them to selected elements and the styles to apply to the elements in that scope (CSS cascading and inheritance).

`@starting-style`

Define the starting property values for an element to transition from when the element receives its first style update, such as when transitioning from `display: none` (CSS transitions).

`@supports`

A conditional group rule applies its content if the browser supports the CSS features of the given condition (CSS conditional rules).

`@view-transition`

Opts the current document into a view transition, and the destination document as well in the case of cross-document navigation transitions.

Comments

A CSS **comment** is used to add explanatory notes to the code or to prevent the browser from interpreting specific parts of the style sheet. By design, comments have no effect on the layout of a document.

Syntax

Comments can be placed wherever white space is allowed within a style sheet. They can be used on a single line, or traverse multiple lines.

```
/* Comment */
```

Examples

```
/* A one-line comment */

/*
A comment
which stretches
over several
lines
*/

/* The comment below is used to
   disable specific styling */
/*
span {
  color: blue;
  font-size: 1.5em;
}
*/
```

Notes

The `/* */` comment syntax is used for both single and multiline comments. There is no other way to specify comments in external style sheets. However, when using the `<style>` element, you may use `<!-- -->` to hide CSS from older browsers, although this is not recommended. As with most programming languages that use the `/* */` comment syntax, comments cannot be nested. In other words, the first instance of `*/` that follows an instance of `/*` closes the comment.

CSS error handling

When an error exists in CSS, such as an invalid value or a missing semicolon, instead of throwing an error like in JavaScript, the browser (or other user agent) will gracefully recover. Browsers don't provide CSS-related alerts or otherwise indicate errors have occurred in styles. They just discard invalid content and parse subsequent valid styles. This is a feature of CSS, not a bug.

This guide discusses how CSS parsers discard invalid CSS.

CSS parser errors

When a CSS error is encountered, the browser's parser ignores the line containing the errors, discarding the minimum amount of CSS code before returning to parsing the CSS as normal. The "error recovery" is just the ignoring or skipping of invalid content.

The fact that browsers ignore invalid code enables the use of new CSS features without worrying about anything being broken in older browsers. A browser may not recognize a new feature, but that is okay. The discarding of invalid content without throwing an error allows both old and new syntaxes to coexist in the same ruleset, although bear in mind that they should be specified in that order. For example:

```
div {
  display: inline-flex;
  display: inline flex;
}
```

The `display` property accepts both legacy single value and multi-keyword syntax. Browsers will render the old syntax until they recognize the new syntax as valid, at which point the new syntax will override the old. If a user has an old browser, the valid fallback won't get overwritten by the new CSS, because the browser perceives it as invalid.

The type and amount of CSS that a browser ignores due to an error depends on the type of error. Some common error situations are listed below:

- For errors in at-rules, whether a single line or the entire at-rule is ignored (fails) depends on the at-rule and the type of error.
- If the error is an invalid selector, the entire declaration block is ignored.
- An error due to a missing semi-colon between property declarations causes an invalid value, in which case, multiple property-value declarations are ignored.
- If the error is a property name or value, such as an unrecognized property name or invalid data type, the property-value declaration is ignored. During the filtering stage, such syntactically invalid declarations are eliminated.
- If the error is due to a missing end-bracket, the extent of what is ignored depends on the browser's ability to parse the error as nested CSS.

After parsing each declaration, style rule, at-rule, and so on, the browser checks the parsed content against its expected grammar for that construct. If the content does not match the expected grammar for that construct, the browser considers it invalid and ignores it.

At-rule errors

The `@` symbol, known in CSS specifications as an `<at-keyword-token>`, indicates the beginning of a CSS at-rule. Once an at-rule begins with the `@` symbol, nothing is considered invalid from the parser's standpoint. Everything up to the first semi-colon (`;`) or the opening curly brace (`{`) is part of the at-rule's prelude. The content of each at-rule is interpreted according to the grammar rules for that particular at-rule.

Statement at-rules, such as `@import` and `@namespace` declarations, contain just a prelude. The semicolon ends the at-rule immediately for statement at-rules. If the contents of the prelude are invalid according to the grammar for that at-rule, the at-rule is ignored, with the browser continuing to parse CSS after it encounters the next semi-colon. For example, if an `@import` at-rule occurs after any CSS declaration other than `@charset`, `@layer` or other `@import` statements, the `@import` declaration is ignored.

```
@import "assets/fonts.css" layer(fonts);
@namespace svg url("http://www.w3.org/2000/svg");
```

If the parser encounters a curly brace (`{`) before a semi-colon is encountered, the at-rule is parsed as a block at-rule. Block at-rules like `@font-face` and `@keyframes`, contain a block of declarations surrounded by curly braces (`{}`). The opening curly brace informs the browser where the at-rule prelude ends and the at-rule's body starts. The parser looks forward, seeking matching blocks (content surrounded by `()`, `{}`, or `[]`) until it finds a closing curly brace (`}`) that isn't matched by any other curly braces: this closes the body of the at-rule.

Different at-rules have different grammar rules, different (or no) descriptors, and different rules for what, if anything, will invalidate the entire at-rule. The expected grammar for each at-rule and how errors are handled are documented on the respective at-rule page. The handling of invalid content depends on the error.

For example, the `@font-face` rule requires both a `font-family` and `src` descriptor. If either of these is omitted or invalid, the entire `@font-face` rule is invalid. Including an unrelated descriptor, any other valid font descriptor with an invalid value, or a property style declaration within the `@font-face` nested block will not invalidate the font declaration. As long as the font name and font source are included and valid, any invalid CSS within the at-rule is ignored, but the `@font-face` block is still parsed.

While the grammar of the `@keyframes` at-rule is very different from the `@font-face` rule grammar, the type of error still impacts what gets ignored. Important declarations (marked with the `important` flag) and properties that can't be animated are ignored in keyframe rules, but they don't impact other styles declared in the same keyframe selector block. Including an invalid keyframe selector (such as a percentage value less than `0%` or greater than `100%`, or a `<number>` omitting the `%`) invalidates the keyframe selector list and therefore the style block is ignored. An invalid keyframe selector only invalidates the invalid selector's style block; it does not invalidate the entire `@keyframes` declaration. Including styles between two keyframe selector blocks, on the other hand, will invalidate the entire `@keyframes` at-rule.

Some at-rules are almost always valid. The `@layer` at-rule comes in both regular and nested forms. The `@layer` statement syntax contains just the prelude, ending with a semi-colon. Alternatively, the nested syntax has layer styles nested between curly braces coming after the prelude. Omitting a closing curly brace may be a logic error but is not a syntax error. In the case of a missing closing brace in `@layer`, any styles coming after where the closing brace should have been are parsed as being in the cascade layer defined in the at-rule's prelude. The CSS is valid as there are no syntax errors; nothing is discarded. A syntax error may cause the named or anonymous layer to be empty, but the layer is still created.

Errors in selector lists

There are many ways you might make a mistake writing a selector, but only invalid selectors cause a selector list to be invalid (See invalid selector list).

If you include a class selector, an id_selectors, or a type selector for a class, id, or element (or custom element) that doesn't exist, it may be a logic error but it's not a syntax error. However, if you have a typo in a pseudo-class or a pseudo-element, it might create an invalid selector, which is an error the parser needs to address.

If a selector list contains any invalid selectors, then the entire style block is ignored. There are exceptions: if the invalid selector is within an `:is` or `:where` pseudo-class (which accept forgiving selector lists) or if the unknown selector is a `-webkit-` prefixed pseudo-element, only the unknown selector is ignored as not matching anything. The selector list is not invalidated.

Outside of these exceptions, a single invalid or unsupported selector in the selector list will invalidate the entire rule and the entire selector block will be ignored. The browser will then look for the closing curly brace and continue parsing from that point onwards.

`-webkit-` exception

Due to legacy issues from the overuse of browser-specific prefixes in selectors and property names (and values), browsers avoid excessive invalidation of selector lists by treating all pseudo-elements that start with a case-insensitive `-webkit-` prefix and don't end with `()` as valid.

This means that a pseudo-element like `::-webkit-works-only-in-samsung` will not invalidate a selector list, regardless of which browser the code is running in. In such cases, the pseudo-element may not be recognized or supported by the browser, but it will not cause the entire selector list and its associated style block to be ignored. On the other hand, an unknown prefixed selector with a function notation of `::-webkit-imaginary-function()` will invalidate the entire selector list, and the browser will ignore the entire selector block.

Errors within CSS declaration blocks

When it comes to CSS properties and values within a declaration block, if either the property or the value is invalid, that property-value pair is ignored and discarded. When a user agent parses or interprets a list of declarations, unknown syntax at any point causes the browser's parser to discard only the current declaration. It then continues parsing CSS after the next semicolon or closing curly bracket is encountered, whichever comes first.

This example contains an error. The parser ignores the error (and the comments), seeks forward until it encounters a semi-colon, then restarts parsing:

```
p {
  /* Invalid syntax due to missing semi-colon */
  border-color: red
  background-color: green;
```

```
  /* Valid syntax but likely a logic error */
  border-width: 100vh;
}
```

The reason the first declaration in this selector block is invalid is because the semi-colon is missing and the declaration is not the last one in the selector block. The property missing the semi-colon is ignored, as is the property-value pair following it because the browser only continues parsing after a semi-colon or closing bracket is encountered. Specifically, the `border-color` value is parsed as `red background-color: green;` which is not a valid `<color>` value.

The `border-width` value of `100vh` is likely a mistake, but it's not an error. As it is syntactically valid, it will be parsed and applied to the elements matching the selector.

Vendor prefixes

Vendor-prefixed property names and property values, when not understood by a browser, are treated as invalid and ignored. Only the individual rules containing an invalid property or value are ignored. The parser looks for the next semi-colon or closing curly brace and then continues parsing from there.

You may come across legacy CSS that looks like the following:

```
/* Prefixed values */
.wrapper {
  display: -webkit-box;
  display: -webkit-flex;
  display: -ms-flexbox;
  display: flex;
  display: block flex;
}
/* Prefixed properties */
.rounded {
  -webkit-border-radius: 50%;
  -moz-border-radius: 50%;
  -ms-border-radius: 50%;
  -o-border-radius: 50%;
  border-radius: 50%;
}
```

In this example, the last declaration in each block is valid in all browsers — `display: flex;` and `border-radius: 50%;`. Because of the cascade order of appearance rule, browsers will apply any prefixed declarations they understand, and then override those values with the standard unprefixed version.

> **Note:** Avoid including prefixed properties or property values where possible. If you must use them, declare the prefixed versions before the non-prefixed version as shown above.

Errors with auto-closed endings

If a stylesheet ends while a rule, declaration, function, string, or comment is still open, the parser will automatically close everything that was left unclosed.

> **Note:** This is true of external style sheets, selector blocks within an HTML `<style>` element, and inline rules within a `style` attribute.

If the content between the last semi-colon and the end of the stylesheet is valid, even if incomplete, the CSS will be parsed normally. For example, if you fail to close out a `@keyframes` declaration before closing your `<style>`, the animation is still valid.

```
<style>
@keyframes move {
  100% {
    transform: translateX(100vw)
</style>
```

Here the `move` animation is valid. Failing to properly close CSS statements doesn't necessarily make the statements invalid. That said, do not take advantage of CSS's forgiving nature. Always close all of your statements and style blocks. It makes your CSS more readable and maintainable and ensures that the browser parses the CSS as you intended.

Unclosed comments

Unclosed comments are logic errors, not syntax errors. If a comment starts with `/*` but is not closed, all CSS code until a closing delimiter (`*/`) in a subsequent comment or the end of the stylesheet, whichever comes first, is part of the comment. While an unclosed comment does not invalidate your CSS, it causes the CSS following the opening delimiter (`/*`) to be ignored.

```
<style>
  /* this comment is not closed
  @keyframes move {
    0% {transform: translateX(0);}
    100% {transform: translateX(100vw);}
  }
</style>
<p style="/* another unclosed comment">Parsed as HTML.</p>
```

In this example, the two CSS comments are not closed, but the closing `</style>` tag closes the first comment and the `style` attribute's close quote closes the second comment.

Grammar check

After parsing each declaration, style rule, at-rule, etc., the user agent checks to make sure the grammar follows the rules for that declaration. For example, if a property value is of the wrong data type or a descriptor is not valid for the at-rule being described, the content that does not match the expected grammar is deemed invalid and gets ignored.

Each CSS property accepts specific data types. For example, the `background-color` property accepts either a valid `<color>` or a CSS global keyword. When the value assigned to a property is of the wrong type, such as `background-color: 45deg`, the declaration is invalid and therefore ignored.

Invalid custom properties

Custom properties are generally considered valid when declared, but may create invalid CSS when accessed, i.e., they may be used as a value (via the `var()` function) for a property that does not accept that value type. The browser parses each custom property when encountered without regard to where the property is consumed.

Generally, when a property value is invalid, the declaration is ignored and the property falls back to the last valid value. Invalid computed custom property values, however, work slightly differently.

When a `var()` substitution is invalid, the declaration is not ignored and the initial or inherited value of the property is used instead. The property is set to a new value, but possibly not the expected one.

Let's look at an example to illustrate this behavior:

```
:root {
  --theme-color: 45deg;
}
```

```
body {
  background-color: var(--theme-color);
}
```

In the above code, the custom property declaration is valid. The `background-color` declaration is also valid at compute time. However, when the browser substitutes the custom property in `var(--theme-color)` with `45deg` as a value of the `background-color` property, the grammar is invalid. An `<angle>` is not a valid `background-color` value. In this case, the declaration is not ignored as invalid. Rather, when a custom property is of the wrong type, if the property is inheritable, the value is inherited from its parent. If the property is not inheritable, the default initial value is used. In the case of `background-color`, the property value is not an inherited value, so the initial value of `transparent` is used.

To better control the way custom properties fall back, use the `@property` at-rule to define the initial value of the property:

```
@property --theme-color {
  syntax: "<color>";
  inherits: false;
  initial-value: rebeccapurple;
}
```

Introduction to CSS syntax: declarations, rulesets, and statements

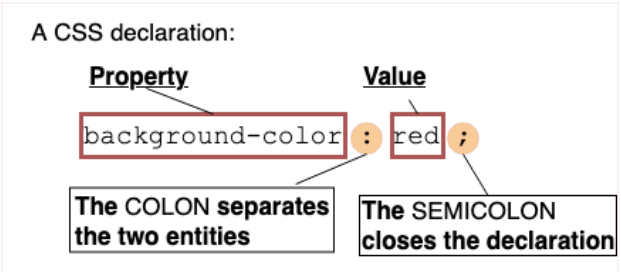
The basic goal of the Cascading Stylesheet (CSS) language is to allow a browser engine to paint elements of the page with specific features, like colors, positioning, or decorations. The *CSS syntax* reflects this goal and its basic building blocks are:

- The **property** which is an identifier, that is a human-readable *name*, that defines which feature is considered.
- The **value** which describe how the feature must be handled by the engine. Each property has a set of valid values, defined by a formal grammar, as well as a semantic meaning, implemented by the browser engine.

CSS declarations

Setting CSS properties to specific values is the core function of the CSS language. A property and value pair is called a **declaration**, and any CSS engine calculates which declarations apply to every single element of a page in order to appropriately lay it out, and to style it.

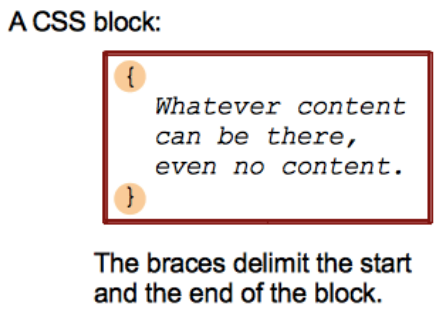
Both properties and values are case-insensitive by default in CSS. The pair is separated by a colon, `:` (U+003A COLON), and white spaces before, between, and after properties and values, but not necessarily inside, are ignored.



There are hundreds of different properties in CSS and a practically endless number of different values. Not all pairs of properties and values are allowed and each property defines what are the valid values. When a value is not valid for a given property, the declaration is deemed *invalid* and is wholly ignored by the CSS engine.

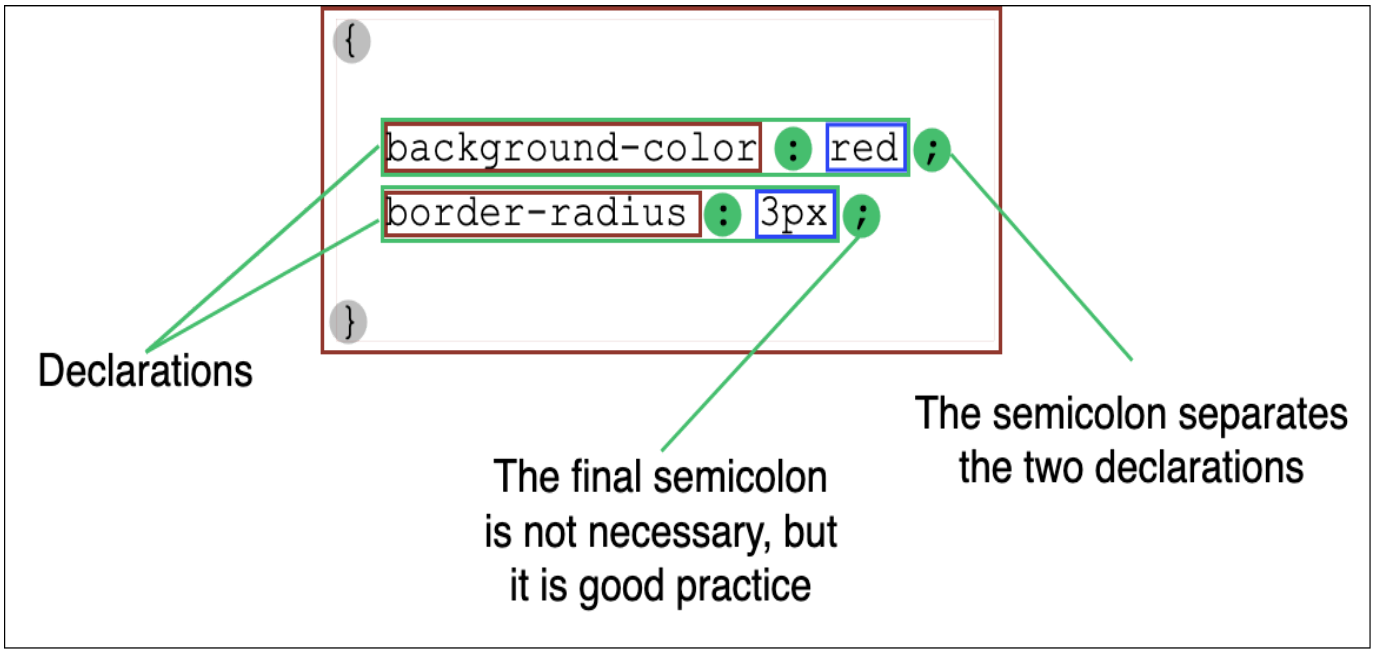
CSS declaration blocks

Declarations are grouped in **blocks**, that is in a structure delimited by an opening brace, `{` (U+007B LEFT CURLY BRACKET), and a closing one, `}` (U+007D RIGHT CURLY BRACKET). Blocks sometimes can be nested, so opening and closing braces must be matched.



Such blocks are naturally called **declaration blocks** and declarations inside them are separated by a semicolon, `;` (U+003B SEMICOLON). A declaration block may be empty, that is containing null declaration. White spaces around declarations are ignored. The last declaration of a block doesn't need to be terminated by a semicolon, though it is often considered *good style* to do it as it prevents forgetting to add it when extending the block with another declaration.

A CSS declaration block is visualized in the diagram below.



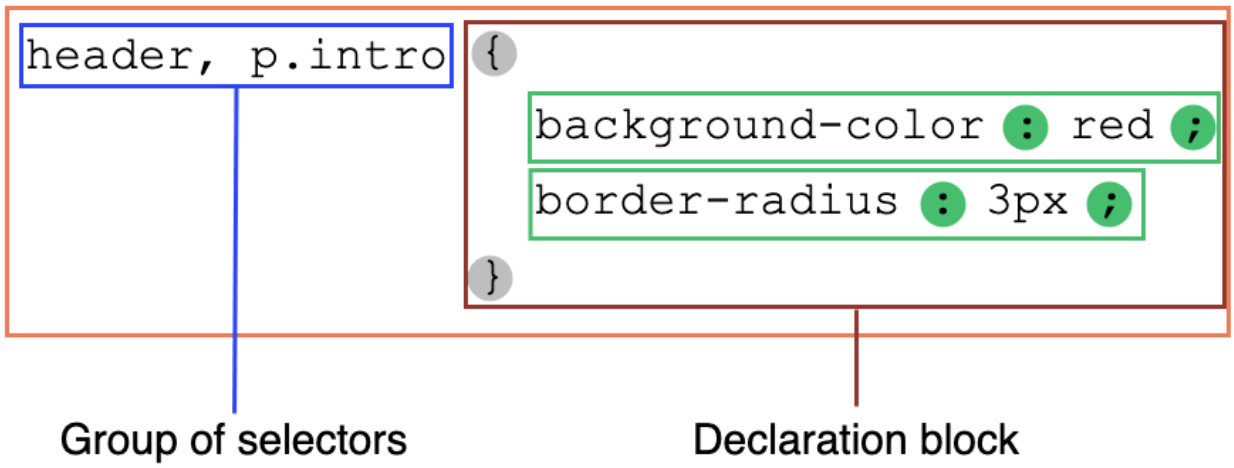
> **Note:** The content of a CSS declaration block, that is a list of semicolon-separated declarations, without the initial and closing braces, can be put inside an HTML `style` attribute.

CSS rulesets

If style sheets could only apply a declaration to each element of a Web page, they would be pretty useless. The real goal is to apply different declarations to different parts of the document.

CSS allows this by associating conditions with declarations blocks. Each (valid) declaration block is preceded by one or more comma-separated **selectors**, which are conditions selecting some elements of the page. A selector list and an associated declarations block, together, are called a **ruleset**, or often a **rule**.

A CSS ruleset (or rule) is visualized in the diagram below.



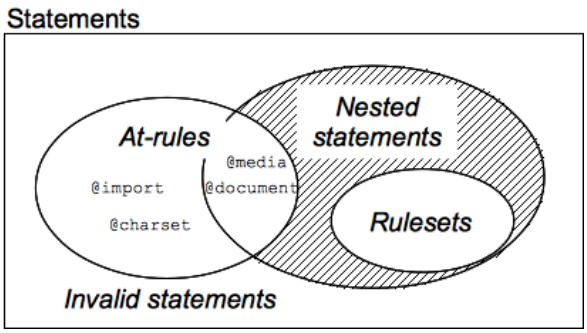
As an element of the page may be matched by several selectors, and therefore by several rules potentially containing a given property several times, with different values, the CSS standard defines which one has precedence over the other and must be applied: this is called the cascade algorithm (see Handling conflicts).

> **Note:** It is important to note that even if a ruleset characterized by a group of selectors is a kind of shorthand replacing rulesets with a single selector each, this doesn't apply to the validity of the ruleset itself.
>
> This leads to an important consequence: if one single basic selector is invalid, like when using an unknown pseudo-element or pseudo-class, the whole *selector* is invalid and therefore the entire rule is ignored (as invalid too).

CSS statements

Rulesets are the main building blocks of a style sheet, which often consists of only a big list of them. But there is other information that a Web author wants to convey in the style sheet, like the character set, other external style sheets to import, font face or list counter descriptions and many more. It will use other and specific kinds of statements to do that.

A **statement** is a building block that begins with any non-space characters and ends at the first closing brace or semicolon (outside a string, non-escaped and not included into another {}, () or [] pair).



There are two kinds of statements:

- **Rulesets** (or *rules*) that, as seen, associate a collection of CSS declarations to a condition described by a selector.
- **At-rules** that start with an at sign, `@` (U+0040 COMMERCIAL AT), followed by an identifier and then continuing up to the end of the statement, that is up to the next semicolon (;) outside of a block, or the end of the next block. Each type of at-rules, defined by the identifier, may have its own internal syntax, and semantics of course. They are used to convey meta-data information (like `@layer` or `@import`), conditional information (like `@media` or `@document`), or descriptive information (like `@font-face`).

Any statement which isn't a ruleset or an at-rule is invalid and ignored.

Nested statements

There is another group of statements – the **nested statements**. These are statements that can be used in a specific subset of at-rules – the *conditional group rules*. These statements only apply if a specific condition is matched: the `@media` at-rule content is applied only if the device on which the browser runs matches the expressed condition; the `@document` at-rule content is applied only if the current page matches some conditions, and so on. In CSS1 and CSS2.1, only *rulesets* could be used inside conditional group rules. That was very restrictive and this restriction was lifted in *CSS Conditionals Level 3*. Now, though still experimental and not supported by every browser, conditional group rules can contain a wider range of content: rulesets but also some, but not all, at-rules.

CSS table

The **CSS table** module helps you define how to lay out table data.

This CSS module defines styles applicable to the HTML `<table>` element, which is used to render tabular data. By default, tables are rendered as a two-dimensional grid with cells lined up in a series of consecutive rows and columns. This layout is generated from the table structure and sized according to the content of the cells. This module also enables defining the position of the table's `<caption>`, if present.

The properties introduced in this module aren't limited to the `<table>` elements; they can be applied to any element with a table-related CSS `display` value.

Handling whitespace

The presence of whitespace in the DOM can cause layout problems and make manipulation of the content tree difficult in unexpected ways, depending on where it is located. This article explores when difficulties can occur, and looks at what can be done to mitigate resulting problems.

What is whitespace?

Whitespace characters consist of different characters in different programming language contexts. *Document white space characters*, as far as the CSS whitespace processing rules are concerned, only include spaces (U+0020), tabs (U+0009), line feeds (LF, U+000A), and carriage returns (CR, U+000D), where CR characters are equivalent to spaces in every regard. These characters allow you to format your code for readability. Much of our source code is full of these whitespace characters, and we tend to remove them only as part of a production build step to reduce file size.

Note that this list does not include non-breaking spaces (U+00A0, ` ` in HTML). So these characters don't trigger any collapsing, which is why they are often used to create longer spaces in HTML.

CSS also defines the concept of *segment breaks*, which in the context of HTML are equivalent to LF characters.

How does HTML process whitespace?

It is a common myth that "HTML ignores whitespace", which is untrue: **HTML preserves all whitespace text content as you wrote them in the source code.** As a markup language, HTML produces a DOM where all whitespace in the text content is preserved, which can be retrieved and manipulated via DOM APIs such as `Node.textContent`. If HTML strips whitespace from the DOM, then CSS, a downstream rendering engine that works on the DOM, would not be able to preserve them using the `white-space` property.

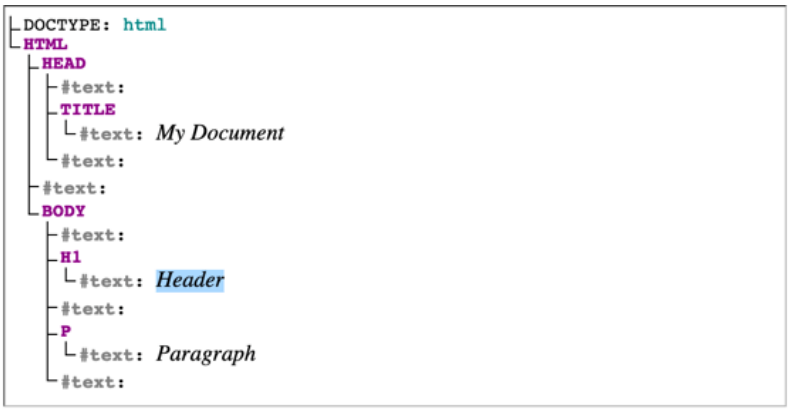
> **Note:** To be clear, we're talking about whitespace *between HTML tags*, which becomes text nodes in the DOM. Any whitespace *inside a tag* (between the angle brackets but not as part of an attribute value) is just part of the HTML syntax and does not appear in the DOM.

> **Note:** Due to the magic that is HTML parsing (quote from DOM spec), there do exist certain places where whitespace characters could be ignored. For example, whitespace between the `<html>` and `<head>` opening tags or between the `</body>` and `</html>` closing tags is ignored and does not appear in the DOM. Also, when parsing the `<pre>` element's text content, a single leading newline character gets stripped. We ignore these edge cases.
>
> Furthermore, the HTML parser does *normalize* certain whitespaces: it replaces CR and CRLF sequences with a single LF. However, CR characters can also be inserted into the DOM either via character references or JavaScript, so the CSS whitespace processing rules still need to define how to handle them.

Take the following document, for example:

```
<!doctype html>
<html lang="en-US">
  <head>
    <meta charset="UTF-8" />
    <title>My Document</title>
  </head>
  <body>
    <h1>Header</h1>
    <p>Paragraph</p>
  </body>
</html>
```

The DOM tree for this looks like so:



Note that:

- Some text nodes will contain only whitespace.
- Other text nodes may have whitespace at the beginning or the end.

> **Note:** Firefox DevTools supports highlighting text nodes, enabling you to see exactly which nodes contain whitespace characters. Pure whitespace nodes are marked with a "whitespace" label.

Conserving whitespace characters in the DOM is useful in many ways, but it can also make certain layouts more difficult to implement and may cause problems for developers who want to iterate over DOM nodes. We'll look at these issues and some solutions later on, in the solving common problems with whitespace nodes section.

How does CSS process whitespace?

When the DOM is passed to CSS for rendering, the whitespace is largely stripped by default. This means that the way your code is formatted is not visible to the end user—creating space around and inside elements is the job of CSS.

```
<!doctype html>

  <h1>      Hello      World!     </h1>
```

This source code contains a couple of line feeds after the `doctype` and a bunch of space characters before, after, and inside the `<h1>` element. But the browser ignores these spaces and just shows the words "Hello World!" as if these characters didn't exist at all:

CSS ignores most, but not all, whitespace characters. In this example, one of the spaces between "Hello" and "World!" still exists when the page is rendered in a browser. CSS uses a specific algorithm to decide which whitespace characters are user-irrelevant and how they are removed or transformed. We'll explain how this processing works in the next few sections.

Collapsing and transformation

Let's look at an example. To make the whitespace characters more salient, we've also added a comment to show all spaces as ◦, all tabs as ↹, and all line breaks as ⏎:

```
<h1>   Hello
                                <span> World!</span>      </h1>

<!--
<h1>◦◦◦Hello◦⏎
↹↹↹↹<span>◦World!</span>↹◦◦</h1>
-->
```

This example is rendered in the browser like so:

The `<h1>` element contains:

- A text node (consisting of some spaces, the word "Hello", a line break, and some tabs).
- An inline element (`<span>`, which contains a space, and the word "World!").
- Another text node (with a tab and spaces after the `<span>`).

Because this `<h1>` element contains only inline elements, it establishes an inline formatting context. This is one of the several layout rendering contexts that browser engines use to arrange content on the page.

Inside this inline formatting context, whitespace characters are processed as follows:

> **Note:** This algorithm can be configured via the `white-space-collapse` property (or its shorthand property `white-space`). We'll start by assuming its default value (`white-space-collapse: collapse`), then look at how different property values affect this algorithm.

1. First, all spaces and tabs immediately before and after a line break are ignored. So, if we take our example markup from before:

   ```
   <h1>◦◦◦Hello◦⏎
   ↹↹↹↹<span>◦World!</span>↹◦◦</h1>
   ```

   ...and apply this first rule, we get:

   ```
   <h1>◦◦◦Hello⏎
   <span>◦World!</span>↹◦◦</h1>
   ```

2. Next, consecutive line breaks are collapsed into a single line break. We don't have any in this example.

3. Next, lines in the source code are joined into single lines by removing any remaining line break characters. They are either transformed into spaces (U+0020) or simply removed, depending on the context before and after the break. The exact choice between the two is browser- and language-dependent. In our example here in English (where spaces separate words), we can expect all line breaks to be "transformed" into spaces. So we end up with:

   ```
   <h1>◦◦◦Hello◦<span>◦World!</span>↹◦◦</h1>
   ```

   Notably, in languages that have no word separators, such as Chinese, lines are joined with no intervening space. So:

   ```
   <div>你好
   世界</div>
   ```

   might be rendered as "你好世界" without any spaces in between, depending on the browser's heuristics.

4. Next, all tab characters are transformed into space characters, so the example becomes:

   ```
   <h1>◦◦◦Hello◦<span>◦World!</span>◦◦◦</h1>
   ```

5. After that, any space immediately following another space (even across two separate inline elements) is ignored, so we end up with:

   ```
   <h1>◦Hello◦<span>World!</span>◦</h1>
   ```

This is why people visiting the web page will see the phrase "Hello World!" nicely written at the top of the page, rather than a weirdly indented "Hello" followed by an even more weirdly indented "World!" on the next line.

After these steps, the browser processes line wrapping and bidirectional text, which we will ignore here. Note that there are still spaces left after the opening `<h1>` tag and before the closing `</h1>` tag, but these are not rendered in the browser. We'll handle that next, as each line is laid out.

Different `white-space-collapse` values skip different steps of this algorithm:

- `preserve` and `break-spaces`: the whole algorithm is skipped, and no whitespace collapsing or transformation happens.
- `preserve-breaks`: steps 2 and 3 are skipped, and line breaks are preserved.
- `preserve-spaces`: the whole algorithm is skipped and replaced with a single step to convert each tab or line break into a space.

In a nutshell, different whitespace characters are collapsed and transformed in the following fashion:

- Tabs are generally converted to spaces.
- If segment breaks are to be collapsed:
  - Sequences of segment breaks are collapsed to a single segment break.
  - They are converted to spaces in languages that separate words with spaces (like English), or removed altogether in languages that do not separate words with spaces (like Chinese).
- If spaces are to be collapsed:
  - Spaces or tabs before or after segment breaks are removed.
  - Sequences of spaces are collapsed to a single space.
- When spaces are preserved, sequences of spaces are treated as non-breaking, except that they will soft wrap at the end of each sequence — that is, the next line will always start with the next non-space character. In the case of the `break-spaces` value, however, a soft wrap could potentially occur after each space, so the next line may start with one or more spaces.

Trimming and positioning

In both inline and block formatting contexts, elements are laid out in *lines*. In an inline formatting context, lines are created by text wrapping. In a block formatting context, on the other hand, each block forms its own line. As each line is laid out, whitespace is processed further. Let's take a look at an example to explain how this works.

In this example, as before, we've marked the whitespace characters in a comment. We have three text nodes that contain only whitespace: one before the first `<div>`, one between the 2 `<div>`s, and one after the second `<div>`.

```
<body>
        <div>   Hello   </div>

   <div>  World!   </div>
</body>

<!--
<body>⏎
→⇥<div>→⇥Hello→⇥</div>⏎
⏎
◦◦◦<div>◦◦World!◦◦◦</div>◦◦⏎
</body>
-->
```

This renders like so:

The whitespace in this example is handled as follows:

> **Note:** This algorithm can be configured via the `white-space-collapse` property (or its shorthand property `white-space`). We'll start by assuming its default value (`white-space-collapse: collapse`), then look at how different property values affect this algorithm.

1. First, the whitespace is collapsed the same way as we saw in the previous section, turning this:

   ```
   <body>⏎
   →⇥<div>→⇥Hello→⇥</div>⏎
   ⏎
   ◦◦◦<div>◦◦World!◦◦◦</div>◦◦⏎
   </body>
   ```

   ...into this:

   ```
   <body>◦<div>◦Hello◦</div>◦<div>◦World!◦</div>◦</body>
   ```

   Lines are then laid out according to the block formatting context established by `<body>`. In this example, each of `<body>`'s five child nodes is laid out as a separate line. (Each line in this code block represents a line in the rendered layout, not a line in our original HTML code):

   ```
   <body>
   ◦
   <div>◦Hello◦</div>
   ◦
   <div>◦World!◦</div>
   ◦
   </body>
   ```

   Note that if the lines become too long, each line may wrap and create more lines. In reality, browsers determine the content of the lines as the lines are laid out. We'll skip the part about how text wrapping works.

2. Sequences of spaces at the beginning of a line are removed, so the example becomes:

   ```
   <body>

   <div>Hello◦</div>

   <div>World!◦</div>

   </body>
   ```

3. Each tab that's preserved at this point is rendered according to `tab-size`. This can only happen with `white-space-collapse` set to `preserve` or `break-spaces` because all other settings turn tabs into spaces.

4. Sequences of spaces at the end of a line are removed, so the above becomes:

   ```
   <body>

   <div>Hello</div>

   <div>World!</div>

   </body>
   ```

The three empty lines we now have are not going to occupy any space in the final layout, because they don't contain any visible content. So we'll end up with only two lines taking up space in the page. People viewing the web page see the words "Hello" and "World!" on two separate lines, just as you'd expect two `<div>`s to be laid out. Browsers essentially ignore all of the whitespace that was included in the HTML code.

Different `white-space-collapse` values skip different steps of this algorithm:

- `preserve` and `break-spaces`: The whole algorithm is skipped except for step 3, so no whitespace collapsing or transformation happens.
- `preserve-spaces`: The whole algorithm is skipped, so whitespace characters at the start and end of lines are preserved.
- `preserve-breaks`: The same algorithm is applied as with the `collapse` value.

How do DOM APIs process whitespace?

As mentioned previously, whitespace is preserved in the DOM. This means that if you retrieve `Node.textContent`, you will get the text content as you wrote it in the HTML source code, and if you retrieve `Node.childNodes`, you will get all the text nodes, including those that contain only whitespace.

Not all DOM APIs preserve whitespace; some APIs deal with the *rendered text* by design. For example, `HTMLElement.innerText` returns the text exactly as it's rendered, with all whitespace collapsed and trimmed. `Selection.toString()` returns the text as it would be pasted, which generally means that whitespace is collapsed. However, in Firefox (which collapses whitespace between Chinese characters, as mentioned in the collapsing and transformation section above), the collapsed whitespace is still preserved both in the string returned by `toString()` and in the pasted text.

```
<div id="test">Hello world!</div>
```

```
const div = document.getElementById("test");
console.log(div.textContent); // "  Hello\n  world!\n"
console.log(div.innerText); // "Hello world!"
const selection = document.getSelection();
selection.selectAllChildren(div);
console.log(selection.toString()); // "Hello world!"
```

Solving common problems with whitespace nodes

Whitespace nodes are invisible to the website visitor due to the CSS processing rules, but they can interfere with certain layouts and DOM manipulation that rely on the exact structure of the DOM. Let's look at some common problems and how to solve them.

Whitespace processing between inline and inline-block elements

Let's look at one layout issue with whitespace nodes: spaces between inline and inline-block elements. As we saw earlier with inline and block elements, most whitespace characters are ignored, but word-separating characters like spaces remain. The extra whitespace that does make it to the layout is helpful to separate the words in the sentence.

With `inline-block` elements, it gets more interesting: these elements behave like inline elements on the outside and blocks on the inside. (They're often used to display more complex pieces of UI, placed side by side on the same line, such as navigation menu items.) Any whitespace between adjacent inline or inline-block elements will result in spaces in the layout, just like the spaces between words in text. (This can surprise developers because they are blocks, and blocks don't normally show extra spaces.)

Consider this example (as before, we've included a comment in the HTML code to show the whitespace characters):

```
.people-list {
  list-style-type: none;
  margin: 0;
  padding: 0;
}

.people-list li {
  display: inline-block;
  width: 2em;
  height: 2em;
  background: #ff0066;
  border: 1px solid;
}
```

```
<ul class="people-list">
  <li></li>

  <li></li>

  <li></li>

  <li></li>

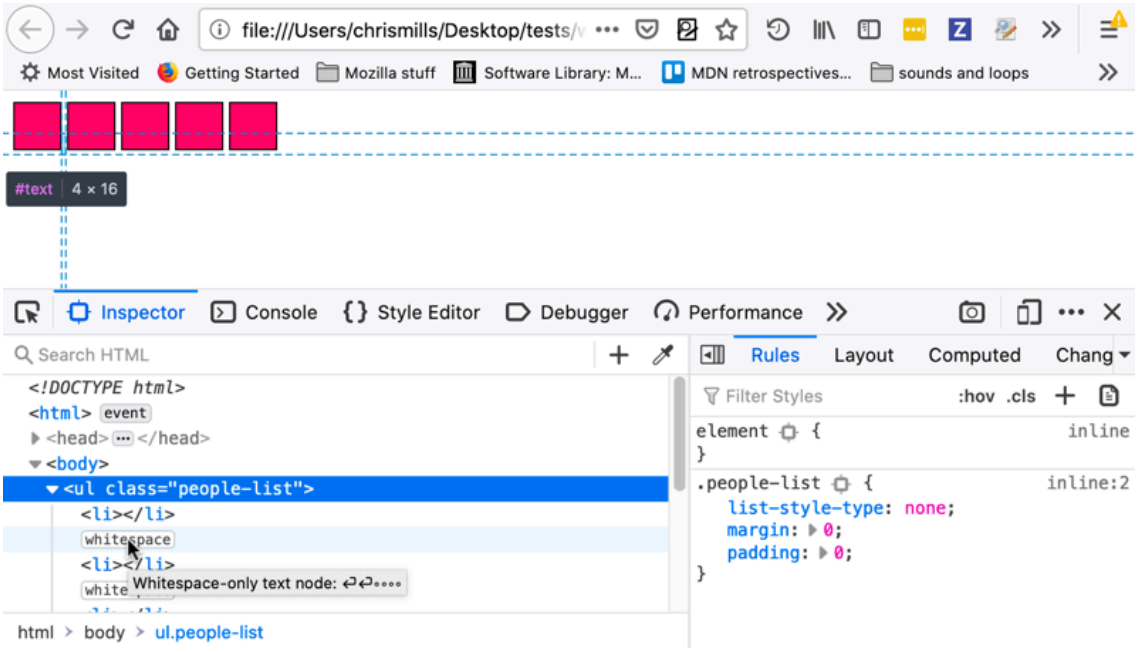
  <li></li>
</ul>

<!--
<ul class="people-list">⏎
◦◦<li></li>⏎
⏎
◦◦<li></li>⏎
⏎
◦◦<li></li>⏎
⏎
◦◦<li></li>⏎
⏎
◦◦<li></li>⏎
</ul>
-->
```

This renders as follows:

You probably don't want the gaps between the blocks. Depending on your use case (such as a list of avatars or a horizontal row of navigation buttons), you probably want the elements to flush against each other, and to be able to control any spacing yourself.

The Firefox DevTools HTML Inspector can highlight text nodes and also show you exactly the area the elements are taking up. This is useful to check out if you suspect there's extra margin or unexpected whitespace causing gaps.



There are a few ways of getting around this problem:

- Use Flexbox to create the horizontal list of items instead of trying an `inline-block` solution. Flexbox handles spacing and alignment for you, and is definitely the preferred solution:

```
ul {
  list-style-type: none;
  margin: 0;
  padding: 0;
  display: flex;
}
```

- If you need to rely on `inline-block`, you could set the `font-size` of the list to `0`. This only works if the blocks are not sized with `em` units (since `em` is based on `font-size`, the block size would also end up being sized as `0`). Using `rem` units would be a good choice here:

```
ul {
  font-size: 0;
  /* … */
}

li {
  display: inline-block;
  width: 2rem;
  height: 2rem;
  /* … */
}
```

- Alternatively, you could set negative margin on the list items:

```
li {
  display: inline-block;
  width: 2rem;
  height: 2rem;
  margin-right: -0.25rem;
}
```

- You can also solve this problem by avoiding whitespace nodes between `<li>` items:

```
<li>
  ...
</li><li>
  ...
</li>
```

Working with whitespace in the DOM

As mentioned previously, whitespace is collapsed and trimmed when rendered, but preserved in the DOM. This may present some pitfalls when trying to do DOM manipulation in JavaScript. For example, if you have a reference to a parent node and want to manipulate its first element child using `Node.firstChild`, a rogue whitespace node just after the opening parent tag will give you the wrong result. The text node would be selected instead of the element you want to target.

As another example, if you want to do something to a subset of elements based on whether they are empty (have no child nodes), you could use `Node.hasChildNodes()`. But if any of those elements contain text nodes, you could end up with false results.

The following JavaScript code shows several functions that deal with whitespace in the DOM:

```
/**
 * Throughout, whitespace is defined as one of the characters
 *  "\t" TAB \u0009
 *  "\n" LF  \u000A
 *  "\r" CR  \u000D
 *  " "  SPC \u0020
 *
 * This does not use JavaScript's "\s" because that includes non-breaking
 * spaces (and also some other characters).
 */
```

```
/**
 * Determine whether a node's text content is entirely whitespace.
 *
 * @param nod  A node implementing the `CharacterData` interface (i.e.,
 *             a `Text`, `Comment`, or `CDATASection` node)
 * @return     `true` if all of the text content of `nod` is whitespace,
 *             otherwise `false`.
 */
function isAllWs(nod) {
  return !/[^\t\n\r ]/.test(nod.textContent);
}

/**
 * Determine if a node should be ignored by the iterator functions.
 *
 * @param nod  An object implementing the `Node` interface.
 * @return     `true` if the node is:
 *                1) A `Text` node that is all whitespace
 *                2) A `Comment` node
 *             and otherwise `false`.
 */
function isIgnorable(nod) {
  return (
    nod.nodeType === 8 || // a comment node
    (nod.nodeType === 3 && isAllWs(nod))
  ); // a text node, all ws
}

/**
 * Version of `previousSibling` that skips nodes that are entirely
 * whitespace or comments. (Normally `previousSibling` is a property
 * of all DOM nodes that gives the sibling node, the node that is
 * a child of the same parent, that occurs immediately before the
 * reference node.)
 *
 * @param sib  The reference node.
 * @return     The closest previous sibling to `sib` that is not
 *             ignorable according to `isIgnorable`, or `null` if
 *             no such node exists.
 */
function nodeBefore(sib) {
  while ((sib = sib.previousSibling)) {
    if (!isIgnorable(sib)) {
      return sib;
    }
  }
  return null;
}

/**
 * Version of `nextSibling` that skips nodes that are entirely
 * whitespace or comments.
 *
 * @param sib  The reference node.
 * @return     The closest next sibling to `sib` that is not
 *             ignorable according to `isIgnorable`, or `null`
 *             if no such node exists.
 */
function nodeAfter(sib) {
  while ((sib = sib.nextSibling)) {
    if (!isIgnorable(sib)) {
      return sib;
    }
  }
  return null;
}

/**
 * Version of `lastChild` that skips nodes that are entirely
 * whitespace or comments. (Normally `lastChild` is a property
 * of all DOM nodes that gives the last of the nodes contained
 * directly in the reference node.)
 *
 * @param sib  The reference node.
 * @return     The last child of `sib` that is not ignorable
 *             according to `isIgnorable`, or `null` if no
 *             such node exists.
 */
function lastChild(par) {
  let res = par.lastChild;
  while (res) {
    if (!isIgnorable(res)) {
      return res;
    }
    res = res.previousSibling;
  }
  return null;
}

/**
 * Version of `firstChild` that skips nodes that are entirely
 * whitespace and comments.
 *
 * @param sib  The reference node.
 * @return     The first child of `sib` that is not ignorable
 *             according to `isIgnorable`, or `null` if no
 *             such node exists.
 */
function firstChild(par) {
  let res = par.firstChild;
  while (res) {
    if (!isIgnorable(res)) {
      return res;
```

```
    }
    res = res.nextSibling;
  }
  return null;
}

/**
 * Version of `data` that doesn't include whitespace at the beginning
 * and end and normalizes all whitespace to a single space. (Normally
 * `data` is a property of text nodes that gives the text of the node.)
 *
 * @param txt  The text node whose data should be returned
 * @return     A string giving the contents of the text node with
 *             whitespace collapsed.
 */
function dataOf(txt) {
  let data = txt.textContent;
  data = data.replace(/[\t\n\r ]+/g, " ");
  if (data[0] === " ") {
    data = data.substring(1, data.length);
  }
  if (data[data.length - 1] === " ") {
    data = data.substring(0, data.length - 1);
  }
  return data;
}
```

The following code demonstrates the use of the functions above. It iterates over the children of an element (whose children are all elements) to find the one whose text is `"This is the third paragraph"`, and then changes the class attribute and the contents of that paragraph.

```
let cur = firstChild(document.getElementById("test"));
while (cur) {
  if (dataOf(cur.firstChild) === "This is the third paragraph.") {
    cur.className = "magic";
    cur.firstChild.textContent = "This is the magic paragraph.";
  }
  cur = nodeAfter(cur);
}
```

Wrapping and breaking text

This guide explains the various ways in which overflowing text can be managed in CSS.

What is overflowing text?

In CSS, if you have an unbreakable string such as a very long word, by default it will overflow any container that is too small for it in the inline direction. We can see this happening in the example below: the long word is extending past the boundary of the box it is contained in.

```
<div class="box">
  Llanfairpwllgwyngyllgogerychwyrndrobwllllantysiliogogogoch
</div>
```

```
.box {
  border: 4px solid #f76707;
  border-radius: 5px;
  padding: 10px;
  inline-size: 150px;
}
```

CSS will display overflow in this way, because doing something else could cause data loss. In CSS data loss means that some of your content vanishes. So the initial value of `overflow` is `visible`, and we can see the overflowing text. It is generally better to be able to see overflow, even if it is messy. If things were to disappear or be cropped as would happen if `overflow` was set to `hidden` you might not spot it when previewing your site. Messy overflow is at least noticeable, and in the worst case, your visitor will be able to see and read the content even if it looks a bit strange.

In this next example, you can see what happens if `overflow` is set to `hidden`.

```
<div class="box">
  Llanfairpwllgwyngyllgogerychwyrndrobwllllantysiliogogogoch
</div>
```

```
.box {
  border: 4px solid #f76707;
  border-radius: 5px;
  padding: 10px;
  inline-size: 150px;
  overflow: hidden;
}
```

Finding the min-content size

To find the minimum size of the box that will contain its contents with no overflows, set the `width` or `inline-size` property of the box to `min-content`.

```
<div class="box">
  Llanfairpwllgwyngyllgogerychwyrndrobwllllantysiliogogogoch
</div>
```

```
.box {
  border: 4px solid #f76707;
  border-radius: 5px;
  padding: 10px;
  inline-size: min-content;
}
```

Using `min-content` is therefore one possibility for overflowing boxes. If it is possible to allow the box to grow to be the minimum size required for the content, but no bigger, using this keyword will give you that size.

Breaking long words

If the box needs to be a fixed size, or you are keen to ensure that long words can't overflow, then the `overflow-wrap` property can help. This property will break a word once it is too long to fit on a line by itself.

```
<div class="box">
  Llanfairpwllgwyngyllgogerychwyrndrobwllllantysiliogogogoch
</div>
```

```
.box {
  border: 4px solid #f76707;
  border-radius: 5px;
  padding: 10px;
  inline-size: 150px;
  overflow-wrap: break-word;
}
```

> **Note:** The `overflow-wrap` property acts in the same way as the non-standard property `word-wrap`. The `word-wrap` property is now treated by browsers as an alias of the standard property.

An alternative property to try is `word-break`. This property will break the word at the point it overflows. It will cause a break-even if placing the word onto a new line would allow it to display without breaking.

In this next example, you can compare the difference between the two properties on the same string of text.

```
<div class="box box1">A Very LongWordThatHasNoBreakingPossibilities</div>

<div class="box box2">A Very LongWordThatHasNoBreakingPossibilities</div>
```

```
.box {
  border: 4px solid #f76707;
  border-radius: 5px;
  padding: 10px;
  inline-size: 30ch;
  margin-block-end: 1em;
}
.box1 {
  word-break: break-all;
}

.box2 {
  overflow-wrap: break-word;
}
```

This might be useful if you want to prevent a large gap from appearing if there is just enough space for the string. Or, where there is another element that you would not want the break to happen immediately after.

In the example below there is a checkbox and label. Let's say, you want the label to break should it be too long for the box. However, you don't want it to break directly after the checkbox.

```
<div class="field">
  <input id="one" type="checkbox" /><label for="one">
    LongWordThatHasNoBreakingPossibilities
  </label>
</div>

<div class="field field-br">
  <input id="two" type="checkbox" /><label for="two">
    LongWordThatHasNoBreakingPossibilities
  </label>
</div>
```

```
.field {
  inline-size: 150px;
  border: 1px solid #cccccc;
  margin-block-end: 1em;
  padding: 10px;
}

.field-br {
  word-break: break-all;
}
```

Adding hyphens

To add hyphens when words are broken, use the CSS `hyphens` property. Using a value of `auto`, the browser is free to automatically break words at appropriate hyphenation points, following whatever rules it chooses. To have some control over the process, use a value of `manual`, then insert a hard (U+2010) or soft break character (U+00AD) into the string. A hard break character can be added using `-` or `‐`, and a soft break character can be added using the ``, ``, or `` HTML character codes. A hard break will always break, even if it is not necessary to do so. A soft break only breaks if breaking is needed.

```
<div class="box">
  Llanfair&shy;pwllgwyngyll&shy;gogerychwyrndrobwllllantysiliogogogoch
</div>
```

```
.box {
  inline-size: 150px;
  overflow-wrap: break-word;
  hyphens: manual;
  border: 4px solid #f76707;
  border-radius: 5px;
  padding: 10px;
}
```

You can also use the `hyphenate-character` property to use the string of your choice instead of the default hyphenation character at the end of the line (before the hyphenation line break) for the language. The `auto` value selects the correct value to mark a mid-word line break according to the typographic conventions of the current content language.

CSS provides additional hyphenation control: the `hyphenate-limit-chars` property can be used to set the minimum word length that allows for hyphenation as well as the minimum number of characters before and after the hyphen.

The <code><wbr></code> element

If you know where you want a long string to be allowed to break, you can also use the HTML `<wbr>` element. The `<wbr>` element introduces a line break opportunity—if the word overflows, it will wrap at this position. This allows you to preserve meaningful segments in the string, such as long URLs.

In the example below, the browser may break the text at the location of the `<wbr>`.

```
<div class="box">
  Llanfair<wbr />pwllgwyngyll<wbr />gogerychwyrndrobwllllantysiliogogogoch
</div>
```

```
.box {
  border: 4px solid #f76707;
  border-radius: 5px;
  padding: 10px;
  inline-size: 150px;
}
```

CSS text decoration

The **CSS text decoration** module defines features relating to text decoration, such as underlines, text shadows, and emphasis marks. Text decoration features can provide visual cues for spelling errors, grammar issues, and links. These features can help improve the usability, accessibility, functionality, and aesthetics of your text.

By varying the color, style, and thickness of text decoration using pseudo-classes and pseudo-elements, you can highlight the emphasis in text in ways that don't rely on color alone.

Several features can help improve text readability:

- `text-decoration-skip-ink` can increase legibility by skipping descenders.
- `text-underline-offset` enables you to fine-tune the underline placement to better match font metrics or design aesthetics, which can be especially useful for unique typefaces.
- `text-shadow` colors that contrast with text `color` can make the text visually pop when placed on a background with insufficient contrast.

These features all help improve legibility, and therefore, accessibility. Reducing visual noise and improving text clarity is especially helpful for users with dyslexia or low vision.

In the writing systems of some languages, overlines and underlines carry semantic meaning. CSS lets you adapt styling to cultural norms. Text decoration features are especially useful for languages that do not use Latin-based scripts and instead follow different underline placements, such as Japanese and Korean.

Text decoration features also enable you to follow editorial and localization standards that come from print media. For example, with a strikethrough (line-through), you can indicate the status of content. Use it to inform users that content has been removed or that prices have been halved. This feature lets you present both the original and the updated content. Overlines or double underlines are commonly used for academic and editorial annotations.

Text decoration in action

```
p {
  margin: 1em 0;
}
.under {
  text-decoration: underline red;
}

.over {
  text-decoration: wavy overline lime;
}

.line {
  text-decoration: line-through;
}

.underover {
  text-decoration: dashed underline overline;
}

.thick {
  text-decoration: solid underline purple 4px;
  text-underline-offset: -5px;
}
.shadow {
  text-shadow: red 4px 4px 0;
}
.emphasis {
  text-emphasis: triangle red;
}
```

```
<p class="under">A red underline</p>
<p class="over">A wavy lime overlines</p>
<p class="line">This has a line-through it</p>
<p class="underover">This has a dashed underline and overline</p>
<p class="thick">An offset solid purple underline</p>
<p class="shadow">This has a red shadow</p>
<p class="emphasis">Emphasized with red triangles</p>
```

Introduction to text shadows

You can apply shadows to your text by using the `text-shadow` property. This property accepts a comma-separated list of shadow values. Each shadow requires at least two `<length>` values but can include up to three `<length>` values and one `color` value.

```
text-shadow: 1px 3px;
text-shadow: 1px -2px 3px white;
text-shadow:
  5px 5px mediumblue,
  10px 10px magenta,
  15px 15px rebeccapurple;
```

To remove any shadow from the text, use the keyword `none`.

```
text-shadow: none;
```

In this guide, we look at the components of text shadows and how you can apply multiple text shadows to an element.

Components of text shadows

Each shadow includes a horizontal offset, a vertical offset, and an optional blur radius, in that order. You can also define the color of the shadow.

Horizontal offset

The first `<length>` in the value of `text-shadow` represents the horizontal offset of the shadow relative to the original text. Positive values move the shadow to the right, while negative values move it to the left. A value of `0` is a common valid value.

In this example, the different `text-shadow` declarations differ only in their horizontal offsets. The first `<length>` value moves the shadow to the left (`-30px`) or to the right (`30px`).

```
.negative {
  text-shadow: -30px 0 1px red;
}

.positive {
  text-shadow: 30px 0 1px red;
}

.zero {
```

```
  text-shadow: 0 0 1px red;
}
```

```
<p class="negative">Negative</p>
<p class="positive">Positive</p>
<p class="zero">Zero</p>
```

```
p {
  border: 1px solid;
  padding: 20px;
  font-family: sans-serif;
  font-size: 1.25rem;
}
```

You may have noticed that the `text-shadow` property has no effect on the CSS box model, similar to the `outline` property. Just like `box-shadow`, text shadows do not affect layout, do not trigger scrolling, and do not impact the size of the scrollable overflow area. While text shadows can make an element's text appear bigger, they have no actual impact on the width (or height) of content.

Vertical offset

The second `<length>` in the value of `text-shadow` represents the vertical offset of the shadow relative to the original text. This required value behaves similarly to the horizontal offset, except that it moves the shadow up or down rather than left or right.

In this example, the `text-shadow` declarations differ only in their vertical offsets. The second `<length>` value moves the shadow up (`-30px`) or down (`30px`).

```
.negative {
  text-shadow: 0 -30px 1px red;
}

.positive {
  text-shadow: 0 30px 1px red;
}

.zero {
  text-shadow: 0 0 1px red;
}
```

Blur radius

The blur radius is defined by the third `<length>` value and is optional. If omitted, the blur radius is `0`, creating a copy of the text positioned by the first two length values. The value must be `0` or greater; the greater the value, the more widely dispersed the shadow effect will be.

In this example, the `text-shadow` declarations differ only in their blur radii. This third `<length>` value is either invalid (`-5px`), blurs the shadow (`5px`), or creates a copy of the text (`0`).

```
.negative {
  /* invalid */
  text-shadow: 30px 30px -5px red;
}

.positive {
  text-shadow: 30px 30px 5px red;
}

.zero {
  text-shadow: 30px 30px 0 red;
}
```

Shadow color

While you can apply multiple shadows to text, each shadow consists of a single base color. That color can be any valid CSS `color` value, defaulting to `currentcolor` if omitted.

The following three shadows are equivalent in terms of their shadow colors:

```
.shadow-color {
  text-shadow:
    5px 5px mediumblue,
    10px 10px magenta,
    15px 15px rebeccapurple;
}

.shadow-color-hex {
  text-shadow:
    5px 5px #0000cd,
    10px 10px #ff00ff,
    15px 15px #663399;
}

.shadow-color-rgb {
  text-shadow:
    5px 5px rgb(0 0 205),
    10px 10px rgb(255 0 255),
    15px 15px rgb(102 51 153);
}
```

Multiple shadows

You can apply multiple shadows to the same text by including multiple shadow values separated by commas.

The shadow effects are applied front-to-back: the first shadow is on top.

In our example of `text-shadow: 5px 5px mediumblue, 10px 10px magenta, 15px 15px rebeccapurple;`, it defines three shadows, with the blue one on top of the pink, which is on top of the purple:

```
p {
  text-shadow:
    5px 5px mediumblue,
    10px 10px magenta,
    15px 15px rebeccapurple;
}
```

```
<p>I have three shadows</p>
```

Multiple shadows with transparent text

Shadows are painted above any background colors or images and below any borders. While shadows overlay each other, they don't overlay the text. There is no equivalent of the `box-shadow` property's `inset` keyword in the text shadow world. Unlike a box shadow, text shadows are not clipped to the shadowed shape and may show through if the text is partially-transparent.

The following examples apply the same shadows to the text but with different `color` property values. The semi-transparent examples are difficult to read but are included to demonstrate how shadows render:

```
p {
  text-shadow:
    5px 5px 0 mediumblue,
    10px 10px 5px magenta,
    15px 15px 10px rebeccapurple;
}

.opaque {
  color: black;
}

.semitransparent {
  color: rgb(0 0 0 / 0.5);
}

.transparent {
  color: transparent;
}

.white {
  color: white;
}

.semi-white {
  color: rgb(255 255 255 / 0.75);
}
```

```
<p class="opaque">The text is opaque black</p>
<p class="semitransparent">The text is semiopaque black</p>
<p class="transparent">The text is transparent black</p>
<p class="white">The text is opaque white</p>
<p class="semi-white">The text is semiopaque white</p>
```

```
p {
  border: 1px solid black;
  padding: 20px;
  font-family: sans-serif;
  font-size: 1.75rem;
  font-weight: bold;
}
```

In the "transparent" example, the text is transparent but is fully legible because the top shadow is not blurred. Note how the shadow appears behind the text and is visible when the text is less than fully opaque. This is especially noticeable in the "semi-opaque white" example. This behavior differs from non-inset box shadows, where shadows are clipped at the border's outer edge.

CSS transforms

The **CSS transforms** module defines how elements styled with CSS can be transformed in two-dimensional or three-dimensional space.

CSS transforms in action

Use the sliders in the example below to modify the translation, rotation, scale, and skew CSS transform properties of the cube in 3D space. As you move the cube through 3D space, notice the way it interacts with the element labeled `z:0px`, which is located at the 3D position `(0, 0, 0)`.

```
<article>
  <fieldset id="allTransformFieldset">
    <legend>
      Transform settings
      <button id="resetAllButton" aria-label="Reset">↻</button>
    </legend>
    <section id="fieldsetSection">
      <fieldset class="transformFieldset">
        <legend>
          <label>
            <span>Translation</span>
          </label>
          <button
            id="translateSectionReset"
            class="resetSectionButton"
            aria-label="Reset">
            ↻
          </button>
        </legend>
        <div class="controlsContainer">
          <div>
            <label>
              <span id="translateXLabel">X</span>
              <input
                type="range"
                min="-100"
                max="100"
                value="0"
                data-default="0"
                id="translateXRange"
                aria-labelledby="translateXLabel" />
            </label>
            <output id="translateXOutput" for="translateXRange"></output>
          </div>
          <div>
            <label>
              <span id="translateYLabel">Y</span>
```

```
          <input
            type="range"
            min="-100"
            max="100"
            value="0"
            data-default="0"
            id="translateYRange"
            aria-labelledby="translateYLabel" />
        </label>
        <output id="translateYOutput" for="translateYRange"></output>
      </div>
      <div>
        <label>
          <span id="translateZLabel">Z</span>
          <input
            type="range"
            min="-100"
            max="100"
            value="0"
            data-default="0"
            id="translateZRange"
            aria-labelledby="translateZLabel" />
        </label>
        <output id="translateZOutput" for="translateZRange"></output>
      </div>
    </div>
  </fieldset>

  outputContainer.style.perspective = `${perspectiveRange.value}px`;
  outputContainer.style.perspectiveOrigin = `${perspectiveOriginXRange.value}% ${perspectiveOriginYRange.value}%`;

  perspectiveDot.style.top = `${perspectiveOriginYRange.value}%`;
  perspectiveDot.style.left = `${perspectiveOriginXRange.value}%`;
}
updateTransform();
```

You can also use the `perspective` slider to modify the `perspective` property of the cube's container, which determines the distance between you and the `z=0` plane.

The `perspective-origin` sliders determine where you, the viewer, are looking into the 3D space for purposes of determining the view's *vanishing point*. This vanishing point is indicated by a small red dot. You can imagine modifying these sliders as physically moving your head up, down, left, and right to see different parts of the cube without moving the cube itself.

The `backface-visibility` checkbox determines whether the cube's back faces are set to `visible` or `hidden`.

The cube in the above example is comprised of six `<div>` elements, all of which are styled with CSS to create the cube's faces. The cube is not drawn using a 2D or 3D canvas context, so **you can inspect the faces of the cube with your browser's developer tools as you would inspect any other DOM element**. Try using your browser's developer tools element picker to inspect different faces of the cube as you transform its position and rotation.

> **Note:** The order in which transformations, including 3D rotations, are applied affects the resultant transformation. In the above example, transforms are translated, scaled, rotated, then skewed. The rotations are applied in the order X → Y → Z.

Using CSS transforms

By modifying the coordinate space, **CSS transforms** change the shape and position of the affected content without disrupting the normal document flow. This guide provides an introduction to using transforms.

CSS transforms are implemented using a set of CSS properties that let you apply affine linear transformations to HTML elements. These transformations include rotation, skewing, scaling, and translation both in the plane and in the 3D space.

> **Warning:** Only transformable elements can be `transformed`; that is, all elements whose layout is governed by the CSS box model except for: non-replaced inline boxes, table-column boxes, and table-column-group boxes.

CSS transforms properties

Two major properties are used to define CSS transforms: `transform` (or the individual `translate`, `rotate`, and `scale` properties) and `transform-origin`.

`transform-origin`

: Specifies the position of the origin. By default, it is at the center of the element and can be moved. It is used by several transforms, like rotations, scaling or skewing, that need a specific point as a parameter.

`transform`

: Specifies the transforms to apply to the element. It is a space-separated list of transforms, which are applied one after the other, as requested by the composition operation. Composite transforms are effectively applied in order from right to left.

Examples

Here is an unaltered image of the MDN logo:

Rotating

Here is the MDN logo rotated 90 degrees from its bottom-left corner.

```
<img src="logo.png" alt="MDN Logo" />
```

```
img {
  rotate: 90deg;
  transform-origin: bottom left;
}
```

Skewing and translating

Here is the MDN logo, skewed by 10 degrees and translated by 150 pixels on the X-axis.

```
<img src="logo.png" alt="MDN logo" />
```

```
img {
  transform: skewX(10deg) translateX(150px);
  transform-origin: bottom left;
}
```

3D specific CSS properties

Performing CSS transformations in 3D space is a bit more complex. You have to start by configuring the 3D space by giving it a perspective, then you have to configure how your 2D elements will behave in that space.

Perspective

The first element to set is the `perspective`. The perspective is what gives us the 3D impression. The farther from the viewer the elements are, the smaller they are.

Setting perspective

This example shows a cube with the perspective set at different positions. How quick the cube shrinks is defined by the `perspective` property. The smaller its value is, the deeper the perspective is.

HTML

The HTML below creates four copies of the same box, with the perspective set at different values.

```
<table>
  <tbody>
    <tr>
      <th><code>perspective: 250px;</code></th>
      <th><code>perspective: 350px;</code></th>
    </tr>
    <tr>
      <td>
        <div class="container">
          <div class="cube perspective-250">
            <div class="face front">1</div>
            <div class="face back">2</div>
            <div class="face right">3</div>
            <div class="face left">4</div>
            <div class="face top">5</div>
            <div class="face bottom">6</div>
          </div>
        </div>
      </td>
```

```
      <td>
        <div class="container">
          <div class="cube perspective-350">
            <div class="face front">1</div>
            <div class="face back">2</div>
            <div class="face right">3</div>
            <div class="face left">4</div>
            <div class="face top">5</div>
            <div class="face bottom">6</div>
          </div>
        </div>
      </td>
    </tr>
    <tr>
      <th><code>perspective: 500px;</code></th>
      <th><code>perspective: 650px;</code></th>
    </tr>
    <tr>
      <td>
        <div class="container">
          <div class="cube perspective-500">
            <div class="face front">1</div>
            <div class="face back">2</div>
            <div class="face right">3</div>
            <div class="face left">4</div>
            <div class="face top">5</div>
            <div class="face bottom">6</div>
          </div>
        </div>
      </td>
      <td>
        <div class="container">
          <div class="cube perspective-650">
            <div class="face front">1</div>
            <div class="face back">2</div>
            <div class="face right">3</div>
            <div class="face left">4</div>
            <div class="face top">5</div>
            <div class="face bottom">6</div>
          </div>
        </div>
      </td>
    </tr>
  </tbody>
</table>
```

CSS

The CSS establishes classes that can be used to set the perspective to different distances. It also includes classes for the container box and the cube itself, as well as each of its faces.

```
/* Shorthand classes for different perspective values */
.perspective-250 {
  perspective: 250px;
}

.perspective-350 {
  perspective: 350px;
}

.perspective-500 {
  perspective: 500px;
}

.perspective-650 {
  perspective: 650px;
}

/* Define the container div, the cube div, and a generic face */
.container {
  width: 200px;
  height: 200px;
  margin: 75px 0 0 75px;
  border: none;
}

.cube {
  width: 100%;
  height: 100%;
  perspective-origin: 150% 150%;
  transform-style: preserve-3d;
}

.face {
  display: block;
  position: absolute;
  width: 100px;
  height: 100px;
  border: none;
  line-height: 100px;
  font-family: sans-serif;
  font-size: 60px;
  color: white;
  text-align: center;
  backface-visibility: visible;
}

/* Define each face based on direction */
.front {
  background: rgb(0 0 0 / 30%);
  transform: translateZ(50px);
}

.back {
```

```
  background: lime;
  color: black;
  transform: rotateY(180deg) translateZ(50px);
}

.right {
  background: rgb(196 0 0 / 70%);
  transform: rotateY(90deg) translateZ(50px);
}

.left {
  background: rgb(0 0 196 / 70%);
  transform: rotateY(-90deg) translateZ(50px);
}

.top {
  background: rgb(196 196 0 / 70%);
  transform: rotateX(90deg) translateZ(50px);
}

.bottom {
  background: rgb(196 0 196 / 70%);
  transform: rotateX(-90deg) translateZ(50px);
}

/* Make the table a little nicer */
th,
p,
td {
  background-color: #eeeeee;
  padding: 10px;
  font-family: sans-serif;
  text-align: left;
}
```

Result

The second element to configure is the position of the viewer, with the `perspective-origin` property. By default the perspective is centered on the viewer, which is not always adequate.

Changing the perspective origin

This example shows cubes with popular `perspective-origin` values.

HTML

```
<section>
  <figure>
    <figcaption><code>perspective-origin: top left;</code></figcaption>
    <div class="container">
      <div class="cube po-tl">
        <div class="face front">1</div>
        <div class="face back">2</div>
        <div class="face right">3</div>
        <div class="face left">4</div>
        <div class="face top">5</div>
        <div class="face bottom">6</div>
      </div>
    </div>
  </figure>

  <figure>
    <figcaption><code>perspective-origin: top;</code></figcaption>
    <div class="container">
      <div class="cube po-tm">
        <div class="face front">1</div>
        <div class="face back">2</div>
        <div class="face right">3</div>
        <div class="face left">4</div>
        <div class="face top">5</div>
        <div class="face bottom">6</div>
      </div>
    </div>
  </figure>

CSS transitions

The **CSS transitions** module specifies functionality for creating gradual transitions between different CSS property values. The behavior of these transitions can be controlled by specifying their easing function, duration, and other values.

Normally, when the value of a CSS property changes, the result of the change from the old value to the new value is immediate. The CSS transitions module enables controlling a progression from the old property state to the new state over a specified period of time. It also provides event handlers to allow code to be run in response to different stages of a transition being reached.

In certain cases, there is no originating "from" value for a transition. For example, if an element gets added to the DOM, the styles defined are for the "to" state. This module provides the `@starting-style` at-rule, which enables defining starting styles for such cases. The module also defines how discrete property values should be transitioned, such as transitioning the discretely animated `display` property from the `none` value to a displayed value.

Using CSS transitions

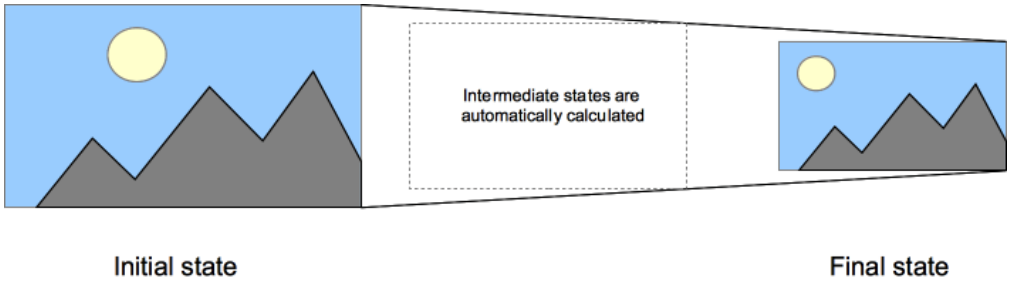
CSS transitions provide a way to control animation speed when changing CSS properties. Instead of having property changes take effect immediately, you can cause the changes in a property to take place over a period of time. For example, if you change the color of an element from white to black, usually the change is instantaneous. With CSS transitions enabled, changes occur at time intervals that follow an acceleration curve, all of which can be customized.

Animations that involve transitioning between two states are often called *implicit transitions* as the states in between the start and final states are implicitly defined by the browser.



CSS transitions let you decide which properties to animate (by *listing them explicitly*), when the animation will start (by setting a *delay*), how long the transition will last (by setting a *duration*), and how the transition will run (by defining an *easing function*, e.g., linearly or quick at the beginning, slow at the end).

Which CSS properties can be transitioned?

The Web author can define which property has to be animated and in which way. This allows the creation of complex transitions. However, some properties are not animatable as it doesn't make sense to animate them.

> **Note:** The `auto` value is often a very complex case. The specification recommends not animating from and to `auto`. Some user agents, like those based on Gecko, implement this requirement and others, like those based on WebKit, are less strict. Using animations with `auto` may lead to unpredictable results, depending on the browser and its version, and should be avoided.

Defining transitions

CSS Transitions are controlled using the shorthand `transition` property. This is the best way to configure transitions, as it makes it easier to avoid out of sync parameters, which can be very frustrating to have to spend lots of time debugging in CSS.

You can control the individual components of the transition with the following sub-properties:

`transition-property`

: Specifies the name or names of the CSS properties to which transitions should be applied. Only properties listed here are animated during transitions; changes to all other properties occur instantaneously as usual.

`transition-duration`

: Specifies the duration over which transitions should occur. You can specify a single duration that applies to all properties during the transition, or multiple values to allow each property to transition over a different period of time.

`transition-timing-function`

: Specifies a function to define how intermediate values for properties are computed. *Easing functions* determine how intermediate values of the transition are calculated. Most easing functions can be specified by providing the graph of the corresponding function, as defined by four points defining a cubic bezier. You can also choose easing from Easing functions cheat sheet.

`transition-delay`

: Defines how long to wait between the time a property is changed and the transition actually begins.

The `transition` shorthand CSS syntax is written as follows:

```
transition: <property> <duration> <timing-function> <delay>;
```

Examples

Basic example

This example performs a four-second font size transition with a two-second delay between the time the user mouses over the element and the beginning of the animation effect:

```
#delay {
  font-size: 14px;
  transition-property: font-size;
  transition-duration: 4s;
  transition-delay: 2s;
}

#delay:hover {
  font-size: 36px;
}
```

Multiple animated properties example

```
<body>
  <p>
    The box below combines transitions for: width, height, background-color,
    rotate. Hover over the box to see these properties animated.
  </p>
  <div class="box">Sample</div>
</body>
```

CSS

```
.box {
  border-style: solid;
  border-width: 1px;
  display: block;
  width: 100px;
  height: 100px;
  background-color: blue;
  transition:
    width 2s,
    height 2s,
    background-color 2s,
    rotate 2s;
}

.box:hover {
  background-color: #ffcccc;
  width: 200px;
  height: 200px;
  rotate: 180deg;
}
```

When property value lists are of different lengths

If any property's list of values is shorter than the others, its values are repeated to make them match. For example:

```
div {
  transition-property: opacity, left, top, height;
  transition-duration: 3s, 5s;
}
```

This is treated as if it were:

```
div {
  transition-property: opacity, left, top, height;
  transition-duration: 3s, 5s, 3s, 5s;
}
```

Similarly, if any property's value list is longer than that for `transition-property`, it's truncated, so if you have the following CSS:

```
div {
  transition-property: opacity, left;
  transition-duration: 3s, 5s, 2s, 1s;
}
```

This gets interpreted as:

```
div {
  transition-property: opacity, left;
  transition-duration: 3s, 5s;
}
```

Using transitions when highlighting menus

A common use of CSS is to highlight items in a menu as the user hovers the mouse cursor over them. It's easy to use transitions to make the effect even more attractive.

First, we set up the menu using HTML:

```
<nav>
  <a href="#">Home</a>
  <a href="#">About</a>
  <a href="#">Contact Us</a>
  <a href="#">Links</a>
</nav>
```

Then we build the CSS to implement the look and feel of our menu:

```
nav {
  display: flex;
  gap: 0.5rem;
```

```
}

a {
  flex: 1;
  background-color: #333333;
  color: white;
  border: 1px solid;
  padding: 0.5rem;
  text-align: center;
  text-decoration: none;
  transition: all 0.5s ease-out;
}

a:hover,
a:focus {
  background-color: white;
  color: #333333;
}
```

This CSS establishes the look of the menu, with the background and text colors both changing when the element is in its `:hover` and `:focus` states:

Transitioning display and content-visibility

This example demonstrates how `display` and `content-visibility` can be transitioned. This behavior is useful for creating entry/exit animations where you want to for example remove a container from the DOM with `display: none`, but have it fade out with `opacity` rather than disappearing immediately.

Supporting browsers transition `display` and `content-visibility` with a variation on the discrete animation type. This generally means that properties will flip between two values 50% through animating between the two.

There is an exception, however, which is when animating to/from `display: none` or `content-visibility: hidden`. In this case, the browser will flip between the two values so that the transitioned content is shown for the entire animation duration.

So for example:

- When animating `display` from `none` to `block` (or another visible `display` value), the value will flip to `block` at `0%` of the animation duration so it is visible throughout.
- When animating `display` from `block` (or another visible `display` value) to `none`, the value will flip to `none` at `100%` of the animation duration so it is visible throughout.

When transitioning these properties `transition-behavior: allow-discrete` needs to be set on the transitions. This effectively enables `display`/`content-visibility` transitions.

When transitioning `display`, `@starting-style` is needed to provide a set of starting values for properties set on an element that you want to transition from when the element receives its first style update. This is needed to avoid unexpected behavior. By default, CSS transitions are not triggered on elements' first style updates when they first appear in the DOM, which includes when `display` changes from `none` to another state. `content-visibility` animations do not need starting values specified in a `@starting-style` block. This is because `content-visibility` doesn't hide an element from the DOM like `display` does: it just skips rendering the element's content.

HTML

The HTML contains two `<p>` elements with a `<div>` in between that we will animate from `display none` to `block`.

```
<p>
  Click anywhere on the screen or press any key to toggle the
  <code>&lt;div&gt;</code> between hidden and showing.
</p>

<div>
  This is a <code>&lt;div&gt;</code> element that transitions between
  <code>display: none; opacity: 0</code> and
  <code>display: block; opacity: 1</code>. Neat, huh?
</div>

<p>
  This is another paragraph to show that <code>display: none;</code> is being
  applied and removed on the above <code>&lt;div&gt; </code>. If only its
  <code>opacity</code> was being changed, it would always take up the space in
  the DOM.
</p>
```

CSS

```
html {
  height: 100vh;
}

div {
  font-size: 1.6rem;
  padding: 20px;
  border: 3px solid red;
  border-radius: 20px;
  width: 480px;

  display: none;
  opacity: 0;
  transition:
    opacity 1s,
    display 1s allow-discrete;
  /* Equivalent to
  transition: all 1s allow-discrete; */
}

.showing {
  opacity: 1;
  display: block;
}

@starting-style {
  .showing {
    opacity: 0;
  }
}
```

Note the `@starting-style` block used to specify the starting style for the transition, and the inclusion of the `display` property in the transitions list, with `allow-discrete` set on it.

JavaScript

Finally, we include a bit of JavaScript to set up event listeners to trigger the transition (via the `showing` class).

```
const divElem = document.querySelector("div");
const htmlElem = document.querySelector(":root");

htmlElem.addEventListener("click", showHide);
document.addEventListener("keydown", showHide);

function showHide() {
  divElem.classList.toggle("showing");
}
```

Result

The code renders as follows:

JavaScript examples

> **Note:** Care should be taken when using a transition immediately after:
>
> - adding the element to the DOM using `.appendChild()`
> - removing an element's `display: none;` property.
>
> This is treated as if the initial state had never occurred and the element was always in its final state. One way to overcome this limitation is to apply a `setTimeout()` of a handful of milliseconds before changing the CSS property you intend to transition to.

Using transitions to make JavaScript functionality smooth

Transitions are a great tool to make things look much smoother without having to do anything to your JavaScript functionality. Take the following example.

```
<p>Click anywhere to move the ball</p>
<div id="foo" class="ball"></div>
```

```
// Make the ball move to a certain position:
const f = document.getElementById("foo");
document.addEventListener("click", (ev) => {
  f.style.transform = `translateY(${ev.clientY - 25}px)`;
  f.style.transform += `translateX(${ev.clientX - 25}px)`;
});
```

With CSS, you can smooth the styles applied through JavaScript. Add a transition to the element and any change will happen smoothly:

```
body {
  background-color: white;
  color: #333333;
  font:
    1.2em / 1.5 "Helvetica Neue",
    "Helvetica",
    "Arial",
    sans-serif;
  padding: 0;
  margin: 0;
}

p {
  margin-top: 3em;
}

main {
  box-sizing: border-box;
  display: flex;
  justify-content: center;
  align-items: center;
  max-width: 660px;
  height: 400px;
  border: 1px solid #cccccc;
  padding: 20px;
}
```

```
.ball {
  border-radius: 25px;
  width: 50px;
  height: 50px;
  background: #cc0000;
  position: absolute;
  top: 0;
  left: 0;
  transition: transform 1s;
}
```

Detecting the start and completion of a transition

You can use the `transitionend` event to detect that an animation has finished running. This is a `TransitionEvent` object, which has two added properties beyond a typical `Event` object:

`propertyName`

A string indicating the name of the CSS property whose transition completed.

`elapsedTime`

A float indicating the number of seconds the transition had been running at the time the event fired. This value isn't affected by the value of `transition-delay`.

As usual, you can use the `addEventListener()` method to monitor for this event:

```
el.addEventListener("transitionend", updateTransition);
```

You detect the beginning of a transition using `transitionrun` (fires before any delay) and `transitionstart` (fires after any delay), in the same kind of fashion:

```
el.addEventListener("transitionrun", signalStart);
el.addEventListener("transitionstart", signalStart);
```

> **Note:** The `transitionend` event doesn't fire if the transition is aborted before the transition is completed because either the element is made `display: none` or the animating property's value is changed.

CSS values and units

Every CSS declaration consists of a property/value pair. The value can take various forms depending on the property, such as a single integer, keyword, function, or a combination of different items; some values have units, while others do not. Every property also accepts the CSS-wide values. The CSS values and units module defines the data types — values and units — that CSS properties accept. This module also defines the CSS value definition syntax, or formal grammar, used to define the set of valid values for every CSS property and function.

> **Note:** This page introduces a CSS module. To find an exhaustive list of all values, types, and functions defined by CSS specifications, see the values reference page.

- `sibling-index()`
- `sign()`
- `sin()`
- `sqrt()`
- `tan()`
- `url()`

The CSS values and units module also introduces the `calc-mix()`, `first-valid()`, `integrity()`, `random-item()`, `src()`, `type()`, and `toggle()` functions. Currently, no browsers support these features.

Data types

- `<angle-percentage>`
- `<angle>`
- `<attr-name>`
- `<attr-type>`
- `<calc-keyword>` (`e`, `pi`, `infinity`, NaN)
- `<calc-size-basis>`
- `<calc-sum>`
- `<custom-ident>`
- `<dashed-ident>`
- `<dimension>`
- `<easing-function>`
- `<ident>`
- `<integer>`
- `<length-percentage>`
- `<length>`
- `<number>`
- `<percentage>`
- `<position>`
- `<ratio>`
- `<resolution>`
- `<rounding-strategy>` (`down`, `up`, `to-zero`)
- `<string>`

- `<syntax>`
- `<time-percentage>`
- `<time>`
- `<url>`
- `<url-modifier>`

The CSS values and units module also introduces the `<frequency>` and `<frequency-percentage>` data types. Currently, no browsers support these features.

Units

- `%` (percentage)
- `cap`
- `ch`
- `cm`
- `deg`
- `dpcm`
- `dpi`
- `dppx`
- `dvb`
- `dvh`
- `dvi`
- `dvmax`
- `dvmin`
- `dvw`
- `em`
- `ex`
- `grad`
- `Hz`
- `ic`
- `in`
- `kHz`
- `lh`
- `lvb`
- `lvh`
- `lvi`
- `lvmax`
- `lvmin`
- `lvw`
- `mm`
- `ms`
- `pc`
- `pt`
- `px`
- `Q`
- `rad`
- `rcap`
- `rch`
- `rem`
- `rex`
- `ric`
- `rlh`
- `s`
- `svb`
- `svh`
- `svi`
- `svmax`
- `svmin`
- `svw`
- `turn`
- `vb`
- `vh`
- `vi`
- `vmax`
- `vmin`
- `vw`
- `x`

Flex units (`fr`) and container units (`cqb`, `cqh`, `cqi`, `cqmax`, `cqmin`, `cqw`) are defined in the CSS grid layout and CSS conditional rules modules, respectively.

Unit categorizations

- Absolute length units (`cm`, `in`, `mm`, `pc`, `pt`, `px`, `Q`)
- Angle units (`deg`, `grad`, `rad`, `turn`)
- Default viewport units (`vb` , `vh`, `vi` , `vmax`, `vmin`, `vw`)
- Dynamic viewport units (`dvb`, `dvh`, `dvi`, `dvmax`, `dvmin`, `dvw`)
- Frequency units (`Hz`, `kHz`)
- Large viewport-percentage units (`lvb`, `lvh`, `lvi`, `lvmax`, `lvmin`, `lvw`)
- Local font-relative length units (`cap`, `ch`, `em`, `ex`, `ic`, `lh`)
- Physical units (`cm`, `in`, `mm`, `pc`, `pt`, `Q`)
- Relative length units (`cap`, `ch`, `em`, `ex`, `ic`, `lh`, `rem`, `rlh`, `vb`, `vh`, `vi`, `vmax`, `vmin`, `vw`)
- Resolution units (`dpcm`, `dpi` , `dppx`, `x`)
- Root font-relative length units (`rcap`, `rch`, `rem`, `rex`, `ric`, `rlh`)
- Small viewport-percentage unit (`svb`, `svh`, `svi`, `svmax`, `svmin`, `svw`)
- Time units (`ms`, `s`)
- Viewport units (`dvh`, `dvw`, `lvh`, `lvw`, `svh`, `svw`, `vb` , `vh`, `vi` , `vmax`, `vmin`, `vw`)
- Visual angle unit (`px`)

Numeric data types

Every CSS declaration consists of a property/value pair. The value can include various data types depending on the property, such as a single number, keyword, function, or a combination of different types; some values have units, while others do not. Numeric data types include `<integer>`, `<number>`, `<dimension>`, and `<percentage>` values. This guide is an overview of numeric data types. Refer to the page for each value type for more detailed information.

Integers

An integer is one or more decimal digits, `0` through `9`, such as `1024` or `-55`. An integer may be preceded by a `+` or `-` symbol, with no space between the symbol and the integer.

Numbers

A `<number>` represents a real number, which may or may not have a decimal point with a fractional component, for example `0.255`, `128` or `-1.2`. Numbers may also be preceded by a `+` or `-` symbol.

Dimensions

A `<dimension>` is a `<number>` with a unit attached to it, for example `45deg`, `100ms`, or `10px`. The attached unit identifier is case insensitive. There is never a space or any other characters between the number and the unit identifier: i.e., `1 cm` is not valid.

CSS uses dimensions to specify:

- `<length>` (Distance units)
- `<angle>`
- `<time>`
- `<frequency>`
- `<flex>`
- `<resolution>`

These are all covered in subsections below.

Distance units

Where a distance unit, also known as a length, is allowed as a value for a property, this is described as the `<length>` type. There are two types of lengths in CSS: relative and absolute. Relative length units specify a length in relation to something else.

There are two types of relative lengths: font-relative lengths and viewport-percentage lengths. These both come in two types. Font-relative length units are either local font-relative or root font-relative. Viewport percentage lengths are either relative to the viewport height or width size or, as defined in the CSS Containment module, relative to a container.

Local font-relative lengths

Local font-relative lengths are relative to the "local" font size or line height, specifying a length in relation to a computed size of a feature of the element itself, or relative to the element's inherited value in the case of a circular reference, such as the `em` value for a `font-size` property or a `lh` value for a `line-height` property. For example, `em` is relative to the font size on the element and `ex` is relative to the x-height of the element's font.

Unit	Relative to
`cap`	Cap height (the nominal height of capital letters) of the element's font.
`ch`	Average character advance of a narrow glyph in the element's font, as represented by the "0" (ZERO, U+0030) glyph.
`em`	Font size of the element's font.
`ex`	x-height of the element's font.
`ic`	Average character advance of a full-width glyph in the element's font, as represented by the "水" (CJK water ideograph, U+6C34) glyph.
`lh`	Line height of the element.

Root font-relative lengths

Root font-relative lengths specify a length in relation to the element's root element ancestor, such as `<HTML>` or `<SVG>`. For example, `rem` is relative to the font size on the root element and `rex` is the x-height of the root element's font.

Unit	Relative to
`rcap`	Cap height (the nominal height of capital letters) of the root element's font.
`rch`	Average character advance of a narrow glyph in the root element's font, as represented by the "0" (ZERO, U+0030) glyph.
`rem`	Font size of the root element's font.
`rex`	x-height of the root element's font.
`ric`	Average character advance of a full-width glyph in the root element's font, as represented by the "水" (CJK water ideograph, U+6C34) glyph.
`rlh`	Line height of the root element.

Viewport units

Viewport unit lengths specify a length relative to the dimensions of the viewport. For example, `vw` is relative to the width of the viewport and `vh` is relative to the height of the viewport.

Unit	Relative to
`dvh`	1% of the dynamic viewport's height.
`dvw`	1% of the dynamic viewport's width.
`lvh`	1% of the large viewport's height.
`lvw`	1% of the large viewport's width.
`svh`	1% of the small viewport's height.
`svw`	1% of the small viewport's width.
`vb`	1% of viewport's size in the root element's block axis.
`vh`	1% of viewport's height.
`vi`	1% of viewport's size in the root element's inline axis.
`vmax`	1% of viewport's larger dimension.
`vmin`	1% of viewport's smaller dimension.
`vw`	1% of viewport's width.

Container units

Container query length units specify a length relative to the dimensions of a query container. For example, `cqw` is relative to the width of the query container and `cqh` is relative to the height of the query container.

Unit	Relative to
`cqb`	1% of a query container's block size
`cqh`	1% of a query container's height
`cqi`	1% of a query container's inline size
`cqmax`	The larger value of `cqi` or `cqb`
`cqmin`	The smaller value of `cqi` or `cqb`
`cqw`	1% of a query container's width

Absolute length units

Absolute length units are fixed to a physical length: either an inch or a centimeter. Many of these units are therefore more useful when the output is a fixed size media, such as print. For example, `mm` is a physical millimeter, 1/10th of a centimeter.

Unit	Name	Equivalent to
`cm`	Centimeters	1cm = 96px/2.54
`in`	Inches	1in = 2.54cm = 96px
`mm`	Millimeters	1mm = 1/10th of 1cm
`pc`	Picas	1pc = 1/6th of 1in
`pt`	Points	1pt = 1/72th of 1in
`px`	Pixels	1px = 1/96th of 1in
`Q`	Quarter-millimeters	1Q = 1/40th of 1cm

When including a length value, if the length is `0`, the unit identifier is not required. Otherwise, the unit identifier is required, is case insensitive, and must come immediately after the numeric part of the value, with no space in-between.

Angle units

Angle values are represented by the type `<angle>` and accept the following values:

Unit	Name	Description
`deg`	Degrees	There are 360 degrees in a full circle.
`grad`	Gradians	There are 400 gradians in a full circle.
`rad`	Radians	There are 2π radians in a full circle.
`turn`	Turns	There is 1 turn in a full circle.

Time units

Time values are represented by the type `<time>`. When including a time value, the unit identifier — the `s` or `ms` — is required. It accepts the following values.

Unit	Name	Description
`ms`	Milliseconds	There are 1,000 milliseconds in a second.
`s`	Seconds	

Frequency units

Frequency values are represented by the type `<frequency>`. It accepts the following values.

Unit	Name	Description
`Hz`	Hertz	Represents the number of occurrences per second.
`kHz`	KiloHertz	A kiloHertz is 1000 Hertz.

`1Hz`, which can also be written as `1hz` or `1HZ`, is one cycle per second.

Flex units

Flex units are represented by the type `<flex>`. It accepts the following value.

Unit	Name	Description
`fr`	Flex	Represents a flexible length within a grid container

Resolution units

Resolution units are represented by the type `<resolution>`. They represent the size of a single dot in a graphical representation, such as a screen, by indicating how many of these dots fit in a CSS inch, centimeter, or pixel. It accepts the following values:

Unit	Description
`dpcm`	Dots per centimeter.
`dpi`	Dots per inch.
`dppx`, `x`	Dots per px unit.

Percentages

A `<percentage>` is a type that represents a fraction of some other value.

Percentage values are always relative to another quantity, for example a length. Each property that allows percentages also defines the quantity to which the percentage refers. This quantity can be a value of another property of the same element, the value of a property of an ancestor element, a measurement of a containing block, or something else.

As an example, if you specify the `width` of a box as a percentage, it refers to the percentage of the box's parent's computed width:

```
.box {
  width: 50%;
```

```
}
```

Mixing percentages and dimensions

Some properties accept a dimension that could be either one of two types, for example a `<length>` **or** a `<percentage>`. In this case the allowed value is detailed in the specification as a combination unit, e.g., `<length-percentage>`. Other possible combinations are as follows:

- `<frequency-percentage>`
- `<angle-percentage>`
- `<time-percentage>`

Special data types (defined in other specs)

- `<color>`
- `<image>`
- `<position>`

Color

The `<color>` value specifies the color of an element feature (e.g., its background color), and is defined in the CSS Color Module.

Image

The `<image>` value specifies all the different types of image that can be used in CSS, and is defined in the CSS Image Values and Replaced Content Module.

Position

The `<position>` type defines 2D positioning of an object inside a positioning area, for example a background image inside a container. This type is interpreted as a `background-position` and therefore specified in the CSS Backgrounds and Borders specification.

Functional notation

- `calc()`
- `min()`
- `max()`
- `minmax()`
- `clamp()`
- `attr()`

Functional notation is a type of value that can represent more complex types or invoke special processing by CSS. The syntax starts with the name of the function immediately followed by a left parenthesis `(` followed by the argument(s) to the notation followed by a right parenthesis `)`. Functions can take multiple arguments, which are formatted similarly to a CSS property value.

White space is allowed, but optional inside the parentheses. (But see notes regarding whitespace within pages for `min()`, `max()`, `minmax()`, and `clamp()` functions.)

Some legacy functional notations, such as legacy syntax for `rgb()`, `rgba()`, `hsl()`, and `hsla()`, used commas, but commas are generally only used to separate items in a list. If a comma is used to separate arguments, white space is optional before and after the comma.

The spec also defines the `toggle()` function. It has not been implemented anywhere yet.

Textual data types

Every CSS declaration consists of a property/value pair. The value can include various data types depending on the property, such as a single keyword, integer, function, or a combination of different types; some values have units, while others do not. This guide provides an overview of the textual data types. Refer to the page for each value type for more detailed information.

Text data types are either `<string>`, a quoted series of characters, an `<ident>`, a "CSS Identifier" which is an unquoted string, or an optionally quoted `<url>`. A `<string>` is quoted with either single or double quotes. CSS identifiers, listed in the specifications as `<ident>` or `<custom-ident>`, must be unquoted.

In CSS specifications, values that can be defined by the web developer — such as keyframe animation names, font-family names, or grid areas — are listed as a `<custom-ident>`, `<string>`, or both.

When both quoted and unquoted user-defined text values are permitted, the specification will list `<custom-ident> | <string>`, meaning quotes are optional, such as is the case with [keyframe animation names]:

```
@keyframes validIdent {
  /* keyframes go here */
}
@keyframes 'validString' {
  /* keyframes go here */
}
```

Some text values are not valid if encompassed in quotes. For example, the value of `grid-area` can be a `<custom-ident>`, so if we had a grid area named `content` we would use it without quotes:

```
.item {
  grid-area: content;
}
```

In comparison, a data type that is a `<string>`, such as a string value of the `content` property, must be quoted:

```
.item::after {
  content: "This is my content.";
}
```

While you can generally create any name you want, including using emojis, the identifier can't be `none`, `unset`, `initial`, or `inherit`, start with a digit or two dashes, and generally you don't want it to be any other pre-defined CSS keyword. See the `<custom-ident>` and `<string>` reference pages for more details.

Pre-defined keyword values

Pre-defined keywords are text values defined by the specification for that property. These keywords are also CSS identifiers, and are therefore used without quotes.

When viewing CSS property value syntax in a CSS specification or the MDN property page, allowable keywords will be listed in the following form. The following enumerated values are the pre-defined keyword values allowed for `float`.

```
left | right | none | inline-start | inline-end
```

Such values are used without quotes:

```
.box {
  float: left;
}
```

CSS-wide keywords

In addition to the pre-defined keywords that are part of the specification for a property, all CSS properties accept the CSS-wide, or "global", property values `initial`, `inherit`, `unset`, `revert`, and `revert-layer`, which explicitly specify defaulting behaviors.

`initial`

Represents the value specified as the property's initial value.

`inherit`

Represents the computed value of the property on the element's parent, provided it is inherited.

`unset`

Acts as either `inherit` or `initial`, depending on whether the property is inherited or not.

`revert`

Resets the property to its inherited value if it inherits from its parent or to the default value established by the user agent's stylesheet (or by user styles if any exist).

`revert-layer`

Rolls back the value of a property in a cascade layer to the value of the property in a CSS rule matching the element in a previous cascade layer. The value of the property with this keyword is recalculated as if no rules were specified on the target element in the current cascade layer.

URLs

A `<url>` type uses functional notation, which accepts a `<string>` that is a URL. This may be an absolute URL or a relative URL. For example, if you wanted to include a background image, you might use either of the following:

```
.box {
  background-image: url("images/my-background.png");
}

.box {
  background-image: url("https://www.exammple.com/images/my-background.png");
}
```

The parameter for `url()` can be either quoted or unquoted. If unquoted, it is parsed as a `<url-token>`, which has extra requirements including escaping certain characters. See `<url>` for more information.

Using CSS math functions

CSS math functions allow a property value - such as the `height`, `animation-duration`, or `font-size` of an element - to be written as a mathematical expression.

Without using any math, the built-in CSS units like `rem`, `vw`, and `%` are often flexible enough to style HTML elements to achieve a particular user experience.

However, there are cases where we might feel limited by expressing an element's style using a single value and unit. Consider the following examples:

1. We want to set the height of a content area to be "the height of the viewport minus the height of a navbar."
2. We want to add the width of two elements together to define the width of a third element.
3. We want to prevent a variable `font-size` of some text from growing beyond a certain size.

In all of these cases, we need to rely on math to achieve the desired outcomes. One solution could be to rely on mathematical functions defined by JavaScript, and dynamically set element styles based on results calculated by our scripts.

In many instances, including in the examples above, **we can instead utilize math functions built directly into CSS**. This solution is often simpler to implement and faster for the browser to execute than using JavaScript.

In total, developers can use a combination of nearly two dozen CSS math functions in their stylesheets. In this guide, we'll exemplify four of the more commonly-used, and introduce those more advanced.

<code>calc()</code>: Basic math operations

In the first two of our three examples above, we want to set the style of an element according to the result of an addition or subtraction operation. This is exactly one of the use cases for `calc()`.

The **`calc()`** function lets you specify CSS property values using **addition, subtraction, multiplication, and division**. It is often used to combine two CSS values that have different units, such as `%` and `px`.

The `calc()` math function takes a mathematical expression as a parameter and returns the result of that expression, e.g.:

```
property: calc(expression);
```

<code>calc()</code> Example

Click on the play icon below to see the `calc()` example in the code playground and try it for yourself.

```
<div class="calc1">
  <code>width: calc(10px + 100px);</code>
</div>
<div class="calc2">
  <code>width: calc(2em * 5);</code>
</div>
<div class="calc3">
```

```
  <code>width: calc(100% - 32px);</code>
</div>
<div class="calc4">
  <code>width: calc(var(--predefined-width) - calc(16px * 2));</code>
</div>
```

```
div {
  background-color: black;
  margin: 4px 0;
  width: 100%;
}

div > code {
  display: block;
  background-color: red;
  color: white;
  height: 48px;
}

.calc1 > code {
  /* Output width: `110px` */
  width: calc(10px + 100px);
}

.calc2 > code {
  /* Output width: `10em` */
  width: calc(2em * 5);
}

.calc3 > code {
  /* Output width: Depends on the container's width */
  width: calc(100% - 32px);
}

.calc4 > code {
  --predefined-width: 100%;
  /* Output width: Depends on the container's width */
  width: calc(var(--predefined-width) - calc(16px * 2));
}
```

<code>min()</code>: Finding the minimum value in a set

There are cases where we don't want the value of a CSS property to exceed a certain number. Say, for example, we want the width of our content container to be the smaller of "the full width of our screen" and "500 pixels." In those cases, we can use the CSS math function `min()`.

The `min()` math function takes a set of comma-separated values as arguments and returns the smallest of those values, e.g.:

```
width: min(32px, 50%, 2rem);
```

This function is often used to compare two CSS values that have different units, such as `%` and `px`.

<code>min()</code> Example

Click on the play icon below to see the `min()` example in the code playground and try it for yourself.

```
<div class="min1">
  <code>width: min(9999px, 50%);</code>
</div>
<div class="min2">
  <code>width: min(9999px, 100%);</code>
</div>
<div class="min3">
  <code>width: min(120px, 150px, 90%);</code>
</div>
<div class="min4">
  <code>width: min(80px, 90%);</code>
</div>
```

```
div {
  background-color: black;
  margin: 4px 0;
  width: 100%;
}

div > code {
  display: block;
  background-color: darkblue;
  color: white;
  height: 48px;
}

.min1 > code {
  /* Output width: Depends on the container's width; */
  /* on this page, likely to be `50%` of the container's width */
  width: min(9999px, 50%);
}

.min2 > code {
  /* Output width: Depends on the container's width; */
  /* on this page, likely to be `100%` of the container's width */
  width: min(9999px, 100%);
}

.min3 > code {
  /* Output width: Depends on the container's width; */
  /* on this page, likely to be `120px` of the container's width */
  width: min(120px, 150px, 90%);
}

.min4 > code {
  /* Output width: Depends on the container's width; */
```

```
  /* on this page, likely to be `80px` of the container's width */
  width: min(80px, 90%);
}
```

<code>max()</code>: Finding the maximum value in a set

Similar to `min()`, sometimes we don't want the value of a CSS property to go below a certain number. For example, we might want the width of our content container to be the *larger* of "the full width of our screen" and "500 pixels." In those cases, we can use the CSS math function `max()`.

The `max()` math function takes a set of comma-separated values as arguments and returns the largest of those values, e.g.:

```
width: max(32px, 50%, 2rem);
```

This function is often used to compare two CSS values that have different units, such as `%` and `px`.

Notice the similarities and differences between the examples for `min()` and `max()`.

<code>max()</code> Example

Click on the play icon below to see the `max()` example in the code playground and try it for yourself.

```
<div class="max1">
  <code>width: max(50px, 50%);</code>
</div>
<div class="max2">
  <code>width: max(50px, 100%);</code>
</div>
<div class="max3">
  <code>width: max(20px, 50px, 90%);</code>
</div>
<div class="max4">
  <code>width: max(80px, 80%);</code>
</div>
```

```
div {
  background-color: black;
  margin: 4px 0;
  width: 100%;
  height: 48px;
}

div > code {
  display: block;
  background-color: darkmagenta;
  color: white;
  height: 48px;
}

.max1 > code {
  /* Output width: Depends on the container's width; */
  /* on this page, likely to be `50%` of the container's width */
  width: max(50px, 50%);
}

.max2 > code {
  /* Output width: Depends on the container's width; */
  /* on this page, likely to be `100%` of the container's width */
  width: max(50px, 100%);
}

.max3 > code {
  /* Output width: Depends on the container's width; */
  /* on this page, likely to be `90%` of the container's width */
  width: max(20px, 50px, 90%);
}

.max4 > code {
  /* Output width: Depends on the container's width; */
  /* on this page, likely to be `80%` of the container's width */
  width: max(80px, 80%);
}
```

<code>clamp()</code>: Constraining a value between two values

We can combine the functions of `min()` and `max()` by using `clamp()`. The `clamp()` math function takes a minimum value, the value to be clamped, and the maximum value as arguments, e.g.:

```
/* clamped value: 50%, minimum: 100px, maximum: 300px */
width: clamp(100px, 50%, 300px);
```

- If the value to be clamped is less than the passed minimum value, the function will return the minimum value.
- If the value to be clamped is greater than the passed maximum value, the function will return the maximum value.
- If the value to be clamped is between the passed minimum and maximum values, the function will return the original value to be clamped.

This function is often used to compare two CSS values that have different units, such as `%` and `px`.

<code>clamp()</code> Example

Click on the play icon below to see the `clamp()` example in the code playground and try it for yourself.

```
<div class="clamp1">
  <code>width: clamp(10%, 1px, 90%);</code>
</div>
<div class="clamp2">
  <code>width: clamp(10%, 9999px, 90%);</code>
</div>
<div class="clamp3">
  <code>width: clamp(125px, 1px, 250px);</code>
</div>
<div class="clamp4">
```

```
  <code>width: clamp(25px, 9999px, 150px);</code>
</div>
```

```
div {
  background-color: black;
  margin: 4px 0;
  width: 100%;
  height: 48px;
}

div > code {
  display: block;
  background-color: darkgreen;
  color: white;
  height: 48px;
}

.clamp1 > code {
  /* Output width: Depends on the container's width; */
  /* on this page, likely to be `20%` of the container's width */
  width: clamp(20%, 1px, 80%);
}

.clamp2 > code {
  /* Output width: Depends on the container's width; */
  /* on this page, likely to be `90%` of the container's width */
  width: clamp(10%, 9999px, 90%);
}

.clamp3 > code {
  /* Output width: `125px` */
  width: clamp(125px, 1px, 250px);
}

.clamp4 > code {
  /* Output width: `150px` */
  width: clamp(25px, 9999px, 150px);
}
```

Advanced CSS Math Functions

When laying out and styling DOM elements, the four basic math functions `calc()`, `min()`, `max()`, and `clamp()` are often sufficient. However, for advanced uses like mathematics learning materials, 3D visualizations, or CSS animations, you may consider using:

- Stepped value functions
  - `round()`: calculates a **value given a rounding strategy**
  - `mod()`: calculates the **remainder** of a division operation with the **same sign as the divisor**
  - `rem()`: calculates the **remainder** of a division operation with the **same sign as the dividend**
- Trigonometric functions
  - `sin()`: calculates the **trigonometric sine** of a number
  - `cos()`: calculates the **trigonometric cosine** of a number
  - `tan()`: calculates the **trigonometric tangent** of a number
  - `asin()`: calculates the **trigonometric inverse** sine of a number
  - `acos()`: calculates the **trigonometric inverse** cosine of a number
  - `atan()`: calculates the **trigonometric inverse** tangent of a number
  - `atan2()`: calculates the **trigonometric inverse** tangent given two numbers
- Exponential functions
  - `pow()`: calculates a number **raised to the power** of another number
  - `sqrt()`: calculates the **square root** of a number
  - `hypot()`: calculates the **square root of the sum of the squares** of the given numbers
  - `log()`: calculates the **logarithm** of a number (with `e` as the default base)
  - `exp()`: calculates `e` **raised to the power** of another number
- Sign functions
  - `abs()`: calculates the **absolute value** of a number
  - `sign()`: calculates the **sign (positive, negative, or zero)** of a number

Final thoughts

- You can use CSS math functions to create responsive user interfaces without writing any JavaScript code.
- CSS math functions can sometimes be used instead of CSS media queries to define layout breakpoints.
- In 2023, members of the Interop Project selected "CSS Math Functions" as a focus area of improvement. This means that browser vendors are working together to ensure that CSS math functions perform the same across browsers and devices.

Using CSS typed arithmetic

CSS typed arithmetic refers to permitted calculations performed with typed CSS values via functions such as `calc()`, and specifically, to the behavior defined in the CSS values and units module. CSS typed arithmetic enables dividing a value with one unit by a value with a different unit of the same data type, resulting in unitless quotients.

These quotients can then be used as a `<number>` in the values of unitless properties, or converted into any numeric data type (such as a `<length>`, `<percentage>`, or `<angle>`) by multiplying them by a numeric typed value.

This typed arithmetic behavior enables relationships to be created between different values on a page. This article explores typed arithmetic and presents several examples that make use of it.

> **Note:** Originally, the CSS values and units module limited the arguments multiplication and division operations could take to make dividing by zero detectable at parse time and avoid issues such as squared units. Typed arithmetic relaxes some of those restrictions in supporting browsers.

CSS typed arithmetic rules

When performing calculations on values in CSS, there are some rules around compatibility of values with different data types.

Addition and subtraction

When adding or subtracting values, all the values must be within the same overall data type. The following examples all produce valid results:

```
/* <length-percentage> units */
calc(250px - 150px)
calc(100% - 50px)
calc(50vw + 2rem)
calc(25cqw + 3in)

/* <angle> units */
calc(40deg + 2rad)
calc(420deg - 1turn)
```

However, the following are invalid. The results of such mixed-type calculations would be meaningless:

```
calc(200px + 100ms)
calc(50% + 90deg)
```

Multiplication

When multiplying values in CSS, only one of the values can have a unit. All other values must be unitless `<number>` values. This is because you want a product that is a greater or lesser amount of the same unit, and do not want to create squared units, which no CSS properties accept.

```
calc(200px * 4) /* 800px */
calc(60deg * 3) /* 180deg */
```

If you try to multiply two values with units — even the same units — normal mathematical rules dictate that the units should be multiplied as well. For example:

```
calc(200px * 4px)
```

In this case, the function is invalid as `800px`^{2} is meaningless in CSS.

Division

When dividing values in CSS, you can divide a value with a unit by a unitless value:

```
calc(1000px / 2) /* 500px */
calc(360deg / 4) /* 90deg */
```

However, you can't divide a unitless value by a value with a unit as that doesn't make sense:

```
calc(1000 / 2px) /* ?!? */
```

When a value of any numeric data type is divided by a value of the same type, the units cancel each other out, and you are left with a unitless value. Behind the scenes, the two values are computed before being divided by one another.

As a result, the same calculation can have very different results depending on the context it is used in and the units of the divisor.

Take the following example:

```
calc(100vw / 1px)
```

The `100vw` is equal to `100%` of the width of the viewport. If the viewport is currently `1000px` wide, the calculation will return the unitless value `1000`. However, if the viewport is `500px` wide, the calculation will return the unitless value `500`.

If we replace the `1px` divisor by `1em`, we get very different results:

```
calc(100vw / 1em)
```

If the viewport is `1000px` wide, and `1em` is equal to the browser default of `16px` at the point of calculation, the previous calculation will return `1000px / 16px = 62.5`.

It used to be the case that you couldn't divide one typed value by another, even if the two values have units of the same type. However, the specification was updated to permit this; check for browser compatibility.

Why is the behavioral update useful?

Being able to divide one typed value by another of the same type may not sound very significant at first, but it enables useful associations between different values that can be used to create responsive UI features.

The key to all of this is being able to represent values in a unitless form via divisions like this one:

```
--viewport-width-in-pixels: calc(100vw / 1px);
```

The result is a `<number>` representing the viewport width in pixels as a unitless value. This can be used anywhere a number is valid, including other `calc()` functions. You can dynamically vary other property values based on this value, regardless of what units they have.

For example, the unitless value can be immediately transferred to `opacity`:

```
opacity: calc(var(--viewport-width-in-pixels) / 1000 - 0.5);
```

You can multiply it by a value such as `1deg` to create an `<angle>` value:

```
rotate: calc(var(--viewport-width-in-pixels) * 1deg);
```

You can multiply it by a value such as `1rem` to create a `<length>` value:

```
font-size: calc(var(--viewport-width-in-pixels) * 1rem / 200);
```

Let's walk through some examples to show how CSS typed arithmetic can be useful.

Basic example: responsive background opacity

The responsive background opacity example (see source code) shows how to vary the opacity of a background image as the viewport width is changed. Having the background image fade out as the screen gets narrower means the image is less likely to affect the readability of the text content as they start to overlap.

HTML

The HTML contains some basic text content wrapped in a `<div>` element.

```
<div class="wrapper">
  <h1>Prose of the century</h1>
  <p>
    Lorem ipsum dolor sit amet, consectetur adipiscing elit. Nulla luctus
    aliquam dolor, eu lacinia lorem placerat vulputate. Duis felis orci,
    pulvinar id metus ut, rutrum luctus orci. Cras porttitor imperdiet nunc, at
    ultricies tellus laoreet sit amet.
  </p>
</div>
```

CSS

We start by defining a CSS custom property called `--width-percentage` on the `:root` element, which contains the result of the calculation `100vw / 2000px`. This value represents the viewport width as a percentage of `2000px` that we will later use as an alpha channel value. When the viewport is `2000px` wide, the calculation will return `1`, which is equivalent to `100%` alpha. Anything less than a `2000px` viewport width will result in a smaller value.

```
:root {
  --width-percentage: calc((100vw / 2000px));
}
```

> **Note:** Any alpha value greater than `1` is treated as `1`, therefore we don't need to clamp the maximum value.

We then set a fixed `width` and some `padding` on the wrapper `<div>`, and center it horizontally using `margin`.

```
.wrapper {
  width: 480px;
  padding: 20px;
  margin: 0 auto;
}
```

Finally, we set multiple backgrounds on the `<body>` element. We'll go through these in reverse order:

1. The last and therefore bottom-most `background` value is a non-repeating background image located near the top-right corner.
2. The top background is a white semi-transparent overlay created using a `linear-gradient()` function with both color stops set to the same color. The color's alpha channel value is calculated as `1` minus the `--width-percentage` custom property we set earlier: As the viewport width gets narrower, `--width-percentage` will get smaller, therefore the white gradient will become more opaque, reducing the opacity of the background image.

```
body {
  background:
    linear-gradient(
      rgb(255 255 255 / calc(1 - var(--width-percentage))),
      rgb(255 255 255 / calc(1 - var(--width-percentage)))
    ),
    url("https://mdn.github.io/shared-assets/images/examples/colorful-heart.png")
      no-repeat top 50px right 50px;
}
```

Result

To see the result, view our responsive background opacity example live (see source code). Try altering the viewport width to see how the background opacity varies as a result.

Varying values of different types based on a single value

The different type variations example (see source code) works in a very similar way to the previous example, except that in this case, we demonstrate the use of a single variable value in the definition of multiple other values with different data types.

Specifically, we set a paragraph's background color *and* font size based on the viewport width.

HTML

The markup for this example contains a paragraph of text:

```
<p>Hello there!</p>
```

CSS

We start off our CSS in a similar way to the previous demo, creating a unitless value based on the viewport width. This time, we calculate it by dividing `100vw` by `1px` and store the resulting number in a custom property called `--viewport-in-pixels`. The value represents the current viewport width in pixels, without any units.

```
:root {
  --viewport-in-pixels: calc(100vw / 1px);
}
```

Now on to the styling of the paragraph itself. We first give it some basic styles (a `border` and `text-align` of `center`), then set two values based on the `--viewport-in-pixels` property created earlier:

1. We set the `font-size` of the paragraph to a value equal to `--viewport-in-pixels` divided by `200`, multiplied by `1em` to convert the numeric quotient into `em`s.
2. We set the `background-color` of the paragraph to an `lch()` color value. The lightness and chroma components are constant values (`75%` and `50%`, respectively), whereas the hue component is set to `--viewport-in-pixels` divided by `10`, plus `100`. We then multiply the result of that by `1deg` to ensure the value is an `<angle>`.

   > **Note:** This last step is not strictly necessary, as `lch()` also accepts unitless hue values. However, a degree value may be more intuitive, and we wanted to show another example of how the unitless value can be converted into a different data type.

```
p {
  border: 5px solid black;
  text-align: center;
  font-size: calc(1em * (var(--viewport-in-pixels) / 200));
  background-color: lch(
    75% 50% calc((100 + (var(--viewport-in-pixels) / 10)) * 1deg)
```

```
  );
}
```

Result

To see the result, view our different type variations example live (see source code). Try altering the viewport width to see how the paragraph font size and background color both vary as a result.

An animated story circle

The animated story circle example (see source code) demonstrates a more complex effect created by leveraging CSS typed arithmetic rules. In this case, the different paragraphs of a body of text are laid out in a circle emanating from a center point. What's more, the circle of paragraphs closes up into a fan shape when the viewport is made narrower, and opens up again when it is made wider.

HTML

The HTML is fairly basic — a `<div>` containing multiple `<p>` elements. The text of the first paragraph is wrapped in a `<strong>` element to provide an indicator of where to start reading.

```
<div class="story-circle">
  <p><strong>Hello there!</strong></p>
  <p>This is</p>
  <p>quite an</p>
  <p>interesting way</p>
  <p>to tell a</p>
  <p>story</p>
  <p>all around in</p>
  <p>a circle.</p>
  <p>What fun!</p>
</div>
```

CSS

We start the CSS by setting a `height` of `100%` on the `:root` element.

```
:root {
  height: 100%;
}
```

Next, we set several properties on the `<body>` element:

- We start by setting a `height` of `inherit`, meaning the `<body>` will inherit the `:root` element's `100%` height and therefore span the full height of the viewport.
- Next, we horizontally center the `<body>` using `margin`, and give it a `max-width`. As you'll see later on, this upper bound is important for controlling the maximum rotation of the fan/circle shape.
- We center the `<div>` with `class="story-circle"` horizontally and vertically inside the `<body>` using flexbox.
- We use the `container-type` property to declare the `<body>` as an inline size query container. This is important because we want to vary the shape rotation based on the `<body>` width, and not the viewport width as we did in previous examples. Setting it as a size query container allows us to reference its size in calculations.

```
body {
  height: inherit;
  margin: 0 auto;
  max-width: 1600px;
  display: flex;
  align-items: center;
  justify-content: center;
  container-type: inline-size;
}
```

We now come to styling the `story-circle` `<div>`. We set its `width` and `height` to `1px`: it will act as a reference point with its child paragraphs positioned in a circle around it. (We don't even need to set positioning on it, as it is fine for the paragraphs to be positioned relative to the `<body>`).

We then create a custom property called `--width-percentage` that contains the result of `100cqw` (100% of the width of the element's parent query container, which is the `<body>` element) divided by `1200px`, minus `0.33333`. This is the key value that will control the amount the circle rotates by as the viewport width is changed.

```
.story-circle {
  width: 1px;
  height: 1px;
  --width-percentage: calc((100cqw / 1200px) - 0.33333);
}
```

We are using the container query width rather than the viewport width to control the rotation because we want to set a maximum bound for the container, which is controlled by the `<body>` `max-width`. If the rotation value becomes greater than a full circle, the last paragraph will start to overlap the first one, which spoils the effect.

Since the `max-width` is `1600px`, you might have expected the calculation to be `100cqw / 1600px`). This would work, but we've instead gone for `(100cqw / 1200px) - 0.33333` (the `0.33333` comes from `1600px/1200px - 1`). Both would cause the maximum rotation to occur at a `<body>` width of `1600px`, but the fan now has a smaller minimum rotation, which gives a better effect at narrow viewport widths.

The final style rule selects the paragraphs themselves. Most of this styling is rudimentary. It is worth pointing out that we have set `position` to `absolute` to cause all of the paragraphs to sit on top of one another, and we've set a `transform-origin` value of `center left` to cause paragraphs to rotate around the center of their left edge, so they will all fan out from a center point over their containing `<div>`.

Now onto the interesting bit — we define a custom property called `--angle` that contains the unitless rotation angle of the paragraph, before setting the `rotate` property to the resulting value. We multiply the resulting number by `1deg` to convert it to a degree value. The `--angle` custom property is the product of three values:

1. The paragraph's `sibling-index()` minus `1`, which causes the first paragraph to have a rotation angle of `0`, as we want it to be horizontal.
2. `360` divided by the paragraph's `sibling-count()`, which causes all the paragraphs to be equally spaced around the circle, meaning the design will still work if the number of paragraphs changes.
3. our `--width-percentage` custom property, which causes the rotation of the paragraphs around the circle to vary as the viewport width changes. Remember that this property has a maximum value of `1`, which will be achieved when the `<body>` element hits its `max-width` of `1600px`.

```
p {
  padding: 10px;
  width: 150px;
  text-align: right;
  background: linear-gradient(to right, red, orange 50%);
  border-radius: 5px;

  position: absolute;
  transform-origin: center left;

  --angle: calc(
    ((sibling-index() - 1) * (360 / sibling-count())) * var(--width-percentage)
  );
```

```
  rotate: calc(var(--angle) * 1deg);
}
```

Result

To see the result, view our animated story circle example live (see source code). Try increasing and decreasing the viewport width to see how the paragraph fan shape unfolds into a circle and back again.

Value definition syntax

CSS value definition syntax, a formal grammar, is used to define the set of valid values for a CSS property or function. In addition to this syntax, the set of valid values can be further restricted by semantic constraints (for example, for a number to be strictly positive).

The definition syntax describes which values are allowed and the interactions between them. A component can be a *keyword*, some characters considered as a *literal*, or a value of a given CSS data type or another CSS property.

Component value types

Keywords

Generic keywords

A keyword with a predefined meaning appears literally, without quotation marks. For example: `auto`, `smaller`, or `ease-in`.

CSS-wide keywords

All CSS properties accept the keywords `inherit`, `initial`, `revert`, `revert-layer`, and `unset`. They are not shown in the value definition and are implicitly defined.

Literals

In CSS, a few characters can appear on their own, like the slash (`/`) or the comma (`,`), and are used in a property definition to separate its parts. The comma is often used to separate values in enumerations, or parameters in mathematical-like functions; the slash often separates parts of the value that are semantically different, but have a common syntax. Typically, the slash is used in shorthand properties; to separate components of the same type, but belong to different properties.

Both symbols appear literally in a value definition.

Data types

Basic data types

Some data types are used throughout CSS and are defined once for all values in the specification. Called *basic data types*, they are represented with their name surrounded by the symbols < and >: `<angle>`, `<string>`, ...

Non-terminal data types

Less common data types, called *non-terminal data types*, are also surrounded by < and >.

Non-terminal data types are of two kinds:

- data types *sharing the same name of a property*, put between quotes. In this case, the data type shares the same set of values as the property. They are often used in the definition of shorthand properties.
- data types *not sharing the same name of a property*. These data types are very close to the basic data types. They only differ from the basic data types in the physical location of their definition. In this case, the definition is usually physically very close to the definition of the property using them.

Component value combinators

Brackets

Brackets enclose several entities, combinators, and multipliers, then transform them as a single component. They are used to **group components to bypass the precedence rules**.

```
example =
  bold [ thin && <length> ]
```

This example matches the following values:

- `bold thin 2vh`
- `bold 0 thin`
- `bold thin 3.5em`

But not:

- `thin bold 3em`, as `bold` is juxtaposed with the component defined by the brackets, it must appear before it.

Juxtaposition

Placing several keywords, literals, or data types, next to one another, only separated by one or several spaces, is called *juxtaposition*. All juxtaposed components are **mandatory and should appear in the exact order**.

```
example =
  bold <length> , thin
```

This example matches the following values:

- `bold 1em, thin`
- `bold 0, thin`
- `bold 2.5cm, thin`
- `bold 3vh, thin`

But not:

- `thin 1em, bold`, as the entities must be in the expressed order
- `bold 1em thin`, as the entities are mandatory; the comma, a literal, must be present
- `bold 0.5ms, thin`, as the `ms` values are not `<length>`

Double ampersand

Separating two or more components, by a *double ampersand*, `&&`, means that all these entities are **mandatory but may appear in any order**.

```
example =
  bold      &&
  <length>
```

This example matches the following values:

- `bold 1em`
- `bold 0`
- `2.5cm bold`
- `3vh bold`

But not:

- `bold`, as both components must appear in the value.
- `bold 1em bold`, as both components must appear only once.

> **Note:** Juxtaposition has precedence over the double ampersand, meaning that `bold thin && <length>` is equivalent to `[ bold thin ] && <length>`. It describes `bold thin <length>` or `<length> bold thin` but not `bold <length> thin`.

Double bar

Separating two or more components by a *double bar*, `||`, means that all entities are options: **at least one must be present, and they may appear in any order**. Typically this is used to define the different values of a shorthand property.

```
example =
  <number>  ||
  <length>  ||
  <color>
```

This example matches the following values:

- `1em 1 blue`
- `blue 1em`
- `1 1px yellow`

But not:

- `blue yellow`, as a component must appear once at most.
- `bold`, as it isn't a keyword allowed as a value of any of the entities.

> **Note:** The double ampersand has precedence over the double bar, meaning that `bold || thin && <length>` is equivalent to `bold || [ thin && <length> ]`. It describes `bold`, `thin <length>`, `bold thin <length>`, or `thin <length> bold` but not `<length> bold thin` as bold, if not omitted, must be placed before or after the whole `thin && <length>` component.

Single bar

Separating two or more entities by a *single bar*, `|`, means that all entities are exclusive options: **exactly one of these options must be present**. This is typically used to separate a list of possible keywords.

```
example =
  <percentage>  |
  <length>      |
  left          |
  center        |
  right         |
  top           |
  bottom
```

This example matches the following values:

- `3%`
- `0`
- `3.5em`
- `left`
- `center`
- `right`
- `top`
- `bottom`

But not:

- `center 3%`, as only one of the components must be present.
- `3em 4.5em`, as a component must be present at most one time.

> **Note:** The double bar has precedence over the single bar, meaning that `bold | thin || <length>` is equivalent to `bold | [ thin || <length> ]`. It describes `bold`, `thin`, `<length>`, `<length> thin`, or `thin <length>` but not `bold <length>` as only one entity from each side of the `|` combinator can be present.

Component value multipliers

A multiplier is a sign that indicates how many times a preceding entity can be repeated. Without a multiplier, an entity must appear exactly one time.

Multipliers cannot be added and have precedence over all combinators.

Asterisk (<code>*</code>)

The *asterisk multiplier* indicates that the entity may appear **zero, one or several times**.

```
example =
  bold smaller*
```

This example matches the following values:

- `bold`
- `bold smaller`
- `bold smaller smaller`
- `bold smaller smaller smaller`, and so on.

But not:

- `smaller`, as `bold` is juxtaposed, and must appear before any `smaller` keyword.

Plus (<code>+</code>)

The *plus multiplier* indicates that the entity may appear **one or several times**.

```
example =
  bold smaller+
```

This example matches the following values:

- `bold smaller`
- `bold smaller smaller`
- `bold smaller smaller smaller`, and so on.

But not:

- `bold`, as `smaller` must appear at least once.
- `smaller`, as `bold` is juxtaposed and must appear before any `smaller` keyword.

Question mark (<code>?</code>)

The *question mark multiplier* indicates that the entity is optional, and **must appear zero or one time**.

```
example =
  bold smaller?
```

This example matches the following values:

- `bold`
- `bold smaller`

But not:

- `bold smaller smaller`, as `smaller` must appear at most once.
- `smaller`, as `bold` is juxtaposed and must appear before any `smaller` keyword.

Curly braces (<code>{}</code>)

The *curly braces multiplier*, enclosing two integers separated by a comma, A and B, indicates that the entity **must appear at least A times and at most B times**.

```
example =
  bold smaller{1,3}
```

This example matches the following values:

- `bold smaller`
- `bold smaller smaller`
- `bold smaller smaller smaller`

But not:

- `bold`, as `smaller` must appear at least once.
- `bold smaller smaller smaller smaller`, as `smaller` must appear at most three times.
- `smaller`, as `bold` is juxtaposed and must appear before any `smaller` keyword

Hash mark (<code>#</code>)

The *hash mark multiplier* indicates that the entity may be repeated one or more times (for example, the plus multiplier), but each occurrence is separated by a comma (','').

```
example =
  bold smaller#
```

This example matches the following values:

- `bold smaller`
- `bold smaller, smaller`
- `bold smaller, smaller, smaller`, and so on.

But not:

- `bold`, as `smaller` must appear at least once.
- `bold smaller smaller smaller`, as the different occurrences of `smaller` must be separated by commas.
- `smaller`, as `bold` is juxtaposed and must appear before any `smaller` keyword.

The hash mark may optionally be followed by curly braces to indicate how many times the entity repeats.

```
example =
  bold smaller#{1,3}
```

This example matches the following values:

- `bold smaller`
- `bold smaller, smaller`
- `bold smaller, smaller, smaller`

But not:

- `bold smaller, smaller, smaller, smaller`, as `smaller` must appear at most three times.

```
example =
  bold smaller#{2}
```

This example matches the following value:

- `bold smaller, smaller`

But not:

- `bold smaller`, as `smaller` must appear exactly two times.

Exclamation point (<code>!</code>)

The *exclamation point multiplier* after a group indicates that the group is required, and must produce at least one value; even if the grammar of the items within the group would otherwise allow the entire contents to be omitted, at least one component value must not be omitted.

```
example =
  [ bold? smaller? ]!
```

This example matches the following values:

- `bold`
- `smaller`
- `bold smaller`

But not:

- neither `bold` nor `smaller`, as one of them must appear.
- `smaller bold`, as `bold` is juxtaposed and must appear before the `smaller` keyword.
- `bold smaller bold`, as `bold` and `smaller` may only appear once.

Bracketed range notation (<code>[min,max]</code>)

Some types can accept numeric values within a certain range. For example, the `column-count` property can accept an integer value between positive 1 and infinity, inclusive. The corresponding syntax looks like this:

```
example =
  <integer [1,∞]>

<integer> =
  <number-token>
```

This syntax reflects the latest standard as per CSS Values and Units Module Level 4. Not all browsers may have implemented every part. See Browser compatibility for support information.

Any value outside this specified range causes the whole declaration to be invalid, therefore the browser will ignore it.

The *bracketed range notation* `[min, max]` indicates an inclusive range between a `min` and `max` value. This notation is used in numeric type notations and can include units, e.g., `<angle [0,180deg]>`. Positive and negative Infinity (-∞ and ∞) must not have units specified. Types specified in units can have zero values specified with or without units, for example `<time [0s,10s]>` or `<time [0,10s]>`.

Here are some more examples:

- `<integer [-∞,∞]>`: Any integer from negative infinity to positive infinity.
- `<integer [0,∞]>`: Any integer from 0 to positive infinity is valid. Negative integers are invalid.
- `<time [0s,10s]>` or `<time [0,10s]>`: Any duration from 0 to 10 seconds is valid.
- `<integer [-∞,-1]> | <integer [1,∞]>`: Any integer except zero is valid.

Summary

Sign	Name	Description	Example
Combinators			
	Juxtaposition	Components are mandatory and should appear in that order	`solid <length>`
`&&`	Double ampersand	Components are mandatory but may appear in any order	`<length> && <string>`
`||`	Double bar	At least one of the components must be present, and they may appear in any order.	`<'border-image-outset'> || <'border-image-slice'>`
`|`	Single bar	Exactly one of the components must be present	`smaller | small | normal | big | bigger`
`[ ]`	Brackets	Group components to bypass precedence rules	`bold [ thin && <length> ]`
Multipliers			
	No multiplier	Exactly 1 time	`solid`
`*`	Asterisk	0 or more times	`bold smaller*`
`+`	Plus sign	1 or more times	`bold smaller+`
`?`	Question mark	0 or 1 time (that is *optional*)	`bold smaller?`
`{min,max}`	Curly braces	At least `min` times, at most `max` times	`bold smaller{1,3}`
`#`	Hash mark	1 or more times, with each occurrence separated by a comma (`,`)	`bold smaller#`
`!`	Exclamation point	Group must produce at least 1 value	`[ bold? smaller? ]!`
Ranges			
`[min,max]`	Numeric bracketed range	Specifies a numeric range	`<integer [0,∞]>`

    - `ViewTransition.transitionRoot`
- `Document.startViewTransition()` method
- `Document.activeViewTransition`
- `Element.startViewTransition()` method
- `Element.activeViewTransition`

Guides

Using the View Transition API

Explains how to create view transitions and customize transition animations, including manipulating active view transitions.

Using view transition types

Shows how to use types along with same-document view transitions and cross-document view transitions.

Using element-scoped view transitions

Covers how element-scoped view transitions work, and how to use them.

CSS viewport

The **CSS viewport** module enables specifying the size, zoom factor, and orientation of the user-agent's initial containing block, or *viewport*.

Content designed for large viewports may exhibit a variety of bugs when viewed in smaller viewports, including unintended wrapping, clipped content, and incorrectly sized scroll containers. HTML provides a viewport meta tag, `<meta name="viewport">`, to provide hints about the initial size of the viewport. If the site isn't designed to work well on small viewports and this tag is omitted, some mobile browsers render the site using a fixed initial containing block width, typically `980px`. The content is then scaled down, making the CSS pixel size smaller than an actual pixel. The resulting page fits into the available screen space but is illegible, requiring the user to zoom and pan to view the content.

The viewport initial containing block for continuous media has the dimensions of the viewport. Since the viewport is generally no larger than the display, devices with smaller displays, such as phones or tablets, typically present a smaller viewport than larger devices like desktops or laptops.

WebXR DOM overlays

The **WebXR DOM overlays** module, an immersive web specification, expands the WebXR Device API to allow HTML content — such as text and controls — to be displayed during an immersive virtual reality (VR) or augmented reality (AR) session.

In a typical WebXR session, content is rendered to a WebGL canvas superimposed on the real-world camera feed (in AR) or displayed as the full immersive view (in VR), with the device tracking the user's position and orientation. The DOM overlay renders a single DOM element and its descendants as a transparent-background 2D rectangle on top of this view, enabling interactive, stylable elements such as menus and dialogs to appear within the immersive experience.

The `:xr-overlay` pseudo-class matches the DOM overlay element when a web page is being viewed in an immersive AR or VR environment, allowing it to be styled appropriately for its underlying content.
